

HEREDITARY COPROPORPHYRIA

AT A GLANCE

- Very rare (fewer than 50 cases reported).
- Autosomal dominant disorder involving a deficiency of coproporphyrinogen oxidase.
- Age of onset in second to third decade of life; rare before puberty.
- Skin findings that are indistinguishable from those of porphyria cutanea tarda occur in fewer than 10 percent of patients; acute attacks similar to those of acute intermittent porphyria are the most common feature (neurocutaneous porphyria).

of COPROGEN III to PROTOGEN. COPROGEN III has four carboxyl groups, each of which is part of a propionate side chain. COPROGEN oxidase catalyzes the sequential oxidative removal of the carboxyl group from two of the propionate groups, forming first the 3-carboxyl porphyrinogen known as *harderoporphyrinogen (HARDEROGEN)* and next the 2-carboxylporphyrinogen known as *PROTOGEN* (see Fig. 132-2).

COPROGEN oxidase is encoded by a single-copy gene of the same name, *COPROGEN oxidase*, as suggested by Southern blot analysis of human restriction fragments. The *COPROGEN oxidase* gene is located on chromosome 3q12, spans a genomic distance of 14 kb, and consists of 7 exons and 6 introns.[215] Multiple mutations have been found in patients with heterozygous and homozygous HCP. These include point mutations resulting in base substitutions or exon skipping. This leads to increased excretion of COPRO in the urine and stool.[215]

CLINICAL MANIFESTATIONS As in VP, the spectrum of clinical symptoms includes both cutaneous manifestations and potentially life-threatening acute neurologic attacks. Cutaneous symptoms apparently occur in fewer than 10 percent of patients, and when they occur they are clinically indistinguishable from those seen in PCT and VP.[186]

The acute attacks are similar to those of AIP, and neurovisceral symptomatology predominates in HCP. This includes abdominal pain, vomiting, constipation, neuropathies, and psychiatric symptoms. The oral hypoglycemic agent glipizide has been reported to exacerbate a coproporphyria-like syndrome that was reversed after discontinuation of the drug.[216]

LABORATORY FINDINGS HCP is characterized by increased excretion of COPRO III in urine and feces. Markedly increased levels (usually 10- to 100-fold) of fecal COPRO, more than 90 percent of which is the III isomer, is present at all times in these patients. The feces may also contain increased amounts of hepta-, hexa-, and pentacarboxylic porphyrins. Urinary COPRO III level is also elevated during attacks, as are levels of the precursors ALA and PBG. The latter may be normal between attacks (see Table 132-3).

HISTOPATHOLOGY Skin lesions usually do not occur. When they are present, histopathologic features are similar to those in PCT.

DIFFERENTIAL DIAGNOSIS In HCP, cutaneous signs are uncommon and, if they do occur, are most often seen in homozygous patients with disease onset in childhood. The skin manifestations resemble those seen in PCT and VP. Fecal predominance of COPRO III is more suggestive of HCP than of VP, in which PROTO and COPRO levels are usually increased.

Acute attacks are similar to those seen in AIP. The differential diagnosis rests on stool porphyrin determinations and measurement of COPROGEN oxidase in fibroblasts or leukocytes. DNA analysis for mutations in the *COPROGEN oxidase* gene can also be performed.

TREATMENT Treatment is the same as for AIP and VP and is described in Box 132-2.

δ-Aminolevulinic Acid Dehydratase Deficiency Porphyria (See Table 132-8)

ALA dehydratase deficiency porphyria is a very rare type of acute hepatic porphyria with an autosomal recessive inheritance pattern; no more than 10 patients with the disorder have been reported.[217–220] Clinically, these patients have symptoms similar to those of AIP. Stress and ethanol ingestion have been reported to precipitate attacks.

The disease results from a profound deficiency of ALA dehydratase, the second enzyme in heme biosynthesis, levels of which are less than 5 percent of normal. ALA dehydratase is a cytosolic enzyme and catalyzes the formation of PBG from two molecules of ALA.

δ-AMINOLEVULINIC ACID DEHYDRATASE DEFICIENCY PORPHYRIA

AT A GLANCE

- Extremely rare (fewer than 10 cases reported).
- Early and late clinical onset has been described.
- Neurologic symptoms similar to those in other acute hepatic porphyrias can occur; no photosensitivity or cutaneous symptoms.

The enzyme is encoded by the ALA dehydratase gene, which is located on chromosome 9q34, and the mutations described to date are very heterogeneous. Although it has been suggested that ALA dehydratase deficiency porphyria may represent a homozygous ALA dehydratase defect, cloning of a mutant ALA dehydratase cDNA in a patient showed that the patient was compound heterozygous for two independent mutant alleles of the enzyme.[218]

In the few patients studied, the urinary porphyrin excretion shows elevated levels of ALA, COPRO, and, to a lesser extent, URO. Analysis of fecal porphyrins revealed mildly elevated levels of COPRO and PROTO in one patient, elevated COPRO levels in another, and a normal profile in two others. Erythrocyte PROTO level was elevated in all patients. Increases in plasma ALA, COPRO, and PROTO have been reported.[221] The porphyrin excretion pattern in these patients is unexplained.

CONFIRMATION OF A SUSPECTED DIAGNOSIS OF PORPHYRIA

Diagnostic procedures traditionally consist of a combination of thorough medical history taking (including, in particular, a complete family history), clinical examination, and biochemical determi-

nation of levels of porphyrins and porphyrin precursors in urine, feces, and blood (Fig. 132-21). In specialized laboratories, these diagnostic procedures can be extended to the measurement of specific enzymatic activities in erythrocytes, lymphocytes, or fibroblasts of affected patients and family members. Molecular techniques now provide the most precise diagnostic information based on isolation of DNA from peripheral blood followed by polymerase chain reaction amplification and automated DNA sequencing. Furthermore, these methodologies permit detailed analyses of genes and their function and allow genetic counseling of affected individuals and their family members.

Even with the use of these sophisticated diagnostic tools, however, there are times when the results may remain inconclusive. This is particularly true for the dual porphyrias.

DUAL PORPHYRIAS

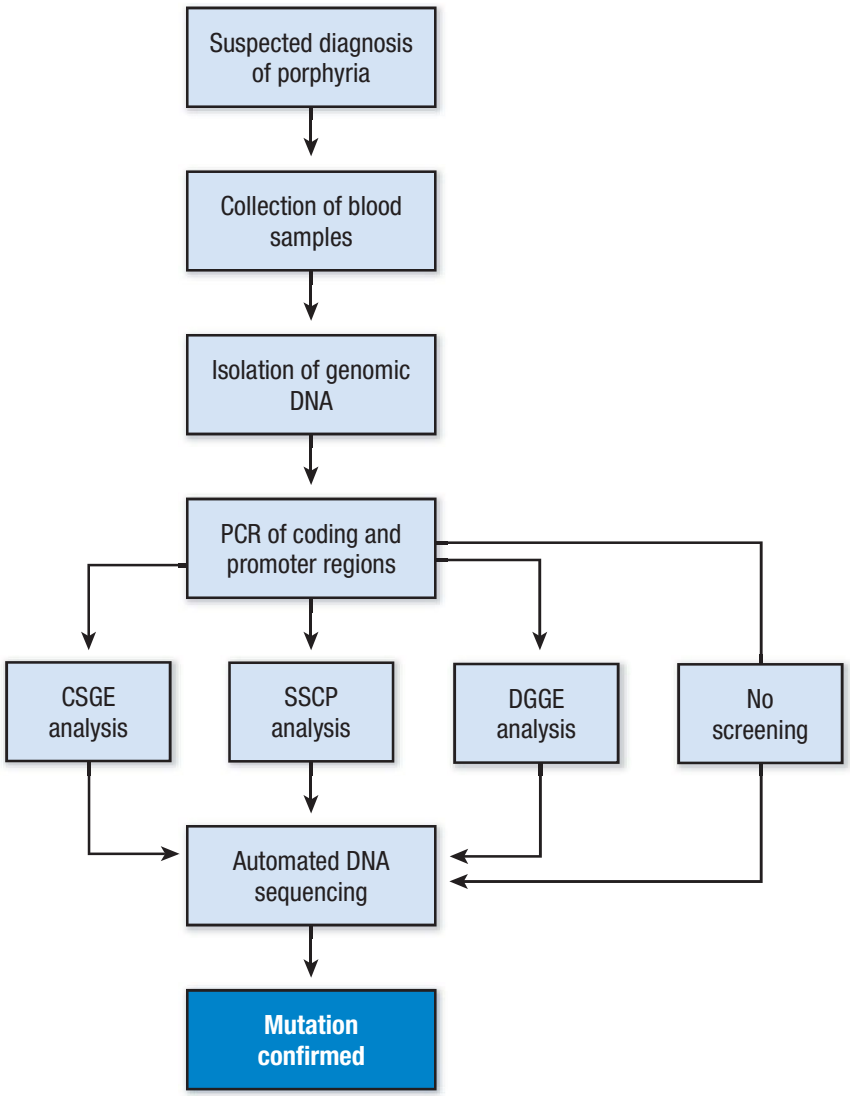
In the dual porphyrias, laboratory test results may point to the simultaneous deficiency of two enzymes in the heme biosynthetic pathway, either in one individual or within one family. To date, approximately 15 patients and families with this constellation of findings have been reported, which indicates that these porphyria variants are very rare.

The majority of the dual porphyrias involve a deficiency of UROGEN decarboxylase combined with a deficiency of PBG deaminase, COPROGEN oxidase, or PROTOGEN oxidase. This is not surprising, because the prevalence of PCT exceeds that of any other type of human porphyria. In three families, the simultaneous deficiency of COPROGEN oxidase and either PBG deaminase, UROGEN III synthase, or ALA dehydratase was detected. In one patient with CEP, the UROGEN III synthase defect was accompanied by a deficiency of UROGEN decarboxylase.

Until recently, the diagnosis of dual porphyria in all patients and families was established based on biochemical measurement of porphyrins and/or porphyrin precursors in urine and feces and enzymatic assays.

Two groups have now independently reported on the first porphyria patients in whom DNA analysis unequivocally confirmed the presence of mutations in two different genes encoding distinct enzymes in the heme synthetic pathway. Harraway et al. described a young female patient who developed skin symptoms on the sun-exposed areas of her body and showed increased urinary PBG excretion.[222] The initial diagnosis of VP could not be confirmed, however, and biochemical analysis of her urine, feces, and plasma suggested a combined deficiency of PBG deaminase and UROGEN decarboxylase. Subsequent automated sequencing of the *PBG deaminase* and *UROGEN decarboxylase* genes revealed mutations in both genes, which confirmed the diagnosis of dual porphyria. Akagi et al. studied a patient who experienced acute porphyric attacks accompanied by increased urinary excretion of ALA, PBG, and COPRO.[223] Although these findings were suggestive of HCP, the authors observed marked elevation of ALA levels and increased erythrocyte zinc PROTO levels, which suggested ALA dehydratase deficiency. Subsequent automated sequencing of both the *COPROGEN oxidase* and *ALA dehydratase* genes led to the detection of disease-causing mutations in each gene. Both genetic defects were confirmed by in vitro expression experiments, which established the molecular basis of dual porphyria in a single individual consisting of simultaneous COPROGEN oxidase and ALA dehydratase deficiencies.

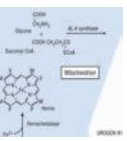
These reports emphasize that for patients for whom biochemical and enzymatic studies indicate co-existent deficiency of two enzymes in the heme biosynthetic pathway, molecular genetic analysis of the corresponding genes should be carried out to identify the disease-causing mutations underlying a particular variant of dual porphyria.



▲ **FIGURE 132-21** Algorithm for assessing the molecular genetics of human porphyria. CSGE = conformation sensitive gel electrophoresis; DGGE = denaturing gradient gel electrophoresis; PCR = polymerase chain reaction; SSCP = single strand conformational polymorphism.

ABNORMAL PORPHYRIN PROFILE AND SIDEROBLASTIC ANEMIA

Some cases of sideroblastic anemia may be associated with abnormal porphyrin profiles.[224–226] These patients may have cutaneous photosensitivity closely resembling that of EPP, and they subsequently develop sideroblastic anemia. In some cases, the two conditions may develop within a few months of each other. All patients have elevated levels of PROTO in RBCs and/or plasma; many also have elevated stool PROTO levels. Urinary COPRO and URO levels are also elevated. The activities of ferrochelatase and, less frequently, of ALA synthase may be decreased. Chromosomal abnormalities, which include deletions in chromosomes 18 and 20, have been described.



MOLECULAR GENETIC RESEARCH STRATEGIES FOR THE PORPHYRIAS

In the various types of porphyrias, discrepancies between clinical findings and the results of biochemical tests or enzyme essays often lead to doubtful or incorrect diagnoses. In the case of the acute porphyrias, this can have fatal consequences for the patient if an accurate diagnosis is not established in a timely manner.

Once a mutation is identified in a patient with porphyria, the detection of asymptomatic gene carriers within the patient's family is easily accomplished using standard molecular biologic techniques. In the acute porphyrias, the identification of these "silent" carriers is the first and most important step in the prevention of life-threatening acute attacks. Genetic analysis provides an effective way to make an early diagnosis and thereby enhance the likelihood of providing patients and asymptomatic gene carriers in their families with advice regarding the avoidance of precipitating factors.

ANIMAL MODELS AND FUTURE OPTIONS FOR GENE THERAPY

Animal models for EPP and PCT have been described.[91,165,227] These models afford unique opportunities to explore the pathogenesis of these types of porphyria using in vivo models and to study the feasibility of achieving phenotypic reversion by gene therapy. Retrovirus-mediated gene transfer of human ferrochelatase cDNA into deficient fibroblasts from an EPP patient has been achieved.[164] In transduced cells, ferrochelatase catalytic activity increased from 7 percent to 550 percent of the normal value, and partial metabolic correction of the phenotype was demonstrated. In CEP, correction of the underlying enzymatic defect in cultured cells was also accomplished by retrovirus-mediated gene transfer, which led to partial normalization.[228] Excessive porphyrin levels in the transduced cells were reduced to normal. These investigations demonstrate the potential usefulness of somatic stem cell gene therapy for the treatment of different types of human porphyria.

CONCLUSIONS AND FUTURE PROSPECTS

The various human porphyrias often present with overlapping clinical and laboratory findings, which makes precise diagnosis a challenging proposition, especially in the acute porphyrias. The clinical signs and symptoms are highly variable in different patients and even in the same patient at different times. Biochemical analyses of urinary and/or fecal porphyrins and precursors often display overlapping values. These methods, as well as the measurement of enzymatic activity in fibroblasts or lymphocytes, are somewhat imprecise, and it is not uncommon to find values that do not distinguish between clinically unaffected gene carriers (so called *silent carriers*) and normal controls. The identification of silent carriers within families affected by the acute porphyrias is the first and foremost step toward the prevention of life-threatening acute attacks. Once a DNA-based diagnosis is made, patients and their families can be provided with genetic counseling and with advice regarding how to avoid precipitating factors. In case of a life-threatening acute attack, a prior genetic diagnosis permits the attending physician to begin appropriate treatment immediately.[186]

CHAPTER 133

Amyloidosis and the Skin

Helen J. Lachmann
Philip N. Hawkins

Amyloidosis is classified according to which protein is deposited (Table 133-1) as well as whether the amyloid deposits are localized, distributed in only one tissue or organ, or deposited more widely.

EPIDEMIOLOGY

Amyloidosis is a rare condition, and the exact incidence remains unclear. The overall sex- and age-adjusted rate per million person-years was reported as 6.1 from 1950 to 1969 and 10.5 from 1970 to 1989 in the United States. Systemic AL amyloidosis is the most common type of systemic amyloidosis, accounting for more than 60 percent of cases. Biopsy and postmortem series suggest that the prevalence of AA amyloidosis deposition in patients with chronic inflammatory diseases is between 3.6 percent and 5.8 percent, although a smaller proportion of patients have clinically significant amyloidosis. Localized amyloidosis accounts for fewer than 10 percent of all diagnoses. Hereditary forms are quite rare, and most are inherited in an autosomal dominant pattern. The most common cause of hereditary amyloidosis is mutations in the gene for transthyretin (TTR), which affects approximately 10,000 individuals worldwide and leads to familial amyloid polyneuropathy. The formerly used term *X-linked cutaneous amyloidosis*, or *Partington syndrome*, has been abandoned for the designation *X-linked reticulate pigmentary disorder*, given the lack of amyloid deposits in the skin.[1] Both localized and systemic forms of amyloidosis become more frequent with increased age, and presentation before the age of 30 years is extremely unusual. No known racial, occupational, geographic, or other environmental factors have been implicated in the genesis of systemic amyloidosis, although there is evidence for a slight male preponderance.

ETIOLOGY AND PATHOGENESIS

Amyloidosis is caused by extracellular deposition of insoluble abnormal fibrils, derived from the aggregation of misfolded plasma protein. More than 20 unrelated proteins are known to form human amyloid fibrils in vivo.[2] The ultrastructural morphology and histochemical properties of all amyloid fibrils, regardless of the precursor protein type, are remarkably similar,[3] and fibril diffraction studies have confirmed that they all share a common core structure consisting of a cross β core and polypeptide chains lying perpendicular to the long axis of the fibril.[4,5] This extremely abnormal highly ordered conformation underlies the distinctive physicochemical properties of amyloid fibrils, including their relative stability and resistance to proteolysis. Amyloid deposits universally contain the normal plasma glycoprotein serum amyloid P component (SAP), heparan sulfate and dermatan sulfate proteoglycans, and glycosaminoglycan chains as non-fibrillar constituents. Other plasma proteins, such as apolipoprotein E, are sometimes detectable in amyloid deposits, but without the universality and abundance of SAP.

Amyloid formation in vivo occurs with both normal wild-type proteins and with genetically variant proteins. The fibrils may contain the intact amyloidogenic protein or proteolytic cleavage fragments. There is always a lag period, often of many years, between the first appearance of the potentially amyloidogenic protein and the deposition of clinically significant amyloid.

Systemic AL Amyloidosis

AL fibrils are derived from monoclonal immunoglobulin light chains and consist of the whole or part of the variable (V_L) domain.[6] AL amyloidosis may occur in association with any monoclonal B cell dyscrasia.[7,8] A degree of amyloid deposition is seen in up to 15 percent of patients with myeloma, but the vast majority (more than 80 percent) of patients who present with clinically significant AL amyloidosis have very low grade and otherwise "benign" monoclonal gammopathies.[9]

Systemic AA Amyloidosis

Reactive systemic AA amyloidosis is a potential complication of any disorder associated with a sustained acute-phase response, and the list of chronic inflammatory, infective, and neoplastic disorders that can underlie it is almost without limit. Although 60 percent of patients have inflammatory arthritis, some of the underlying diseases may require dermatologic input, including psoriatic arthritis, epidermolysis bullosa, basal cell carcinoma, chronic cutaneous ulcers, and hereditary periodic fever syndromes, particularly Muckle-Wells syndrome.[10] The amyloid fibrils are derived from cleavage fragments of the circulating acute-phase reactant serum amyloid A protein (SAA).[11] SAA is an apolipoprotein of high-density lipoprotein[12] that, like C-reactive protein, is synthesized by hepatocytes under the transcriptional regulation of cytokines. A sustained high plasma level of SAA is a prerequisite for the development of AA amyloidosis, but why amyloidosis develops in only a small proportion of cases remains unclear.

Hereditary Amyloidosis

In addition to familial amyloid polyneuropathy, which is caused by mutations in the TTR gene, there are other hereditary systemic amyloidoses associated with mutations in apolipoproteins A1 and A2, fibrinogen A α chain, gelsolin, and lysozyme.[13]

Localized Amyloidosis

Localized amyloid deposition is not uncommon, although it is often undiag-

AMYLOIDOSIS AT A GLANCE

- In amyloidosis, normally soluble plasma proteins are deposited in the extracellular space in an abnormal insoluble fibrillar form.
- Amyloid deposition is remarkably diverse and can be localized or systemic, rapidly lethal or incidental.
- Diagnosis of amyloidosis relies on the demonstration of pathognomic red-green birefringence when biopsy specimens stained with Congo red are viewed under cross-polarized light.
- Management relies on determining the type (defined by the precursor protein) and discriminating systemic from localized forms. Treatment of systemic disease centers on reducing the production of the fibril precursor protein; management of localized disease is usually surgical or symptomatic.

TABLE 133-1
Classification of Systemic Amyloidosis

Type	Fibril Protein Precursor	Clinical Syndrome
AA	Serum amyloid A protein	Reactive systemic amyloidosis associated with chronic inflammatory diseases
AL	Monoclonal immunoglobulin light chains	Systemic amyloidosis associated with monoclonal plasma cell dyscrasias
Aβ_2M	β_2-Microglobulin	Periarticular and, occasionally, systemic amyloidosis associated with long-term dialysis
ATTR	Normal plasma transthyretin	Senile systemic amyloidosis with prominent cardiac involvement
ATTR	Genetically variant transthyretin	Autosomal dominant systemic amyloidosis Familial amyloid polyneuropathy
ACys	Genetically variant cystatin C	Hereditary cerebral hemorrhage with cerebral and systemic amyloidosis
AGel	Genetically variant gelsolin	Autosomal dominant systemic amyloidosis Predominantly cranial nerve involvement with lattice corneal dystrophy
ALys	Genetically variant lysozyme	Autosomal dominant systemic amyloidosis Non-neuropathic with prominent liver and renal involvement
AApoA1	Genetically variant apolipoprotein-A1	Autosomal dominant systemic amyloidosis May be neuropathic or with prominent liver and renal involvement
AApoA2	Genetically variant apolipoprotein-A2	Autosomal dominant systemic amyloidosis Non-neuropathic with prominent renal involvement
AFib	Genetically variant fibrinogen A α chain	Autosomal dominant systemic amyloidosis Non-neuropathic with prominent renal involvement

nosed, and accounts for 9.3 percent of all amyloidoses.[14] It results either from local production of fibril precursors or from properties inherent to the particular microenvironment that favor fibril formation in a widely distributed precursor protein. The vast majority of deposits are AL in type, and symptomatic deposits occur most frequently in the eye, skin, and respiratory and urogenital tracts.[15] They are often associated with extremely subtle focal monoclonal B-cell proliferation confined to the affected site, and surgical resection of these localized "amyloidomas" can sometimes be curative. Symptomatic apparently localized amyloid deposits can in rare cases be manifestations of systemic disease, and a full investigation should always be made to exclude more generalized amyloid deposition.[16] Progression from localized to systemic amyloidosis is very rare. In lichen and macular amyloidosis the fibrils are derived from keratin released from apoptotic keratinocytes. The etiology is not entirely clear, but the association with other pruritic conditions suggests that mechanical factors associated with chronic scratching and skin friction are probably crucial.[17]

CLINICAL FINDINGS

Most important in approaching amyloidosis is to determine whether the patient has systemic in addition to cutaneous involvement (Fig. 133-1).

History

In the majority of patients with systemic amyloidosis the presentation is non-specific, and as a result, amyloid is often an unexpected finding on biopsy of an affected organ.

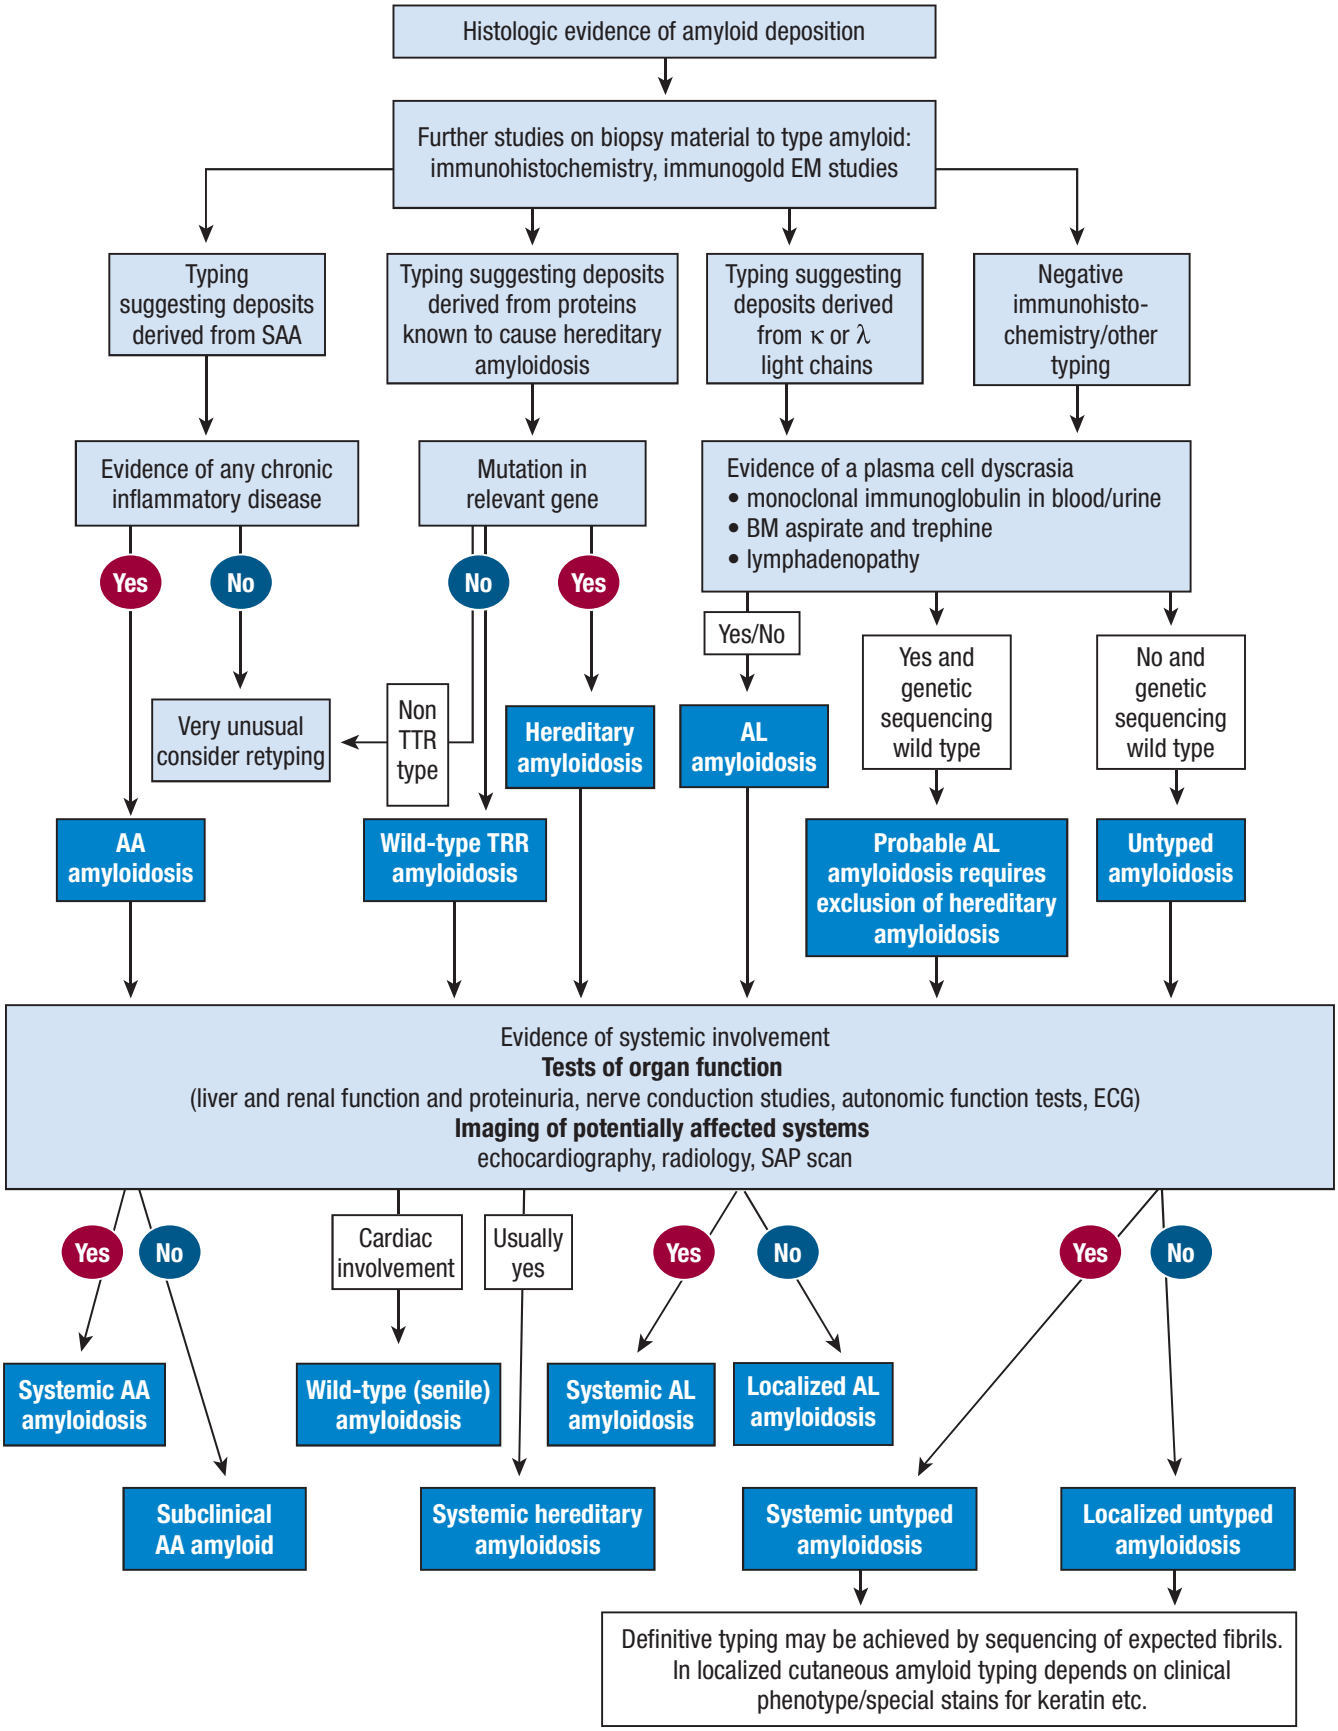
AL AMYLOIDOSIS AL amyloidosis usually occurs in patients over the age of 50 years, although it can appear in very young adults.[9] In the majority of cases the underlying plasma cell clone is not detected until the patient presents with amyloid-related organ dysfunction. Clinical manifestations are extremely variable, because almost any organ other than the brain can be directly involved.[18] Although certain clinical features such as macroglossia and periorbital ecchymoses are very strongly suggestive of AL amyloidosis (Table 133-2) and multiple vital organ dysfunction is common, many patients have non-specific symptoms such as malaise and weight loss.

SYSTEMIC AA AMYLOIDOSIS AA amyloidosis can present anytime between childhood and old age, with a median age at presentation of 48 years in the United Kingdom. Almost 95 percent of patients have a previously diagnosed chronic inflammatory disease such as rheumatoid arthritis or one of the other inflammatory arthritides; chronic sepsis, usually with bronchiectasis; complications of paraplegic conditions; or drug abuse. The disorder is slightly more common in men, and although disease can develop very rapidly, the median latency between presentation with a chronic inflammatory disorder and clinically significant amyloidosis is almost two decades. Amyloidosis usually presents with proteinuria followed by progressive renal dysfunction, often accompanied by nephrotic syndrome.

SYSTEMIC HEREDITARY AMYLOIDOSIS The presentation of hereditary amyloidosis varies depending on the variant protein and mutation, and even differs within kindreds. Severe progressive peripheral and/or autonomic neuropathy is the major feature of hereditary TTR amyloidosis (familial amyloid polyneuropathy), but cardiac involvement is also common. Apolipoprotein-A1 amyloidosis sometimes causes neuropathy, but this is not a feature of the other hereditary types, which typically involve the viscera. All the amyloidogenic mutations are dominant, but they are variably penetrant and there may be no family history of the disorder.

Cutaneous Lesions

SYSTEMIC AL AMYLOIDOSIS Cutaneous manifestations are common in systemic amyloidosis, particularly the AL type, and are reported in up to 40 percent of patients.[9] The lesions usually reflect capillary infiltration and fragility, and manifest as petechiae and purpura, particularly affecting the eyelids, beard area, and upper chest (Fig. 133-2A). Xanthomatous papules or plaques are also frequently observed, and amyloidotic hyperpigmented keratotic lesions have been reported occasionally. *Pinch purpura* describes a phenomenon



▲ **FIGURE 133-1** Approach to the patient with amyloidosis. Management of amyloidosis depends entirely on correct typing. This is both highly specialized and complex. Definitive typing requires a number of special tests and is best carried out in experienced centers. BM = bone marrow; ECG = electrocardiography; EM = electron microscopy; SAA = serum amyloid A protein; SAP = serum amyloid P component; TTR = transthyretin.

TABLE 133-2
Clinical Features That May Be Seen in Association with Systemic AL Amyloidosis

Visible tissue infiltration	Bruising (particularly periorbital) Macroglossia Muscle or joint pseudohypertrophy
Kidneys	Proteinuria Hypertension Chronic renal failure
Heart	Restrictive cardiomyopathy Arrhythmias Congestive cardiac failure
Liver	Hepatomegaly Liver failure (very rare)
Peripheral nervous system	Carpal tunnel syndrome Symmetric sensorimotor neuropathy
Autonomic nervous system	Orthostatic hypotension Impotence Disturbed bowel motility Impaired bladder emptying
Gastrointestinal system	Weight loss Gastrointestinal blood loss Disturbed bowel motility
Lymphoreticular system	Splenomegaly Lymphadenopathy
Adrenal axis	Hypoadrenalism

that appears when an amyloid papule or plaque is pinched or rubbed and hemorrhage into the tissue occurs (see eFig. 133-2.1 in on-line edition). Other rare cutaneous lesions include scleroderma-like changes (see Fig. 133-2B), alopecia, and nail dystrophy (see Fig. 133-2C). Bullous amyloidosis has been described in a few individuals. The bullae of the skin and mucosae can be intradermal or sub-epidermal and present as tense, often hemorrhagic blisters. Generalized infiltration of cutaneous tissues can frequently cause the appearance of skin thickening with loss of facial wrinkles and can be sufficient to limit mouth opening.

HEREDITARY AMYLOIDOSIS Lysozyme amyloidosis frequently causes petechial rashes (see eFig. 133-2.2 in on-line edition), and apolipoprotein-A1 amyloidosis can also manifest as yellowish infiltrated plaques and acanthosis nigricans–type lesions.[19] Cutaneous lesions in familial amyloid polyneuropathy seem to be largely due to the peripheral neuropathy and included xerosis in 82 percent, seborrheic dermatitis in 22 percent, trauma or burn lesions in 20 percent, neuropathic ulcers in 14 percent, and onychomycosis in 10.5 percent of 142 Portuguese patients.[20]

▲ **FIGURE 133-2** Cutaneous manifestations of systemic AL amyloidosis. **A.** Purpura caused by capillary fragility. **B.** Scleroderma-like skin changes affecting the hands. **C.** Nail dystrophy.

LOCALIZED CUTANEOUS AL AMYLOIDOSIS As in systemic AL amyloidosis, the fibrils in localized AL amyloidosis are derived from N-terminal cleavage fragments of monoclonal immunoglobulin light chains. The lesions are those seen in systemic AL amyloidosis and present as single or, more frequently, multiple lesions anywhere on the skin. In a series of 20 patients; 35 percent had indolent

▲ **FIGURE 133-3** **A–C.** Localized AL amyloidosis resulting in slowly progressive papular to plaque lesions.

papular, nodular, or xanthomatous lesions (Fig. 133-3); 20 percent had purpuric rash; 20 percent had pruritus; 15 percent had local bleeding; and 10 percent had localized swelling. In only 15 percent of cases were the lesions painful.[21]

MACULAR AMYLOIDOSIS AND LICHEN AMYLOIDOSIS Macular and lichen amyloidosis are variants of a single pathology in which the amyloid fibrils are derived from keratin after epidermal damage and keratinocyte apoptosis. They are usually idiopathic or friction related but have been reported in association with connective tissue diseases (primary biliary cirrhosis and systemic lupus erythematosus)[22] and in a few kindreds with pachyonychia congenita[23] and multiple endocrine neoplasia type 2a.[24]

Macular amyloidosis usually affects the upper back and limbs and can persist for many years (Fig. 133-4). The rash is pruritic in the great majority of cases and consists of small brownish macules distributed in a rippled pattern. There may be a female preponderance,[25] and the disorder is more common among Central and South Americans, Middle Easterners, and non-Chinese Asians. Amyloid deposits usually are confined to the papillary dermis and do not involve blood vessels or adnexal structures. Early lesions contain small, multifaceted, amorphous globules within the papillae, and these are missed easily without the use of special stains. Later lesions show globules that coalesce, expand the papillae, and displace the rete ridges laterally.

Lichen amyloidosis is the most common type of cutaneous amyloidosis in Chinese individuals and usually affects adults. It is clinically characterized by an intensely pruritic eruption of multiple discrete hyperkeratotic papules that may coalesce to form gray-brown plaques (Fig. 133-5). They are usually distributed on the extensor surfaces of the lower extremities, although lesions may also involve the extensor aspects of the arms and the trunk. Histologically the deposits are very similar to those in macular amyloidosis but slightly larger and are accompanied by irregular acanthosis and hyperkeratosis of the overlying epidermis.

▲ **FIGURE 133-4** Macular amyloidosis of the back in a patient of Arab extraction.

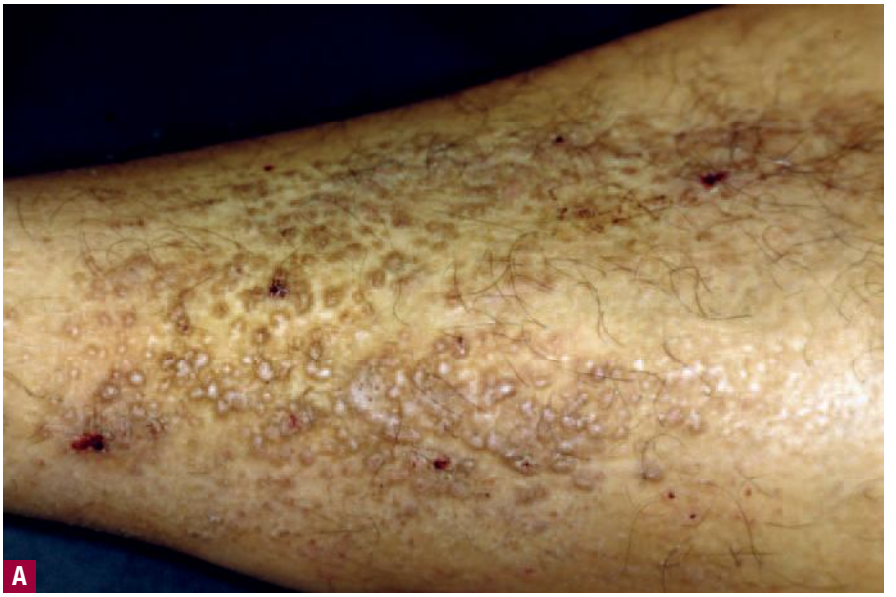
ANOSACRAL CUTANEOUS AMYLOIDOSIS Anosacral cutaneous amyloidosis is a rare syndrome described in Japanese and Chinese males in which pigmented macules and glossy hyperkeratotic lesions radiate out from the anus.[24]

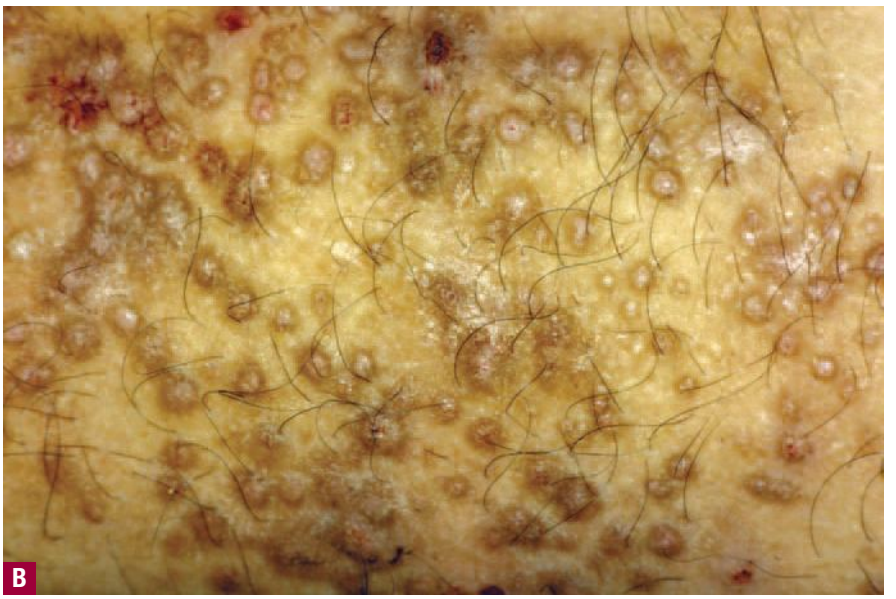
OTHER TYPES OF LOCALIZED CUTANEOUS AMYLOIDOSIS Deposition of insignificant microscopic amounts of amyloid in association with a variety of cutaneous lesions is well recognized. Reported predisposing conditions include intradermal nevi, sweat gland tumors, pilomatrixoma, dermatofibroma, seborrheic keratosis, solar elastosis, photosensitive annular elastolytic giant cell granuloma, actinic keratosis, porokeratosis of Mibelli, Bowen disease, basal cell carcinoma, and treatment with psoralen plus ultraviolet A radiation.

Related Physical Findings

SYSTEMIC AL AMYLOIDOSIS Systemic AL amyloidosis is protean in its manifestations (see Table 133-2), it can present with visible lymphadenopathy, macroglossia, muscle pseudohypertrophy, and periorbital purpura (Fig. 133-6) and can cause signs in any organ system except the brain.

SYSTEMIC AA AMYLOIDODOSIS Systemic AA amyloidosis presents with nephrotic





▲ **FIGURE 133-5** Lichen amyloidosis. **A.** Multiple extremely pruritic hyperkeratotic papules. **B.** Larger magnification to show the hyperkeratotic appearance of the lesions.

syndrome in just under half of patients. Clinically, splenomegaly is frequent and hepatomegaly is detected in 10 percent of cases. Cardiac involvement and peripheral or autonomic neuropathy are very rare.

HEREDITARY AMYLOIDOSIS The physical findings in hereditary amyloidosis depend on the variant protein and specific mutations and may differ even within individual families.

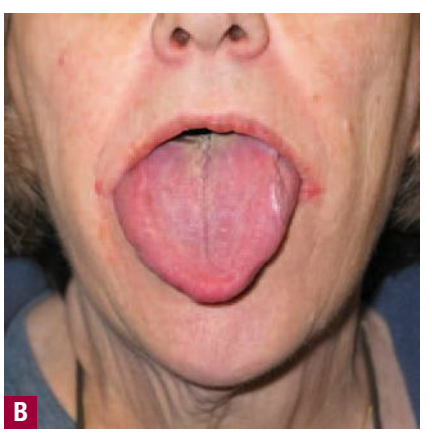
LABORATORY TESTS

All patients should undergo comprehensive assessment of renal and liver function, including blood tests and quantification of creatinine clearance and proteinuria.[27] A search should be made for evidence of an underlying plasma cell dyscrasia by serum and urine electrophoresis and immunofixation.[28] In suspected amyloidosis of the AL type, bone marrow aspiration and trephine sampling are usually mandatory. Where available, serum assays of potential fibril precursor proteins, free immunoglobulin light chains in AL type, and SAA in AA amyloidosis are very valuable.[29]

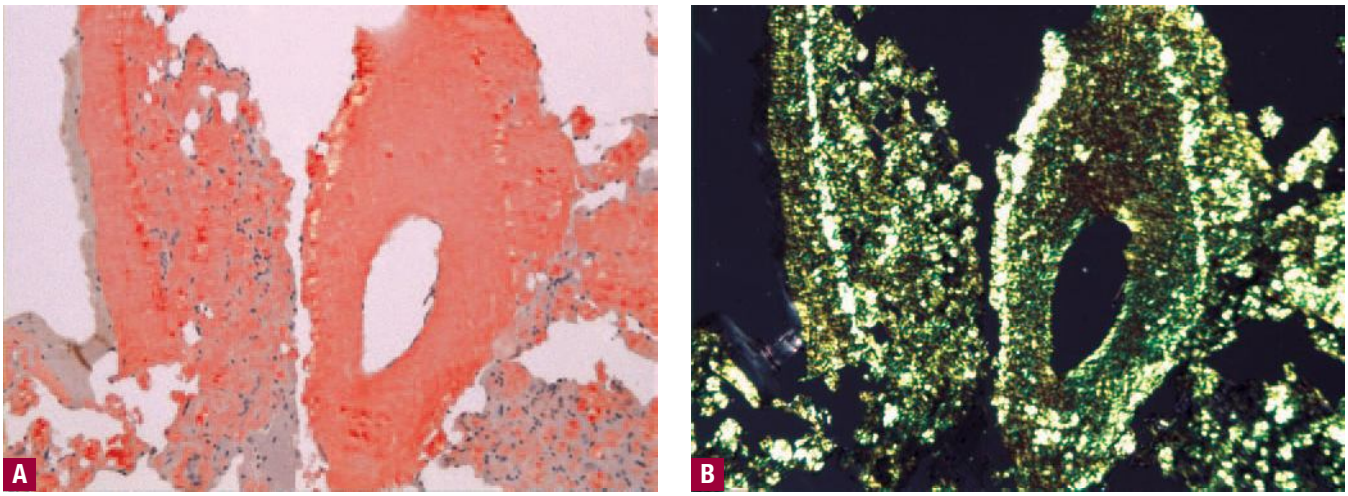
SPECIAL TESTS

Histopathology

The identification of amyloid depends on the pathognomonic red-green dichroism observed when tissue stained with the aniline dye Congo red is viewed under cross-polarized light[30] (Fig. 133-7). This optical effect is produced by alignment of the dye molecules along the fibrils. Binding of thioflavin T usually corresponds to Congo red birefringence but is less specific. Congo red staining for amyloid is not a very sensitive test and requires the presence



▲ **FIGURE 133-6** Visible tissue infiltration in systemic AL amyloidosis, causing lymphadenopathy (**A**), macroglossia (**B**), and periorbital purpura (**C**).



▲ **FIGURE 133-7** Typical appearances of amyloid deposits. **A.** Congo red staining. **B.** Same section viewed under cross-polarized light with red-green birefringence.

of an adequate amount of amyloid, the use of sufficiently thick tissue sections, technically correct staining and visualization procedures, and adequate observer experience. In negatively stained electron microscopic specimens, amyloid fibrils are usually approximately 10 nm in diameter, straight, rigid, nonbranching, of indeterminate length, and composed of twisted protofibrils.

Positive results for amyloid on histologic analysis must be followed up by immunohistochemical testing to determine the fibril protein type.[16] Suitable antibodies are widely available, but although immunohistochemical analysis usually yields definitive results in AA amyloidosis, it is frequently not diagnostic for AL deposits.[31] Expertise in the immunohistochemical typing of amyloid in hereditary disease is limited, and definitive immunohistochemical typing of amyloid deposits cannot always be achieved.[32] Direct sequencing of extracted fibrils permits identification of the amyloid type, but the required techniques are generally available only in a research setting.

Genetic Sequencing

Amyloidogenic mutations should be sought in all patients in whom the amyloid type remains undetermined, because hereditary amyloidosis accounts for a substantial number of these cases.[32]

Imaging of Amyloid In Vivo

SERUM AMYLOID P COMPONENT SCINTIGRAPHY SAP is a highly conserved, invariant plasma glycoprotein of the pentraxin family that becomes specifically and highly concentrated in amyloid deposits of all types as a result of its calcium-dependent binding to amyloid fibrils. Radiolabeled SAP scintigraphy can be used for diagnosis and quantitative monitoring of amyloid deposits.[33] This safe and non-invasive method provides information on the presence, distribution, and extent of visceral amyloid deposits (except in the heart), and serial scans allow monitoring of progress and response to therapy (see eFig. 133-7.1 in on-line edition).

CARDIAC IMAGING Cardiac amyloidosis is best evaluated by a combination of echocardiography and electrocardiography.[34] Two-dimensional Doppler echocardiography classically reveals concentric biventricular wall thickening with a restrictive filling pattern. Amyloid causes diastolic dysfunction with well-preserved contractility until a very late stage. The electrocardiogram may be normal in patients with substantial cardiac amyloidosis, but in advanced disease commonly shows small voltages, pathologic Q waves (pseudo-infarct pattern).[35] Newer magnetic resonance imaging techniques can also contribute to assessment of the severity of cardiac amyloidosis,[36] as can serum assays of the cardiac biomarkers N-terminal pro-brain natriuretic peptide[37] and troponin T.[38]

DIFFERENTIAL DIAGNOSIS

See Box 133-1.

COMPLICATIONS

Systemic AL Amyloidosis

Restrictive cardiomyopathy is the presenting feature in up to one-third of patients and ultimately the cause of death in one-half.[39] Renal involvement is frequent and presents with proteinuria and progressive renal impairment.[40] Gut involvement can cause motility disturbances (often secondary to autonomic neuropathy), malabsorption, perforation, hemorrhage, or obstruction.[41] Peripheral neuropathy occurs in one-fifth of cases and typically manifests as a painful sensory polyneuropathy followed later by motor deficits.[9] Autonomic neuropathy causing orthostatic hypotension, impotence, and gastrointestinal disturbances may occur in isolation or with a peripheral neuropathy.[18]

Systemic AA Amyloidosis

Progressive renal failure and nephrotic syndrome are the usual complications in AA amyloidosis. Although splenic amyloid deposits are almost universally

- Systemic amyloidosis

present in the AA type, they are usually asymptomatic. Hepatic involvement and autonomic neuropathy are well recognized but usually occur very late in the disease. Cardiac amyloidosis occurs in fewer than 2 percent of cases.

Hereditary Amyloidosis

Familial polyneuropathy causes progressive peripheral and/or autonomic neuropathy and cardiomyopathy and in some cases visual loss due to vitreous amyloid deposits. Apolipoprotein-A1 amyloidosis can cause peripheral neuropathy, but as with apolipoprotein-A2, lysozyme, and fibrinogen A α chain types, renal or hepatic amyloidosis is typical. Gelsolin-related amyloidosis causes a characteristic clinical picture of corneal lattice dystrophy and cranial neuropathy.

Localized Cutaneous Amyloidosis

Localized cutaneous amyloidosis produces only local complications, usually in the form of pruritus or bleeding, and is rarely painful.

PROGNOSIS AND CLINICAL COURSE

Although recent advances have greatly extended median survival time, the prognosis for systemic amyloidosis remains grave.

Systemic AL Amyloidosis

Prognosis is particularly poor in AL disease, because the diagnosis is often made late when patients already have substantial visceral and/or neural involvement. A 5-year survival rate of approximately 10 percent and a 10-year survival rate of less than 5 percent have been reported for the AL type.[9] Most affected individuals eventually die of heart failure, uremia, or autonomic failure.

Systemic AA Amyloidosis

The prognosis of AA amyloidosis depends on how much renal dysfunction is present at diagnosis and whether the underlying chronic inflammatory disease can be effectively suppressed, so that the plasma SAA level is maintained within the normal healthy range.[42] In a cohort of 374 patients, median survival was just over 11 years, and a third of patients developed end-stage renal failure, which was the major cause of death.

Hereditary Amyloidosis

In familial amyloid polyneuropathy, median survival time is 10 to 15 years without liver transplantation.[43] Death is from progressive neuropathy and/or cardiomyopathy. In the other hereditary amyloidoses, either renal or hepatic failure is the major cause of mortality, but the time to reach end-stage organ failure is very variable.

Localized Cutaneous Amyloidosis

The localized cutaneous amyloidoses are skin-limited conditions that are not usually associated with any increase in mortality.

TREATMENT

Treatment of all types of amyloidosis centers on measures that can reduce the supply of the respective amyloid fibril precursor protein, while supporting or replacing compromised organ function.[29,42] Under favorable circumstances, this results in regression of existing amyloid deposits, preservation or recovery of the function of amyloidotic organs, and much improved patient survival. Such treatment requires precise identification of the amyloid fibril type, for which specialist diagnostic expertise and immunohistochemical testing, DNA sequencing, and direct fibril sequencing may be required. Monitoring of therapeutic efficacy and rational decision making about further treatment options are enhanced by the current availability of routine assays for circulating free immunoglobulin light chains in AL amyloidosis[44] and SAA in AA amyloidosis.[45]

Systemic AL Amyloidosis

Treatment in AL amyloidosis aims to suppress proliferation of the underlying B-cell clone and, therefore, production of the amyloidogenic monoclonal immunoglobulin. This approach is not without problems.[46] Chemotherapy regimens are based on those used in the treatment of multiple myeloma, but the majority of plasma cell dyscrasias in AL patients are low grade and may be less chemosensitive. Diagnosis can be delayed, and many patients have advanced multisystem disease,[47] which limits their options for chemotherapy. Regression of amyloid is a gradual process that may not lead to measurable clinical improvement or recovery of organ function for many months, or even years, after successful suppression of the causative plasma cell dyscrasia.[48,49] Mobilization of amyloid from the heart is much slower than mobilization from the liver or kidneys, and many patients with cardiac or multisystem dysfunction do not live long enough to benefit from chemotherapy, even when it has suppressed their clonal disease. Nonetheless, many patients with AL amyloidosis do benefit substantially from chemotherapy. Prolonged low-intensity cytotoxic regimens such as oral melphalan and prednisolone are beneficial in approximately 20 percent of patients, and this is the only treatment to have been proven helpful in placebo-controlled trials.[50,51] Although there have been no comparative clinical trials, dose-intensive infusional chemotherapy regimens such as vincristine, doxorubicin (Adriamycin), and dexamethasone (VAD)[52] and autologous peripheral blood stem cell transplantation are almost certainly much more effective.[53,54] Very rigorous patient selection for high-dose chemotherapy is essential, because the procedure-related mortality is extremely high in individuals with multiple-organ involvement.[55]

Systemic AA Amyloidosis

Significant reduction of SAA values by treatment of the primary inflammatory conditions responsible for AA amyloidosis dramatically improves survival and is associated with arrest of amyloid deposition and frequently regression of deposits.[56] The new biologic drugs targeting key cytokine mediators of inflammation potently suppress the acute-phase response in many patients with inflammatory arthritis, Crohn disease, and some hereditary periodic fevers. Treatment with colchicine is mandatory to prevent AA amyloidosis in familial Mediterranean fever.

Hereditary Amyloidosis

At present, apart from transplantation to replace failed organs and liver transplantation to reduce production of amyloidogenic proteins that are synthesized by the liver, only symptomatic treatment is available for hereditary systemic amyloidosis. The liver is the source of plasma TTR, and almost 1000 liver transplants have been performed for treatment of hereditary TTR amyloidosis since this "surgical gene therapy" approach was introduced in 1991.[43] In younger patients carrying the common Val30Met mutation the outcome is gen-

erally good, with arrest of neuropathy and regression of visceral amyloid, but the outcome in patients with other mutations has been less positive.[57]

Systemic Amyloidosis: Novel Treatments

Better understanding of the mechanisms underlying amyloid formation[58] has led to the development of novel treatment strategies aimed at inhibiting fibrillogenesis or destabilizing existing amyloid deposits.[59,60]

Localized Cutaneous AL Amyloidosis

Small localized amyloid deposits can be removed surgically or by laser if they are cosmetically disfiguring or bleeding, but there is a very high rate of local recurrence. The possibility that systemic chemotherapy may be of any benefit in localized AL amyloidosis has not been systematically tested.

Macular and Lichen Amyloidosis

Persistent friction is a major etiologic factor in the macular and lichen forms of localized amyloidosis. Treatment modalities should be directed toward minimizing trauma and relief of pruritus in these conditions.[61] Sedating antihistamines have been found to be moderately effective, and intralesional steroids are beneficial if combined with other modalities. Topical dimethylsulfoxide has been used with moderate success but is often unacceptable to patients due to the smell. Treatment with ultraviolet B light can provide symptomatic relief.[62] There is one report of improvement after treatment with 0.1 percent topical tacrolimus ointment.[63] Administration of acitretin may also be beneficial.[64]

CHAPTER 134

Systemic Autoinflammatory Diseases

John G. Ryan
Daniel L. Kastner

ABNORMAL INFLAMMATORY RESPONSE

The autoinflammatory diseases are a group of disorders that are characterized by seemingly unprovoked inflammation. Unlike autoimmune diseases, these conditions are notable for the general absence of high titers of autoantibodies or autoreactive T-cell populations.[1] Advances in our knowledge of these diseases suggest that abnormalities in proteins involved in activation of the innate immune system may result in abnormal triggering of the body's proinflammatory cytokine network. The number of conditions falling under the rubric of autoinflammatory continues to expand. It now encompasses a broad range of seemingly disparate disorders, including vasculitic syndromes (Behçet disease), granulomatous diseases (Blau and Crohn diseases), metabolic disorders (gout and pseudogout), and fibrosing disorders (idiopathic pulmonary fibrosis) as well as the group of hereditary recurrent fevers that established the autoinflammatory disease grouping. The focus of this chapter is the Mendelian autoinflammatory diseases, which include all of the hereditary recurrent fever syndromes and the syndrome of pyogenic arthritis with pyoderma gangrenosum and acne. The hereditary recurrent fever syndromes are characterized by self-limiting episodes of fevers with localized inflammatory manifestations, including skin rashes, serositis, and arthritis. Based on clinical features and inheritance patterns, distinct groups of conditions can be identified among these hereditary recurrent fever syndromes (Table 134-1). Two of these conditions, familial Mediterranean fever and hyperimmunoglobulinemia D with periodic fever syndrome, are inherited in an autosomal recessive manner. The other diseases are dominantly inherited. Specific gene mutations have been identified in each of these conditions.

FAMILIAL MEDITERRANEAN FEVER

Epidemiology, Etiology, and Pathogenesis

Familial Mediterranean fever (FMF) is the prototype autoinflammatory disease. FMF [Online Mendelian Inheritance in Man (OMIM) #249100][2] is a rare, recessively inherited disease most frequently observed in those of Jewish, Arabic, Armenian, Turkish, or Italian ancestry.[3] A male predominance has been reported.[4] FMF is caused by mutations in *MEFV* (MEditerranean FeVer), a 10-exon gene encoded on the short arm of chromosome 16. To date, over 70 disease-associated mutations have been described, with many clustered on exon 10.[5,6] In high-risk populations, the carrier frequency for *MEFV* mutations may reach one in three. An on-line database of periodic fever mutations, INFEVERS,[7] has been established that provides an updated list of *MEFV* mutations and polymorphisms. *MEFV* codes for a 781–amino acid protein called *pyrin*, which may act as a regulatory molecule in the innate immune system. Abnormal pyrin may lead to an excess of interleukin 1β (IL-1β) secretion.[8]

Clinical Findings

A typical FMF attack is characterized by a prodromal period of a few hours, during which some patients experience chills, followed by episodes of fever that usually last 1 to 3 days, associated with serositis, synovitis, or skin rash.[9] The first clinical episode usually occurs in childhood or adolescence.[10] The time between attacks may vary from days to years. At some point during their illness up to 95 percent of patients experience FMF-associated episodes of abdominal

SYSTEMIC AUTOINFLAMMATORY DISEASES AT A GLANCE

- Seemingly unprovoked inflammation without high titers of autoantibodies or antigen-specific T cells.
- Disorders of innate immunity.
- Mendelian autoinflammatory diseases include hereditary recurrent fever syndromes and the syndrome of pyogenic arthritis with pyoderma gangrenosum and acne (PAPA).
- Hereditary recurrent fevers are characterized by episodes of fever with localized inflammation. Skin, joints, and serosal membranes are commonly affected. Symptom onset usually occurs in childhood.
- Two recessively inherited recurrent fever syndromes: Familial Mediterranean fever (FMF) and hyperimmunoglobulinemia D with periodic fever syndrome (HIDS).
- Four dominantly inherited syndromes: Tumor necrosis factor receptor–associated periodic syndrome (TRAPS) and three cryopyrinopathies—familial cold autoinflammatory syndrome (FCAS), Muckle-Wells syndrome (MWS), and neonatal-onset multisystem inflammatory disease (NOMID).
- FMF, MWS, FCAS, and NOMID are caused by mutations in the pyrin family of proteins, which play a key role in the innate immune system.
- Characteristic skin rashes are noted in each of the recurrent fever syndromes.
- Colchicine prevents the attacks and amyloidosis in FMF.
- Targeted anti-cytokine therapy appears promising in the treatment of TRAPS, HIDS, the cryopyrinopathies, and resistant cases of FMF.
- PAPA syndrome is a dominantly inherited disorder caused by mutations in a pyrin-binding protein. Anecdotal reports of therapeutic responses to targeted anti-cytokine therapy are encouraging.

pain, which may range from a dull ache to full-blown peritonitis. Pleuritic episodes may occur without fever. Scrotal pain may occur in 5 percent of prepubertal boys. Acute monoarticular arthritis is most characteristic of FMF and may affect the hip, knee, or ankle. Febrile myalgia may occur, notable for excruciating muscle pain lasting as long as several weeks.[11] Attacks may vary both in intensity and clinical features. Very young children may have fever alone.[12] Strenuous physical activity or emotional stress may precipitate attacks.

Erysipeloid erythema is the most characteristic rash of FMF.[13] It consists of warm, tender, swollen erythematous plaques, 10 to 15 cm in diameter, with well-defined borders. Lesions are located on the lower limbs, usually below the knee, and may in particular affect the dorsum of the foot, ankle, or lower leg. The lesions may be bilateral, may be initiated by prolonged walking, and subside within 24 to 48 hours. On palpation the lesion is hot, tender, and swollen. Other cutaneous manifestations of FMF have been described, including localized edema affecting the upper or lower limbs, face, or neck, and subcutaneous nodules.[14] Vasculitic purpura, including Henoch-Schönlein purpura, has also been described in up to 5 percent of FMF patients. Episodic scattered non-specific purpuric papular lesions affecting the face, trunk, or extremities are more frequently observed in children.[15]

Laboratory Tests and Special Tests

During attacks, complete blood counts demonstrate leukocytosis, with elevated erythrocyte sedimentation rate and elevated levels of acute-phase reactants, including C-reactive protein, fibrinogen, haptoglobin, and serum amyloid A (SAA) (see Chap. 133). Transient albuminuria and microscopic hematuria may be noted during attacks. In ethnicities with a high incidence of FMF, typical symptoms and a therapeutic response to colchicine may suffice to establish the diagnosis of FMF. Genetic testing for mutations in *MEFV* may be used as an adjunct in the diagnosis of FMF in atypical cases and in ethnicities with a low prevalence of FMF. The interpretation of genetic testing is complicated by the observation that a significant fraction of patients with typical clinical symptoms may have only one *MEFV* mutation, rather than two as would be expected in an autosomal recessive condition.

Histopathology

Biopsy specimens of patients with erysipeloid erythema demonstrate slight edema of the superficial dermis with sparse perivascular infiltrates of lymphocytes, polymorphonuclear leukocytes, histiocytes, and nuclear dust. Immunofluorescence demonstrates C3 deposits in the capillary walls in the papillary and, occasionally, the upper reticular dermis.[13]

Differential Diagnosis

The differential diagnosis in a particular patient is specific to the type of attack (Box 134-1). In patients with peritonitis, acute appendicitis may be suspected; however, spontaneous resolution of fever is a clue to the diagnosis of FMF. Hereditary angioedema may present with abdominal pain but usually does not cause fever. Hypertension and a pattern of dominant inheritance help to differentiate porphyria from FMF in patients with abdominal pain and fever. In children, systemic-onset juvenile idiopathic arthritis (SOJIA) is a consideration. Evanescent rash, quotidian fever pattern, lymphadenopathy, and polyarthritis are highly suggestive of SOJIA.

Complications

The most serious complication of FMF is the development of systemic amyloidosis due to deposition of the acute-phase reactant SAA (see Chap. 133). SAA may be deposited in the kidneys, gastrointestinal tract, spleen, testes, thyroid, adrenal glands, and lung. Amyloid deposits in the kidney may result in nephrotic syndrome and subsequent renal failure. Amyloidosis is associated with significant morbidity and mortality. Before the use of colchicine, renal failure secondary to amyloidosis was the most common cause of death in patients with FMF.

Prognosis and Clinical Course

Daily use of colchicine results in near complete remission in three-fourths of patients, with 95 percent noting a marked improvement. Widespread use of colchicine has reduced the incidence of amyloidosis and resultant complications. Rarely, patients may develop polyarteritis nodosa, an arteritis of small- and medium-sized vessels affecting multiple sites, especially the intestine,

AD = autosomal dominant; AR = autosomal recessive; IL-1 = interleukin 1; TNF = tumor necrosis factor.

kidney, and peripheral nerves[16] (see Chap. 165).

Treatment and Prevention

Daily oral colchicine is the mainstay of treatment. Adults and children over 5 years may require 1.2 to 1.8 mg for clinical effect.[17] Lower dosages may suffice for younger children. A common side effect of colchicine is diarrhea, which can be minimized by commencing treatment at a low dosage and gradually titrating upward. Lactose intolerance may develop in some patients treated with colchicine and should be appropriately addressed. Elderly patients or those with renal impairment treated with colchicine may develop myopathy or neuropathy.[18] In patients with amyloidosis, the aim of therapy is to reduce SAA levels below 10 mg/L. Patients with incomplete response to colchicine may benefit from biologic therapies targeted at IL-1β or tumor necrosis factor (TNF), or administration of subcutaneous interferon-α, although these therapies remain investigational for this condition. Those who develop vasculitis may require corticosteroids alone for Henoch-Schönlein purpura or corticosteroids and cyclophosphamide for manifestations of polyarteritis nodosa.

HYPERIMMUNOGLOBULINEMIA D WITH PERIODIC FEVER SYNDROME

Epidemiology, Etiology, and Pathogenesis

Hyperimmunoglobulinemia D with periodic fever syndrome (HIDS) is a rare condition (OMIM #260920) that occurs most commonly in persons of northern European ancestry,[19] although cases

Box 134-1

Differential Diagnosis of the Hereditary Recurrent Fever Syndromes

All Recurrent Fever Syndromes

- Systemic-onset juvenile idiopathic arthritis

have now been reported in many other ethnic groups.[20] HIDS is inherited as a monogenic autosomal recessive trait. In 1999, the genetic basis for HIDS was discovered[19,21] with the demonstration of mutations in the gene encoding mevalonate kinase, an enzyme involved in cholesterol and nonsterol isoprene biosynthesis.[21] HIDS-associated mutations result in low levels of residual enzyme function, which lead to increased levels of the substrate, mevalonic acid, in the urine, particularly during febrile episodes. Mutations producing complete loss of enzyme activity result in mevalonicaciduria, a condition associated with mental retardation, cataracts, and failure to thrive, in addition to those features seen in HIDS. Elevation of serum immunoglobulin D (IgD) levels is not considered to cause the clinical syndrome, because IgD levels do not correlate with disease activity, either in any given patient or across patients. It has been postulated that an excess of mevalonic acid or deficiency of isoprenoid may result in perturbation of the innate immune system.

Clinical Findings

Attacks are characterized by recurrent episodes of fever, frequently preceded by chills and accompanied by severe headache, abdominal pain, and diarrhea. Bilateral painful cervical lymphadenopathy is considered a characteristic finding in HIDS. Splenomegaly is common during attacks. Median age of onset is 6 months of age, and attacks sometimes follow childhood immunizations. Other triggers may include trauma, surgery, and menses. Episodes may occur once or twice a month from childhood to adolescence, but may become less frequent when the patient reaches adulthood.[22]

CUTANEOUS LESIONS Most patients develop skin manifestations with febrile episodes. Erythematous macules 0.5 to 2.0 cm in diameter are the most common skin lesions and may be confluent or solitary in distribution (Fig. 134-1).[23] Large macules may show an annular formation with normal skin centrally and slight irregularity of the margin. Lesions may be widespread but occur predominantly on the extremities and, unlike in FMF, show no predilection for the lower limbs. Other less common lesions include erythematous papules and nodules and a morbilliform rash. HSP and erythema elevatum et diutinum (see Chap. 166) have been described.

▲ **FIGURE 134-1** Erythematous macular and papular rash distributed over the lower and upper extremities and trunk during an attack of hyperimmunoglobulinemia D with periodic fever syndrome. (From Takada K et al: Favorable preliminary experience with etanercept in two patients with the hyperimmunoglobulinemia D and periodic fever syndrome. *Arthritis Rheum* **48**:2645, 2003. Copyright © 2003 by the American College of Rheumatology. Reprinted with permission of Wiley-Liss, Inc., a subsidiary of John Wiley & Sons, Inc.)

Laboratory Tests and Special Tests

During attacks, leukocytosis and elevated levels of acute-phase reactants are notable. The diagnosis of HIDS can be established in patients with a compatible history and clinical findings by measuring elevated urinary mevalonate levels during attacks or by demonstrating two mutations in *MVK* on genetic analysis. A small percentage of mutation-positive patients with recurrent fevers have normal IgD levels. Serum IgD levels do not correlate with the frequency or severity of attacks. Elevated serum IgA levels have been noted in up to 80 percent of patients during attacks.[23]

Histopathology

Biopsy specimens from affected skin may demonstrate varying degrees of cutaneous vasculitis, with endothelial swelling and perivascular inflammatory infiltrates composed of varying numbers of lymphocytes and polymorphonuclear cells. Sweet syndrome–like changes have been noted in some biopsy specimens.[24]

Differential Diagnosis

An important consideration is the syndrome of periodic fever with aphthous stomatitis, pharyngitis, and cervical adenopathy, a relatively common disorder in children (see Box 134-1). The presence of a rash and the triggering of attacks by childhood vaccinations are suggestive of HIDS.

Complications

There have been reports of systemic amyloidosis in rare instances.[25]

Prognosis and Clinical Course

Symptoms appear to improve with age, rarely persisting into adulthood. In the absence of amyloidosis, HIDS does not appear to have any significant effect on longevity.

Treatment and Prevention

There is no satisfactory treatment for HIDS. Colchicine therapy does not result in clinical improvement. Cyclosporine, intravenous immunoglobulin, and corticosteroids are not generally effective. A modest benefit from the use of hydroxymethylglutaryl–coenzyme A reductase inhibitors, a group of medications commonly known as *statins*, has

been described.[26] A pilot study involving two patients treated with etanercept, the p75 TNF receptor fusion protein, demonstrated dramatic clinical improvement.[27] Anecdotal reports suggest that some patients benefit from the use of the oral leukotriene receptor antagonist montelukast or treatment with anakinra, an IL-1 receptor antagonist.

TUMOR NECROSIS FACTOR RECEPTOR–ASSOCIATED PERIODIC SYNDROME

Epidemiology, Etiology, and Pathogenesis

TNF receptor–associated periodic syndrome (TRAPS) is a rare, dominantly inherited condition (OMIM #191190) caused by mutations in *TNFRSF1A*, which is found on the short arm of chromosome 12 and encodes the p55 receptor for TNF.[28] Before the recognition of the genetic defect, this condition was known by a number of clinical names, including *familial Hibernian fever*. To date, over 50 mutations in *TNFRSF1A* have been identified. The p55 receptor has four highly conserved extracellular cysteine-rich domains, a transmembrane domain, and an intracellular death domain. Roughly one-half of the currently known mutations result in amino acid substitutions at the cysteine residues. These cysteines participate in disulfide bonds that are required to maintain the receptor's three-dimensional conformation. Other mutations have been shown to interfere with hydrogen bonding or to result in the addition or deletions of amino acids in the receptor's extracellular domains. As yet, no patients with TRAPS have been identified with mutations affecting the intracellular or transmembrane domains. Reports have emphasized the finding that two variants of *TNFRSF1A*, P46L and R92Q, are seen at high frequency in the African American and Caucasian populations, respectively.[29] These variants may be associated with a wide spectrum of clinical symptoms.

Initial studies suggested that mutations in *TNFRSF1A* may result in an inability to shed TNF receptors from the cell surface, leading to excess TNF signaling.[28] Under normal circumstances the p55 TNF receptor is cleaved by metalloproteinases from the cell membrane after activation. This prevents further activation and, in addition, creates a pool of soluble receptors that may compete with membrane-bound receptors for TNF. Consistent with this, serum assays in patients with TRAPS demonstrated low levels of soluble p55 receptors when patients were not experiencing an attack, and initial in vitro studies confirmed impaired cleavage of the extracellular domains after activation. A number of other functional abnormalities have been identified, including impaired trafficking of receptor to the cell surface,[30] a finding which suggests that cellular activation may occur through multiple pathways and independently from ligand (TNF) binding.

Clinical Findings

Attacks usually begin in early childhood. Episodes typically last longer than in the other periodic fever syndromes, often continuing for more than 1 week, and there are reports of individual attacks lasting longer than 1 month. Ocular involvement is common, with periorbital edema seen in up to 90 percent of patients, and conjunctivitis or uveitis may occur. Serositis that may result in pleuritic chest pain or abdominal pain is frequently described; however, frank peritonitis is less common. Arthralgia rather than frank arthritis is common. Local trauma or stressful episodes may trigger an attack.[31]

CUTANEOUS LESIONS The cutaneous lesions may be quite distinctive. Migratory macular erythematous areas ranging in size from 1 cm to 30 cm can occur on the torso or limbs (Fig. 134-2). The rash, when present on the limbs, typically migrates distally. Migratory erythematous lesions on the limbs may be associated with severe myalgia in the underlying muscle groups. These lesions are tender and warm and blanch on palpation. Other less characteristic lesions include

▲ **FIGURE 134-2** Migratory erythematous rash on the right lower extremity of a patient with tumor necrosis factor receptor–associated periodic syndrome.

▲ **FIGURE 134-3** Annular lesion in the inguinal region of a patient with tumor necrosis factor receptor–associated periodic syndrome.

annular patches (Fig. 134-3) and serpiginous patches and plaques (see eFig. 134-3.1 in on-line edition).[31]

Laboratory Tests and Special Tests

Acute attacks are notable for a brisk acute-phase response and leukocytosis. Thrombocytosis is a prominent finding in children. In patients with symptoms suggestive of TRAPS, the detection of a mutation in *TNFRSF1A* is considered the gold standard.

Histopathology

Biopsy specimens usually demonstrate superficial and deep perivascular and interstitial mononuclear infiltrates. A low-grade lymphocytic vasculitis is less commonly seen.

Granulomata, mast cells, and eosinophils have not been described in typical lesions.[32]

Differential Diagnosis

In patients with prolonged episodes, TRAPS may be confused with SOJIA or adult-onset Still disease, but a characteristic migratory erythematous rash with underlying myalgia and periorbital edema is seen in TRAPS, and a quotidian fever pattern is observed in SOJIA (see Box 134-1).

Complications, Prognosis, and Clinical Course

Systemic amyloid A (AA) amyloidosis may occur in approximately 10 percent of patients, with associated high morbidity and mortality. The risk of amyloidosis may be elevated in those with a family

history of amyloidosis and those with mutations causing substitutions in cysteine residues (see eFigs. 134-3.2 and 134-3.3 in on-line edition).[29] In the absence of amyloidosis, however, prognosis is good.

Treatment and Prevention

Use of nonsteroidal anti-inflammatory drugs may suffice for mild attacks, with corticosteroids reserved for more severe cases. However, patients in need of corticosteroids frequently require increasing dosages with time. Colchicine neither reduces the frequency of clinical attacks nor prevents the development of amyloidosis. Studies of etanercept, the p75 TNF receptor fusion protein (see Chap. 235), suggest a favorable clinical response.[31,33] In patients at risk of amyloidosis, tailoring the dose of anti-TNF therapy in response to SAA levels may prevent development of amyloidosis. There are anecdotal reports indicating that patients who are unable to tolerate etanercept therapy may respond to the use of anakinra, an IL-1 inhibitor (see Chap. 235), a finding that supports the hypothesis of a ligand-independent pathogenesis in TRAPS.

CRYOPYRINOPATHIES

Epidemiology, Etiology, and Pathogenesis

The cryopyrinopathies include familial cold autoinflammatory syndrome (FCAS; OMIM #120100),[34] Muckle-Wells syndrome (MWS; OMIM #191900),[35] and neonatal-onset multisystem inflammatory disease (NOMID; OMIM #607115).[36] These represent three clinical disorders that are caused by dominantly inherited mutations in *CIAS1*.[37–39] This gene encodes the cryopyrin protein, which forms part of a macromolecular complex called the *inflammasome*. The inflammasome complex activates caspase 1, which cleaves IL-1β from its precursor protein; this produces a biologically active 17-kd fragment.[40] Mice deficient in cryopyrin are unable to produce IL-1β in response to certain bacteria. Leukocytes from patients with the cryopyrinopathies exhibit accentuated IL-1β production both at baseline and in response to various stimuli.

Clinical Findings

The cardinal presenting signs are an urticaria-like skin rash in infancy with fevers. The severity of joint and neurologic involvement serves in part to differentiate among the syndromes. However, there is considerable overlap among them. FCAS,[34] previously known as *familial cold urticaria*, is the mildest, with episodic cold-induced episodes of fever, skin rash, and polyarthralgia.[41] NOMID, also known as *chronic infantile neurologic, cutaneous, and articular syndrome* (CINCA), has a more severe phenotype with nearly continuous inflammation that results in a deforming arthropathy, chronic aseptic meningitis, sensorineural hearing loss, and loss of vision. Lymphadenopathy and splenomegaly are notable on clinical examination.

▲ **FIGURE 134-4** Urticaria-like skin rash in a patient with Muckle-Wells syndrome.

MWS patients demonstrate an intermediate phenotype with fever, skin rash, and joint pains with sensorineural hearing loss.

In FCAS, generalized cold exposure results in the development of urticaria-like skin lesions. The rash may present as petechiae or erythematous plaques. Symptoms begin early in childhood, within the first 6 months of life, with the characteristic rash initially affecting the extremities or face and then becoming generalized. The rash usually begins 1 hour after cold exposure and may last for 12 to 24 hours. Localized exposure to cold objects does not induce attacks.[42] In MWS, similar urticarial lesions are noted (Fig. 134-4). These may begin in infancy. Attacks are associated with both hot and cold temperatures. Emotional stress may provoke episodes.[43] In NOMID, urticarial lesions are present constantly but may wax and wane in severity. Rash onset occurs days after birth. The rash is migratory and usually non-pruritic; however, exposure to sunlight and fever may result in itch.

Laboratory Tests and Special Tests

Leukocytosis and elevated levels of acute-phase reactants are noted in each of these diseases. In addition, NOMID is associated with anemia of chronic inflammation (previously called *anemia of chronic disease*), thrombocytosis, and eosinophilia. The diagnosis of these conditions usually involves a combination of clinical and genetic analysis. Among patients suspected to have NOMID by experienced clinicians, genetic analysis reveals mutations in only 50 percent of patients.

Histopathology

Affected skin typically demonstrates perivascular and interstitial infiltration of neutrophils and lymphocytes in the papillary dermis, with no evidence of vasculitis, and the epidermis is normal.[36,44] Mast cells are not seen in increased numbers, and serum histamine levels are normal. These features serve to differentiate these lesions from true urticaria (see Chap. 37).[4]

Differential Diagnosis

In FCAS, a consideration is acquired cold urticaria (ACU) (see Chap. 37), which usually presents in adulthood. Spontaneous remission, the presence of mast cells in biopsy specimens, and increased serum histamine levels are notable in ACU. In contrast to patients with FCAS, those with ACU develop symptoms in response to localized cold exposure. Angioedema, wheezing, and hypotension may also be seen in patients with ACU. (See Box 134-1.)

Prognosis and Clinical Course

NOMID, the most severe phenotype, is associated with 20 percent mortality by age 20.[45] Mental retardation and painful arthropathy result in significant morbid-

ity. Persistent inflammation leads to the development of systemic AA amyloidosis with resultant high mortality. MWS is less severe but is associated with sensorineural deafness and the development of AA amyloidosis. FCAS rarely results in amyloidosis.

Treatment and Prevention

For all three of the cryopyrinopathies, promising reports of dramatic clinical responses to the IL-1 receptor antagonist anakinra have been reported (see Chap. 235). Patients with FCAS and MWS experience almost complete remission of the disease. One trial involving 18 patients with NOMID who were treated with anakinra demonstrated disappearance of rash and conjunctivitis within 3 days.[46] Before enrollment all patients had failed to respond to either corticosteroids or TNF blockers. Clinical improvement in hearing and neurologic symptoms was demonstrated, and in eight patients headache resolved completely. Vision remained stable in all patients. Complete remission of inflammatory symptoms occurred in 10 of the 18 patients after 6 months of treatment. Magnetic resonance imaging demonstrated a marked reduction in cochlear and leptomeningeal enhancement. These findings suggest that the manifestations of NOMID are mediated by an excess of IL-1β, and that these symptoms can be ameliorated by the administration of anakinra. Longer follow-up will be required to determine if anakinra can prevent the intellectual impairment caused by NOMID. Continuous treatment with anakinra was required to maintain clinical response. A significant reduction in acute-phase response was noted, including a decrease in SAA levels. This raises the possibility that anakinra may prevent the development of amyloidosis in these patients.

PYOGENIC ARTHRITIS WITH PYODERMA GANGRENOSUM AND ACNE

Epidemiology, Etiology, and Pathogenesis

Pyogenic arthritis with pyoderma gangrenosum and acne (PAPA) is a dominantly inherited condition (OMIM #606347) caused by mutations in the gene encoding PSTPIP1, a protein that interacts with pyrin and is involved in cytoskeletal organization.[47,48]

▲ **FIGURE 134-5** Forearm of a patient with the syndrome of pyogenic arthritis with pyoderma gangrenosum and acne demonstrating a large ulcerated lesion with irregular borders that are slightly elevated and erythematous. A hemorrhagic purulent exudate is evident. Features are typical of pyoderma gangrenosum. (From Shoham NG et al: Pyrin binds the PSTPIP1/CD2BP1 protein, defining familial Mediterranean fever and PAPA syndrome as disorders in the same pathway. *Proc Natl Acad Sci U S A* **100**:3501, 2003, with permission. © 2003 by The National Academy of Sciences of the USA.)

Clinical Findings

Pyogenic arthritis may be a sequela of minor trauma and may result in the development of destructive arthropathy. Synovial fluid is purulent but sterile on culture.

Pyoderma gangrenosum (PG) lesions evolve from a small erythematous pustules to necrotic ulcers in days (see Chap. 32). Minor trauma may be sufficient to provoke the development of large PG lesions, which may cover large areas on the arm, leg, or trunk (Fig. 134-5). Severe cystic acne develops, affecting the face, chest, and back.[49] Pathergy is notable, and patients may develop large sterile abscesses at sites of injections.

Laboratory Tests and Special Tests

During acute episodes, levels of acute-phase reactants are elevated, and leukocytosis and anemia of chronic disease are present. As with the other autoinflammatory diseases, results of serologic testing are usually negative.

Histopathology

Affected skin demonstrates intense infiltrates of polymorphonuclear cells with no evidence of vasculitis.

Differential Diagnosis

PG may be associated with a wide range of systemic diseases, as described in Chap. 32. Genetic testing may facilitate the correct diagnosis of PAPA in ambiguous cases. (See Box 134-1.)

Complications, Prognosis, and Clinical Course

The psychological consequences of widespread scarring from both acne and PG cannot be minimized. Destructive arthropathy has been described.[49,50]

Treatment and Prevention

Early institution of high-dose corticosteroids is the most effective treatment. Affected joints may require aspiration and drainage. Chap. 32 outlines the management of PG in detail. Local wound care and pain management are extremely important. Case reports suggest that the use of biologic therapies targeted at IL-1 or TNF may have clinical benefit.[51]

CHAPTER 135

Xanthomatoses and Lipoprotein Disorders

Lucile E. White

XANTHOMAS

Xanthomas are plaques or nodules consisting of abnormal lipid deposition and foam cells. They do not represent a disease but rather are symptoms of different lipoprotein disorders or arise without an underlying metabolic effect. Xanthomas develop through several mechanisms. Through scavenger receptors for enhanced low-density lipoprotein (LDL) uptake, macrophages incorporate lipid that has been transported through the capillary walls, thus becoming foam cells. Foam cells can also develop as a result of in situ lipid synthesis by the macrophage. Further, lipid that has been extravasated by the capillaries can also recruit additional foam cells into an already established xanthoma. Extravasated and oxidized LDL recruits foam cells by inducing vascular cellular adhesion molecule and E-selectin.[1,2] Local factors such as heat, movement, and friction may increase LDL capillary leakage, and, hence, result in the development of xanthomata.[3] These local factors help explain the location of tuberous xanthomas, tendinous xanthomas, and xanthelasmata.

Clinical Findings

CUTANEOUS LESIONS Clinically, xanthomas can be classified as eruptive, tuberoeruptive or tuberous, tendinous, or planar.[4] Planar xanthomas include xanthelasma palpebrarum/xanthelasma, xanthoma striatum palmare, and intertriginous xanthomas. There are characteristic clinical phenotypes associated with specific metabolic defects (Table 135-1).

Eruptive xanthomata are multiple, reddish-yellow papules that appear suddenly and are arranged in crops on the extensor surface of the extremities and the buttocks (Figs. 135-1 and 135-2). Tuberous xanthomata are nodules that are frequently localized to the extensor surfaces of the elbows, knees, knuckles, and buttocks (Fig. 135-3). Tendinous xanthomata are firm subcutaneous nodules found in fascia, ligaments, Achilles tendons, or extensor tendons of the hands, knees, and elbows (Fig. 135-4). Planar xanthomata are yellow macules, soft papules, or plaques found commonly on the upper eyelids (xanthelasma palpebrarum), the palms (xanthoma striatum palmare) (Fig. 135-5), and in intertriginous areas.

HISTOPATHOLOGY Foam cells are macrophages that contain lipid. These cells characterize xanthomata. Along with foam cells, eruptive xanthomata often consist of lymphoid cells, histiocytes, neutrophils, and, frequently, free lipid in the dermis. Tuberous xanthomata reveal foam cells and cholesterol clefts (Fig. 135-6). Cholesterol is doubly refractile whereas other types of lipid are not. Tendon xanthomata are histopathologically similar to tuberous xanthomata; however, xanthelasmata can be differentiated by their superficial location. Along with the foam cells, xanthelasmata may reveal striated muscle, vellus hair, and/or a thinned epidermis, indicative of the superficial location.[5]

Differential Diagnosis

See Box 135-1.

▲ **FIGURE 135-1** Eruptive skin xanthomata characteristic of severe chylomicronemia.

Treatment

The treatment for xanthomas depends on the underlying etiology.[6]

LIPOPROTEINS AND THEIR METABOLISM[7,8]

Chylomicrons

Most dietary lipid is triglyceride. In the intestine, triglycerides are hydrolyzed by pancreatic lipase into fatty acids and monoglycerides, which are solubilized by the bile and taken up by the intestinal mucosa (Fig. 135-7). In the enterocyte, fatty acids and monoglycerides are resynthesized into triglycerides and are incorporated into lipoproteins called chylomicrons. Chylomicron particles have an inner core of triglycerides plus small amounts of cholesterol ester and a surface coat composed of unesterified cholesterol, phospholipids, and proteins (apolipoproteins). The major apolipoprotein of the chylomicron is apolipoprotein-B48 (apo-B48); other apolipoproteins that affect the metabolism of chylomicrons are apo-C, apo-E, apo-A1, and apo-A4.

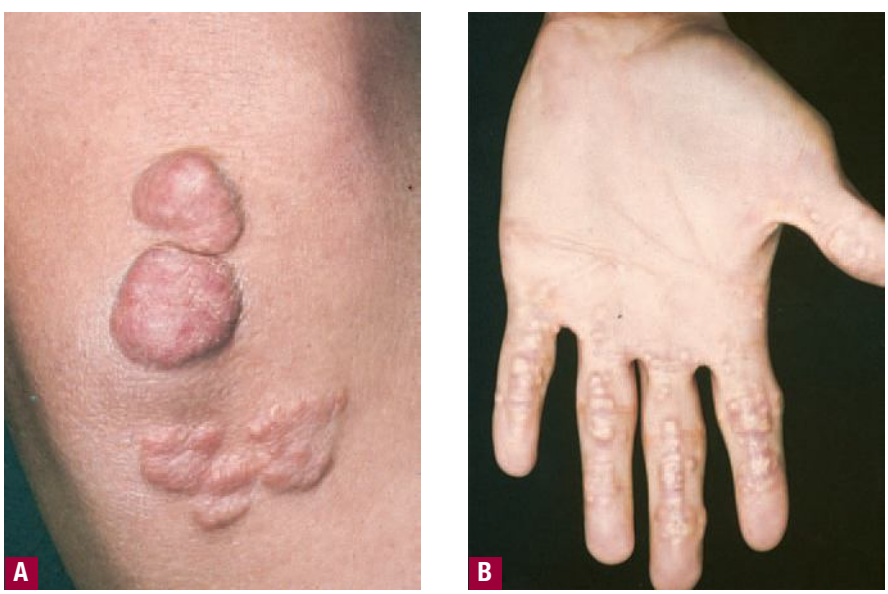
Chylomicrons are secreted into the intestinal lymph and enter the systemic circulation through the thoracic duct, passing into the capillary bed of the peripheral circulation where they come into contact with lipoprotein lipase (LPL) in the capillary walls. This enzyme, located on the endothelial surfaces of capillaries, hydrolyzes the triglycerides of chylomicrons into fatty acids. Several other surface components of chylomicrons are lost to the circulation during triglyceride lipolysis. When most of the triglycerides in chylomicrons have been hydrolyzed by LPL, a residual particle (chylomicron remnant) returns to the circulation. These chylomicron remnants disappear quickly from the circulation in the liver, facilitated by the presence of apo-E.

Very-Low-Density Lipoproteins

Very-low-density lipoproteins (VLDLs) are triglyceride-rich lipoproteins that are derived from the liver. VLDL particles contain less triglyceride than chylomicrons but relatively more cholesterol. Their synthesis in hepatocytes is analogous to chylomicron synthesis in enterocytes. In contrast to chylomicrons, however, VLDL particles contain apo-B100 as their major apolipoprotein; they also have apo-Cs and apo-Es. The total amount of triglyceride secreted daily associated with VLDL is only approximately one-fourth that entering through chylomicrons from the typical American diet. Like chylomicrons, circulating VLDLs pass into the peripheral circulation, where they interact with LPL, which hydrolyzes most of the VLDL tri-

▲ **FIGURE 135-4** Tendon xanthomata typical of heterozygous familial hypercholesterolemia. Similar xanthomata occur in patients with familial defective apolipoprotein B-100, cerebrotendinous xanthomatosis, and sitosterolemia.

▲ **FIGURE 135-2** Eruptive skin xanthomata in an African American woman characteristic of severe chylomicronemia.



▲ **FIGURE 135-3** Tuberoeruptive and tuberous xanthomata typical of familial dysbetalipoproteinemia. **A.** Knee **B.** Palm.

▲ **FIGURE 135-5** Xanthoma striatum palmare characteristic of familial dysbetalipoproteinemia.

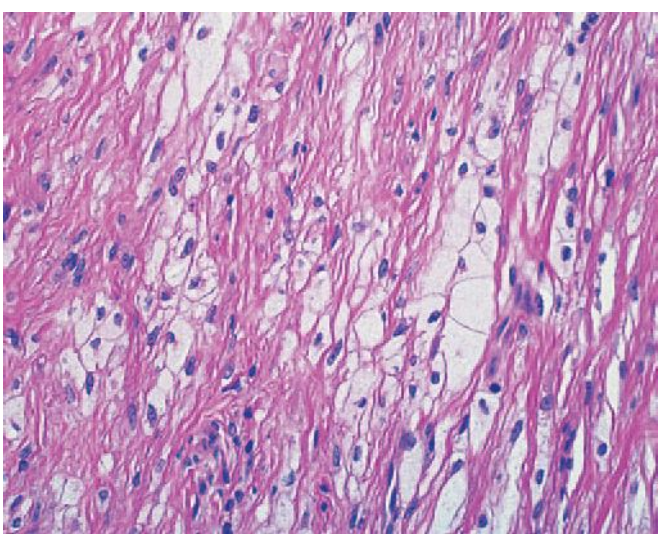
glycerides. After much of the triglyceride is removed, a residual particle, called a *VLDL remnant,* returns to the circulation. Approximately one-half of VLDL remnants are removed directly by hepatic uptake, facilitated by apo-E. A portion of VLDL remnant uptake occurs via receptors for LDLs located on the surface of hepatocytes, where they bind both to apo-E and apo-B100. When VLDL remnants attach to liver cells, many are internalized and degraded. A portion of these particles interacts with hepatic lipase, which removes residual triglycerides and converts them into LDL. Newly formed LDL particles are released from hepatocytes and returned to the circulation.

Low-Density Lipoproteins

LDL particles carry most of the cholesterol present in the fasting serum. LDLs are smaller than VLDLs and contain mostly cholesterol esters in their lipid cores. The only apolipoprotein associated with LDL is apo-B100. Approximately three-fourths of circulating LDL is removed through LDL receptors on liver cells. Lesser amounts of LDL are cleared via nonreceptor pathways or by extra-hepatic tissues. When LDL particles bind to LDL receptors, they are internalized and pass into lysosomes, where they are degraded.

High-Density Lipoproteins

High-density lipoproteins (HDLs) perform a "clean-up" function. Excess unesterified (free) cholesterol in the membranes of peripheral tissue cells may be taken up by HDL. This uptake is the first step of a process called *reverse cholesterol transport*; the process is so named because cholesterol synthesized in peripheral tissues is eventually returned to the liver for its disposal from the body. HDLs have many surface proteins. Apo-A1 and apo-A2 proteins on HDL are derived by direct secretion from the liver.



▲ **FIGURE 135-6** The histopathology of a tuberous xanthoma reveals foam cells.

Box 135-1

Differential Diagnosis of Xanthomas

- Eruptive xanthomas
  - Sarcoid
  - Interstitial granuloma annulare
  - Xanthoma disseminatum (non-Langerhans cell histiocytosis)
- Tuberous or tendinous xanthomas
  - Cyst
  - Lipoma
  - Neurofibroma
- Plane xanthomas
  - Pseudoxanthoma elasticum
  - Amyloidosis
  - Sarcoidosis
- Xanthelasma
  - Syringoma
  - Sebaceous hyperplasia
  - Adnexal neoplasms

FAMILIAL CHYLOMICRONEMIA SYNDROME (FREDERICKSON TYPE I HYPERLIPIDEMIA)

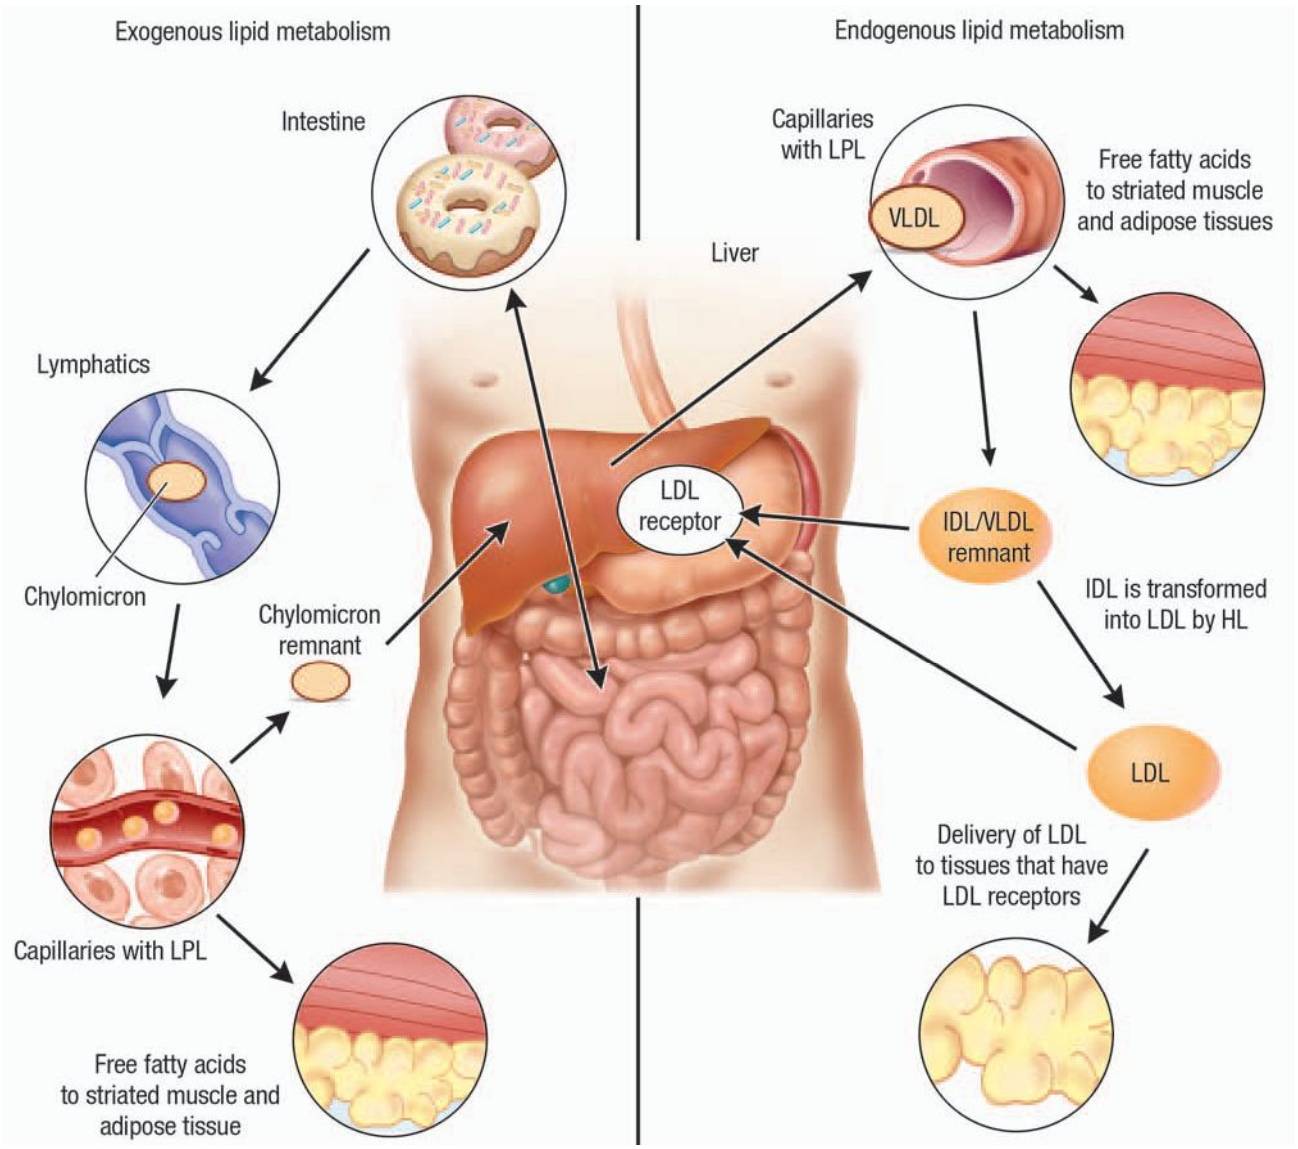
Lipoprotein Lipase Deficiency

EPIDEMIOLOGY LPL deficiency is a rare condition with 1 per 1 million patients homozygous for genetic defects in LPL function.[4]

ETIOLOGY AND PATHOGENESIS A large series of mutations in the LPL gene prevent the normal function of LPL. Patients who are homozygous for LPL defects typically manifest severe chylomicronemia.

When triglyceride levels are below 500 mg/dL, most of the triglycerides are carried in VLDLs. At higher concentrations, chylomicrons consisting of triglycerides begin to accumulate in the serum. Some patients manifest severe chylomicronemia, with triglyceride levels ranging from 1000 to 10,000 mg/dL. These marked elevations result from genetic defects in triglyceride metabolism or genetic defects combined with aggravating acquired factors.

CLINICAL FINDINGS ***Cutaneous Lesions.*** In LPL deficiency, only eruptive xanthomata occur (see Fig. 135-1). Typical locations are over the buttocks, shoulders, and extensor surfaces of the extremities (see Fig. 135-2). Their rapid appearance usually signifies a striking rise of triglyceride concentrations. Eruptive xantho-



▲ **FIGURE 135-7** Lipid metabolism. The exogenous pathway of lipid metabolism involves eating foods that contain fat and delivering the fatty acids to tissues. The triglycerides in the intestines are packaged into chylomicrons in the intestinal enterocytes. Capillary lipoprotein lipase (LPL), which requires apolipoprotein-C (apo-C) as a co-factor, hydrolyzes the triglycerides and releases fatty acids to the peripheral tissues. The remaining chylomicron particle is called a *chylomicron remnant* and is recycled by the liver. The endogenous pathway of lipid metabolism involves the hepatic production of very-low-density lipoprotein (VLDL) and the delivery of free fatty acids to peripheral tissues. VLDL particles have apo-B100 instead of apo-B48. LPL, which requires apo-C as a co-factor, hydrolyzes the triglycerides and releases fatty acids to the peripheral tissues. This remnant is called an *intermediate-density lipoprotein* (IDL). The LDL receptor of the liver removes these remnants by binding to apo-E on the remnant. IDL can also be transformed into LDL by hepatic lipase (HL) in the liver. The new particles of LDL can bind to the LDL receptor through apo-B100.

mata are often associated with lipemia retinalis and pancreatitis.

Laboratory Tests. Triglyceride levels can be severely elevated from birth. Patients who are heterozygous for LPL deficiency either have normal serum triglycerides or have mild hypertriglyceridemia.

PROGNOSIS AND CLINICAL COURSE When serum triglyceride concentrations exceed 2000 mg/dL, patients are at high risk for developing acute pancreatitis.

Patients with LPL deficiency generally are not at increased risk for coronary heart disease (CHD). Although a few patients with LPL deficiency have manifested some atherosclerosis, premature CHD is rare.

TREATMENT There are no available drugs that can effectively treat the severe chylomicronemia of LPL deficiency. The most effective management is through dietary modification. The formation of chylomicrons can be curtailed by reducing the fat content of the diet to less than 10 percent of total calories. Medium-chain triglycerides (MCTs) can be used as a substitute for dietary fat. The fatty acids of MCT are not incorporated into chylomicrons; thus, 10 percent to 15 percent of total calories can be safely consumed as MCTs. The goal of therapy is to keep total triglyceride levels below 1500 mg/dL, which greatly reduces the risk for pancreatitis.

Eruptive xanthomas can also be a result of secondary causes, and it is important to rule out obesity, excessive alcohol intake, diabetes (type 2), and drugs as a cause of these lesions. Drugs that can cause eruptive xanthomas include retinoids, estrogen therapy, and protease inhibitors.

FAMILIAL CHYLOMICRONEMIA SYNDROME (FREDERICKSON TYPE I HYPERLIPIDEMIA)

AT A GLANCE

- Chylomicronemia often presents with eruptive xanthomas.
- Chylomicronemia is due to lipoprotein lipase deficiency or apolipoprotein-C2 deficiency.
- Secondary causes of elevated chylomicrons include obesity, diabetes, alcohol abuse, or medications.
- Medications that can cause elevated triglycerides, and thus eruptive xanthomas, include oral retinoids, estrogen therapy, and protease inhibitors.
- There is very little risk of coronary atherosclerosis.
- Eruptive xanthomas can also be seen in Frederickson type IV and V hyperlipidemia.
- Treatment is most commonly through dietary modification.

Apolipoprotein-C2 Deficiency

EPIDEMIOLOGY Apo-C2 deficiency is a rare condition.

ETIOLOGY AND PATHOGENESIS Apo-C2 is carried on triglyceride-rich lipoproteins and activates LPL. Without LPL, chylomicrons are not degraded.

CLINICAL FINDINGS: CUTANEOUS LESIONS These patients develop severe chylomicronemia and eruptive xanthomata resembling those developed in LPL deficiency.

TREATMENT Treatment of chylomicronemia associated with apo-C2 deficiency is the same as in patients with LPL deficiency.

HYPERCHOLESTEROLEMIA (FREDERICKSON TYPE II HYPERLIPIDEMIA)

Familial Homozygous Hypercholesterolemia

EPIDEMIOLOGY Approximately 1 per 1 million persons in the general population are affected with familial hypercholesterolemia (FH).[4]

ETIOLOGY AND PATHOGENESIS The primary defect in FH is a genetic deficiency of the LDL receptors, which remove LDL from the circulation. Homozygous FH is a condition with defects in both alleles, and these patients have either no LDL receptor activity or very low activity.

CLINICAL FINDINGS ***Cutaneous Lesions.*** Patients with homozygous FH usually have severe xanthomatosis. Multiple types of xanthomata are found (Fig. 135-8). These include tuberous xanthomata (especially over the elbows), subperiosteal xanthomata (below the knees and over the olecranon process), tendon xanthomata (especially in the Achilles tendon and in the extensor tendon of the hand), and elevated xanthomatous plaques (over the extremities, buttocks, and hands). Intertriginous xanthomas are rare but usually associated with this condition. The rate of xanthoma deposition and growth is associated with the duration and severity of the LDL elevation.

Laboratory Tests. In homozygous FH, serum LDL-cholesterol levels are markedly elevated, often in the range of 800 to 1000 mg/dL.

PROGNOSIS AND CLINICAL COURSE These patients commonly develop CHD or other forms of atherosclerotic disease before their teenage years.

TREATMENT Because LDL receptor function is largely absent, drugs that act by enhancing LDL receptor activity, such as bile acid sequestrants and HMG-coenzyme A (HMG-CoA) reductase inhibitors (statins), produce little benefit. High doses of statins, however, may cause moderate reductions in LDL-cholesterol levels in homozygous FH patients, probably by partial inhibition of VLDL secretion. A more radical approach to treatment of homozygous FH is liver transplantation. This procedure supplies normal LDL receptors from the donor liver. A more practical approach is to remove LDL periodically from the circulation by plasmapheresis or LDL-apheresis.[9]

HYPERCHOLESTEROLEMIA (FREDERICKSON TYPE II HYPERLIPIDEMIA)

AT A GLANCE

- Homozygous familial hypercholesterolemia, heterozygous familial hypercholesterolemia, or defective apoliprotein-B100 cause this type of hyperlipidemia.
- Severe hypercholesterolemia can present with tendinous or tuberous xanthomas.
- These conditions are usually treated by HMG-coenzyme A reductase inhibitors.
- There is a significant risk of coronary atherosclerosis.

Familial Heterozygous Hypercholesterolemia

EPIDEMIOLOGY The more common form of FH is heterozygous FH. The prevalence of heterozygous FH is approximately 1 in 500 people.[4]

ETIOLOGY AND PATHOGENESIS Heterozygous FH occurs from the inheritance of a single abnormal allele for the LDL receptor.

CLINICAL FINDINGS ***Cutaneous Lesions.*** In contrast to patients with homozygous FH, heterozygotes only rarely show tuberous xanthomata; tendon xanthomata, however, are common (see Fig. 135-4). In fact, the majority of patients with tendon xanthomata have heterozygous FH.

Laboratory Tests. Heterozygous hypercholesterolemia usually presents on routine adult screening with serum LDL-cholesterol levels approximately twice the normal value.

◀ **FIGURE 135-8 A–C.** Xanthomata typical of homozygous familial hypercholesterolemia.

PROGNOSIS AND CLINICAL COURSE Men with heterozygous FH commonly develop CHD in their 30s and 40s; affected women typically manifest CHD in their 50s and 60s.

TREATMENT Statins have proven to be effective drugs for the treatment of heterozygous FH.[10] These agents inhibit HMG-CoA reductase, the rate-limiting enzyme in cholesterol synthesis.[11] A reduction in cellular cholesterol content sends a signal to the nucleus of the cell to stimulate the synthesis of LDL receptors. In patients with heterozygous FH, the one functional allele for the LDL receptor is "upregulated" by statin therapy; this supplies more LDL receptors and reduces serum LDL levels.

The major side effects of statins are myopathy and hepatotoxicity. These side effects are relatively rare but increase in frequency with increasing doses. The risk for myopathy is increased substantially when the statin is given with either a fibric acid (e.g., gemfibrozil) or cyclosporine. In patients with heterozygous FH, the lowering of LDL cholesterol levels can be enhanced substantially by combining a statin with a bile acid sequestrant (e.g., cholestyramine or colestipol).

In patients with type II hyperlipidemia that were treated with a low cholesterol diet and colestipol, tendinous xanthomas subsided in 2 of 11 patients and improved in 9 of 11 patients. Xanthelasma subsided in two of four patients and improved in two of four patients.[12] Probucol, diet, statins, and LDL apheresis have also been effective in decreasing the size of Achilles tendon xanthomas in patients with FH.[13,14]

Familial Defective Apolipoprotein-B100

Familial defective apo-B100 (FDB) is another cause of moderately severe hypercholesterolemia.[15,16] In this condition, the primary structure of apo-B100 is defective, and LDL does not bind the hepatic LDL receptor effectively. As a result, serum LDL levels are elevated. Patients with FDB frequently resemble those with heterozygous FH except that they typically have somewhat lower LDL cholesterol levels. Most patients with FDB are heterozygotes, and only one-half their LDL particles are defective in binding to LDL receptors. Rare patients are homozygous and have more severe hypercholesterolemia, although usually not to the degree seen in patients with homozygous FH. Some patients with heterozygous FDB develop tendon xanthomata that are identical in appearance to those associated with heterozygous FH. Patients with FDB are prone to premature CHD,[17] and their hypercholesterolemia usually responds well to statin therapy.

DEFECTIVE METABOLISM OF LIPOPROTEIN REMNANTS

Dysbetalipoproteinemia (Frederickson Type III Hyperlipidemia)

ETIOLOGY AND PATHOGENESIS Dysbetalipoproteinemia (type III hyperlipoproteinemia) denotes a category of lipid disorders defined by accumulation of remnant lipoproteins (i.e., chylomicron remnants and VLDL remnants). The usual abnormality is the presence of an

DYSBETALIPOPROTEINEMIA (FREDERICKSON TYPE III HYPERLIPIDEMIA)

AT A GLANCE

- Dysbetalipoproteinemia is defined by accumulation of chylomicron remnants and very-low-density lipoprotein remnants.
- Xanthoma striatum palmare is the characteristic cutaneous feature of this condition.
- Tuberous xanthomas can also be seen with this condition.
- Treatment consists of fibric acids, nicotinic acid, or statin therapy.

abnormal isoform of apo-E, named *apo-E2*. Normal isoforms are apo-E3 and apo-E4; these isoforms promote remnant uptake by the liver. When apo-E2 is present, especially in the homozygous form of the disease, remnant uptake is impaired; as a result, remnant lipoproteins are removed slowly and accumulate in the serum. Isolated homozygous apo-E2 typically produces mild remnant accumulation but not categoric hyperlipidemia. However, hyperlipidemia of the dysbetalipoproteinemic type can develop when lipoprotein metabolism is otherwise disturbed (i.e., in patients with obesity, diabetes mellitus, or endogenous hypertriglyceridemia).

CLINICAL FINDINGS ***Cutaneous Lesions.*** Approximately two-thirds of these patients have tuberoeruptive and tuberous xanthomata (see Fig. 135-3). They also have a characteristic lipid deposition in the creases of the palms of the hands (xanthoma striatum palmare) (see Fig. 135-5). Occasionally, patients manifest tendon xanthomata and xanthelasma. Some patients with dysbetalipoproteinemia exhibit tuberous xanthomata in the absence of raised serum levels of total cholesterol and triglyceride; in these patients, tissue susceptibility combined with increased remnant lipoproteins appears to be responsible for tuberous xanthomata. Tuberous xanthomata of the hands have been observed in two normolipidemic patients who were homozygous for apo-E2. In one patient, xanthomata apparently developed in the fingers because of heavy manual labor.[18]

Laboratory Tests. Typically, in hyperlipidemic patients with dysbetalipoproteinemia, serum concentrations of cholesterol and triglycerides are approximately equally raised. The cholesterol to triglyceride ratio in the VLDL fraction usually exceeds 0.30. A definite diagnosis of dysbetalipoproteinemia is made by identifying the apo-E2 isoform.

PROGNOSIS AND CLINICAL COURSE Hyperlipidemic patients with dysbetalipoproteinemia are at increased risk for CHD and often have peripheral arterial disease.

TREATMENT The hyperlipidemia in patients with dysbetalipoproteinemia is responsive to fibric acids or nicotinic acid; however, if total cholesterol levels are markedly raised, statin therapy is more effective. Reducing serum lipids with drug therapy often causes xanthomata to regress.

MULTIFACTORIAL HYPERLIPIDEMIAS

Familial Hypertriglyceridemia (Frederickson Type IV Hyperlipidemia)

In familial hypertriglyceridemia, the liver overproduces VLDL. Xanthomas are rarely seen. This condition is usually detected only because of routine adult lipid screening, and treatment consists of a low fat diet and fibric acids.

Familial Hypertriglyceridemia: Chylomicronemia Combined with Endogenous Hypertriglyceridemia (Frederickson Type V Hyperlipidemia)

ETIOLOGY AND PATHOGENESIS Chylomicronemia combined with endogenous hypertriglyceridemia is defined by combined elevations in levels of chylomicrons and VLDL. Most cases appear to result from a dual defect in triglyceride metabolism, namely, overproduction of VLDL and defective lipolysis of triglyceride-rich lipoproteins.[19] Both abnormalities can have multiple causes, including the heterozygous state for LPL mutations, a functional reduction of LPL activity, obesity, insulin resistance, and non-insulin–dependent diabetes mellitus.[19]

OVERPRODUCTION OF VERY-LOW-DENSITY-LIPOPROTEIN (FREDERICKSON TYPE IV HYPERLIPIDEMIA)

AT A GLANCE

- Usually detected only because of routine lipid screening.
- Underlying defect unknown.
- Xanthomas as unusual; eruptive xanthomas have been described but are rare.
- Laboratory testing shows elevated very-low-density lipoprotein with normal or only mildly elevated cholesterol levels (> 250 mg/dL).
- Treatment consists of dietary modification, fibrates, and niacin.

CLINICAL FINDINGS ***Cutaneous Lesions.*** Eruptive xanthomas can be a feature of chylomicronemia combined with endogenous hypertriglyceridemia. The cutaneous findings for the familial hyperlipidemias are reviewed in Table 135-2.

Laboratory Tests. Chylomicronemia combined with endogenous hypertriglyceridemia is defined by elevations of chylomicrons and VLDL.

PROGNOSIS AND CLINICAL COURSE Patients with type 5 hyperlipoproteinemia appear to be at increased risk for CHD, and they commonly manifest peripheral arterial disease. The risk for acute pancreatitis rises sharply when triglyceride levels exceed 2000 mg/dL.

TREATMENT Treatment of type 5 hyperlipoproteinemia consists of a low-fat diet (less than 10 percent of total calories as fat) and fibric acids (e.g., gemfibrozil). In addition, weight reduction in obese patients reduces triglyceride levels and may improve glucose control in diabetic patients.

FAMILIAL HYPERTRIGLYCERIDEMIA: CHYLOMICRONEMIA COMBINED WITH ENDOGENOUS HYPERTRIGLYCERIDEMIA (FREDERICKSON TYPE V HYPERLIPIDEMIA)

AT A GLANCE

- Chylomicronemia combined with endogenous hypertriglyceridemia is defined by elevations of chylomicrons and very-low-density lipoprotein.
- Eruptive xanthomas can be seen with this condition.
- Treatment consists of a low-fat diet and fibric acids.

TABLE 135-2
Frederickson Classification of Familial Hyperlipidemias

Frederickson Classification	Condition	Type of Xanthoma
Type I	Familial chylomicronemia	Eruptive xanthomata
Type IIa	Familial hypercholesterolemia	Tendon, tuberous, plane xanthomas (xanthelasma and intertriginous)
	Heterozygous	15% with xanthoma by second decade
	Homozygous	Xanthomata by age 6 yr
Type IIb	Familial combined hypercholesterolemia	Usually absent, but can have xanthomas as in type IIa
Type III	Familial dysbetalipoproteinemia	Palmar, tuberous, tuberoeruptive xanthoma, xanthelasma
Type IV	Familial hypertriglyceridemia	Rare eruptive xanthomas
Type V	Mixed hyperlipidemia	Eruptive xanthomas

XANTHOMATOSES WITHOUT ELEVATED SERUM LIPIDS

A suggested classification of normocholesterolemic xanthomatoses has been proposed.[20] Type I normocholesterolemic xanthomatoses are conditions that result in xanthomas due to altered lipoproteins. Type II normocholesterolemic xanthomatoses are caused by lymphoproliferative diseases, and type III conditions are xanthomatoses associated with local tissue alterations.

Sitosterolemia (Phytosterolemia)

EPIDEMIOLOGY Sitosterolemia is rare condition for which the prevalence is unknown.

ETIOLOGY AND PATHOGENESIS Sitosterolemia, a rare, autosomal-recessive disorder results from accumulation of plant sterols such as β-sitosterol in the serum.[21] The molecular defect in sitosterolemia is in the adenosine triphosphate-binding cassette (ABC) transmembrane transporters encoded by ABCG5 and ABCG8.[22] These defects cause cellular retention of both cholesterol and plant sterols.

CLINICAL FINDINGS ***Cutaneous Lesions.*** Tendon and tuberous xanthomata are common in sitosterolemia; they resemble those of patients with heterozygous FH (see Fig. 135-4).[23]

Laboratory Findings. Early in life, serum cholesterol levels are extremely elevated, similar to those of homozygous FH. Hence, sitosterolemia has been called *pseudohomozygous FH*. Later in life, cholesterol levels decline, but serum sitosterol levels remain elevated. Elevated serum sitosterol concentrations of a few milligrams per deciliter promote xanthoma formation, even without significant hypercholesterolemia.

PROGNOSIS AND CLINICAL COURSE Patients with sitosterolemia are at high risk of atherosclerosis and CHD.

TREATMENT Treatment of sitosterolemia consists of a reduced intake of cholesterol and plant sterols. In addition, bile acid sequestrants and ezetimibe are often used to treat this condition. Ezetimibe is a newer medication that has been shown to block the intestinal absorption of cholesterol and plant sterols.[24,25]

Cerebrotendinous Xanthomatosis

EPIDEMIOLOGY The prevalence of cerebrotendinous xanthomatosis (CTX) is approximately 1 per 50,000.[26]

ETIOLOGY AND PATHOGENESIS The genetic abnormality results in incomplete oxidation of cholesterol into bile acids in the liver due to mutations in mitochondrial C27-steroid 26-hydroxylase (CYP27A1).[27] A by-product of this defect is increased synthesis of the sterol cholestanol.

CLINICAL FINDINGS In CTX, xanthomata develop in the tendons and brain. CTX causes severe neurologic manifestations. Patients with juvenile cataracts should undergo testing for CTX, which can be diagnosed by elevated plasma cholestanol.

PROGNOSIS AND CLINICAL COURSE Patients with CTX are at increased risk for CHD.

TREATMENT Treatment consists of replacement of the bile acid pool with oral chenodeoxycholic acid. This therapy reduces cholestanol synthesis and has been reported to alleviate neurologic symptoms. HMG-CoA reductase inhibitor and LDL apheresis are also reported as possible treatments.[28,29] A combination of LDL apheresis, chenodeoxycholic acid, and a HMG-CoA reductase inhibitor more effectively reduce serum cholestanol than LDL apheresis alone.[30]

Tangier Disease

ETIOLOGY AND PATHOGENESIS Tangier disease is a rare, autosomal-recessive condition caused by defects in the gene ABCA1.[31] This protein is responsible for transporting cellular cholesterol to the cell surface where it is delivered to circulating HDL. A defect in the transmembrane transporter causes an accumulation of cholesterol in peripheral tissues due to the inability to perform "reverse transport" via the HDL particles.

CLINICAL FINDINGS ***Cutaneous Lesions.*** Tangier homozygotes accumulate cholesterol esters in tonsils, spleen, lymph nodes, bone narrow, thymus, and intestinal mucosa. These accumulations most commonly produce yellow/orange hyperplastic tonsils, mild lymphadenopathy, and splenomegaly.

Laboratory Findings. Patients with Tangier disease have low plasma HDL cholesterol and apo-A1 levels.

PROGNOSIS AND CLINICAL COURSE Older patients with Tangier disease often develop CHD.

High-Density Lipoprotein Metabolic Defects: Apolipoprotein A1 Deficiency

ETIOLOGY AND PATHOGENESIS Apo-A1 is the major lipoprotein in HDL. Mutations in apo-A1 can reduce HDL synthesis and produce HDL deficiency.[32]

CLINICAL FINDINGS Patients with defects limited to synthesis of apo-A1 may manifest plane xanthomata.[32]

PROGNOSIS AND CLINICAL COURSE It is uncertain whether these patients are prone to premature CHD; however, they do not appear to develop fulminant atherosclerosis. In some cases, there is a concomitant defect in synthesis of apo-C3 and apo-A4. When the latter defects are present, complex abnormalities are present in lipoprotein metabolism, and affected patients are prone to premature CHD.

Dysproteinemias

ETIOLOGY AND PATHOGENESIS Diffuse plane xanthomata have been reported in multiple myeloma, monoclonal gammopathy, cryoglobulinemia, leukemia, lymphoma, eosinophilic granulomatosis, and rheumatoid arthritis.[33] When diffuse xanthomas are found in monoclonal gammopathies, the M protein is usually immunoglobulin G.[33] Xanthomas are produced as a result of a complex between the paraprotein and a lipoprotein. Cellular uptake of these complexes by macrophages produces plane xanthomata.

CLINICAL FINDINGS: CUTANEOUS LESIONS A number of forms of dysglobulinemia or paraproteinemias are accompanied by diffuse plane xanthomata that typically manifest as yellow-orange macules or slightly raised plaques over the eyelids, neck (Fig. 135-9), and trunk.[34]

◀ **FIGURE 135-9** Diffuse plane xanthoma in a patient with lymphoma.

PROGNOSIS AND CLINICAL COURSE All patients with negative laboratory studies should have routine follow-up for the future development of dysproteinemias.

TREATMENT Treatment is dependent on the underlying condition.

SPECIAL CONSIDERATIONS

Biliary Obstruction or Hypoplasia

ETIOLOGY AND PATHOGENESIS Prolonged obstruction of the biliary tree leads to accumulation of cholesterol in the serum. Causes include primary biliary cirrhosis and secondary biliary obstruction. Serum cholesterol is high in unesterified cholesterol, which leads to the formation of an abnormal lipoprotein called *lipoprotein X*.

In children, Alagille syndrome is an inherited syndrome of biliary hypoplasia leading to elevated serum cholesterol.

CLINICAL FINDINGS: CUTANEOUS LESIONS Prolonged hypercholesterolemia leads to plane xanthomata (beige-orange plaques on hands, feet, and trunk), xanthelasma, and occasionally, tuberous xanthomata. Patients with prolonged biliary obstruction can also manifest jaundice, pruritus, and hyperpigmentation of the skin.

Children with Alagille syndrome have a characteristic facies with a prominent forehead, hypertelorism, pointed chin, and nasal dystrophy.

PROGNOSIS AND CLINICAL COURSE In Alagille syndrome, serum cholesterol is elevated when patients are young but can decrease over time. Cirrhosis develops in approximately 12 percent of patients with Alagille syndrome.

TREATMENT Treatment involves relieving the underlying cause of obstruction. Treatment for Alagille syndrome is medical management or, if cirrhosis develops, liver transplantation. Xanthomas have been found to resolve after liver transplantation.[35]

Xanthomas in Children

Xanthomas in children are uncommon and must always be investigated. The differential for xanthomas in children includes homozygous FH, sitosterolemia, CTX, and Alagille syndrome. If laboratory investigation reveals a childhood hyperlipidemia, treatment algorithms are available.[36]

Normolipemic Xanthelasma

Although the presence of xanthelasma warrants and investigation to rule out hyperlipidemia,[37] more than 50 percent of patients with xanthelasma may have normal serum lipids.[38,39] In these cases, the removal of xanthelasma is often a cosmetic concern. Treatment options include surgical excision, ablative laser therapy, trichloroacetic acid, or cryotherapy.[40]

Verruciform Xanthoma

Verruciform xanthoma commonly occurs in the oral cavity and are discussed in Chap. 74. Histologically it shows foamy histiocytes within elongated dermal papillae. Verruciform xanthoma is the characteristic lesion in *c*ongenital *h*emidysplasia with *i*chthyosiform erythroderma and *l*imb *d*efects (CHILD) syn-

drome (see Chap. 47), and mutations in the 3β-hydroxysteroid dehydrogenase gene (the gene that is mutated in CHILD syndrome), has been shown to underlie two cases of sporadic verruciform xanthoma.

Xanthoma Disseminatum

Xanthoma disseminatum is a histiocytic condition associated with diabetes insipidus and is discussed in Chap. 149.

Xanthogranuloma

Xanthogranulomas are also histiocytic conditions and are discussed in Chap. 149.

CHAPTER 136

Fabry Disease

Margarita M. Larralde
Paula C. Luna

EPIDEMIOLOGY

Fabry disease is the second most prevalent lysosomal storage disorder, after Gaucher disease,[1] with an estimated incidence ranging between 1:40,000 to 1:170,000 persons. Some authors consider this incidence to be underestimated given the existence of milder variants (renal and cardiac), postmortem diagnoses, and diagnoses in the setting of affected relatives.[2] The majority of patients are Caucasians, but it has been reported in other ethnicities.[1]

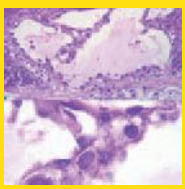
ETIOLOGY AND PATHOGENESIS

Fabry disease (Online Mendelian Inheritance in Man #301500) is a rare X-linked metabolic disorder caused by the partial or complete deficiency of a lysosomal enzyme, α-galactosidase A (Fig. 136-1). As a result of this enzyme deficiency, neutral sphingolipids with terminal α-galactosyl residues [predominantly globotriaosylceramide (Gb3)] accumulate in the lysosomes of different tissues and fluids (epithelial cell of glomeruli and tubules of the kidneys; cardiac myocytes; ganglion cells of the autonomic system; cornea; endothelial, perithelial, and smooth muscle cells of blood vessels; and histiocytic and reticular cells of connective tissue) (Fig. 136-2).[3] It manifests primarily in affected hemizygous men and, to some extent, in heterozygous females. Clinical onset is variable (Fig. 136-3); the disease usually appears during childhood, but may not appear until the second or third decade.

The gene GAL for α-galactosidase A is located at the Xq22.1 region. The entire 12Kb seven exon gene has been completely sequenced,[4] and mutations have been found in all seven exons.[1] More than 300 mutations of the gene have been detected, showing a wide variety of molecular lesions that have been demonstrated to be responsible for Fabry disease. Approximately 57 percent of alleles are missense mutations, 11 percent nonsense mutations, 18 percent partial gene deletions, 6 percent insertion, and 6 percent RNA processing defects due to aberrant splicing. Most families have "private" mutations, that is, mutations found only in that particular family.[3] No clear genotype-phenotype correlation has been demonstrated. Different mutations may cause similar phenotypes and, even within families, the same mutation may cause different phenotypes.

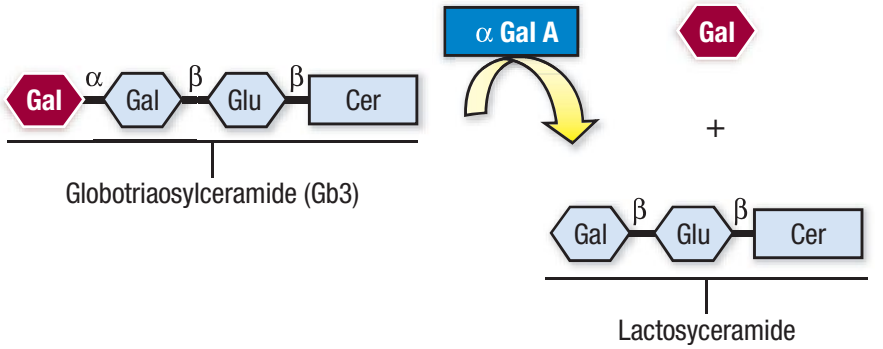
The Fabry gene is highly penetrant in males. Female heterozygotes (previously known as *carriers*) have variable expressivity ranging from completely asymptomatic to complete clinical and biochemical expression similar to hemizygous patients.[5–7] This variable expression is attributed to the Lyon hypothesis (where one X chromosome is inactivated on a random basis in the female, while the other provides the genetic information).[8]

FABRY DISEASE AT A GLANCE

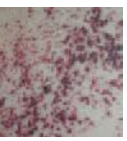


- Incidence estimated at 1:40,000 to 1:170,000 in all ethnicities.
- X-linked lysosomal storage disorder.
- Highly penetrant in males; female heterozygotes have variable expressivity.
- Partial or complete deficiency of α-galactosidase A with deposition of glycosphingolipids (mostly globotriaosylceramide).
- Typical variants affect predominantly skin, kidneys, heart, eyes, and brain.
- Life expectancy shortened by 20 years in males and 15 years in females.
- Atypical variants: Renal and cardiac.
- Dermatologic manifestations: Angiokeratomas and hypohidrosis.
- Light microscopy: Thinned epidermis over dilated or vacuolated blood vessels.
- Electron microscope: Zebra-like inclusion bodies.
- Treatment: Palliative, enzyme replacement.

HISTORICAL ASPECTS



▲ **FIGURE 136-1** Metabolic pathway of globotriaosylceramide into galactose (Gal) and lactosylceramide secondary to the activity of α-galactosidase A (α Gal A). Cer = ceramide; Glu = glucose.

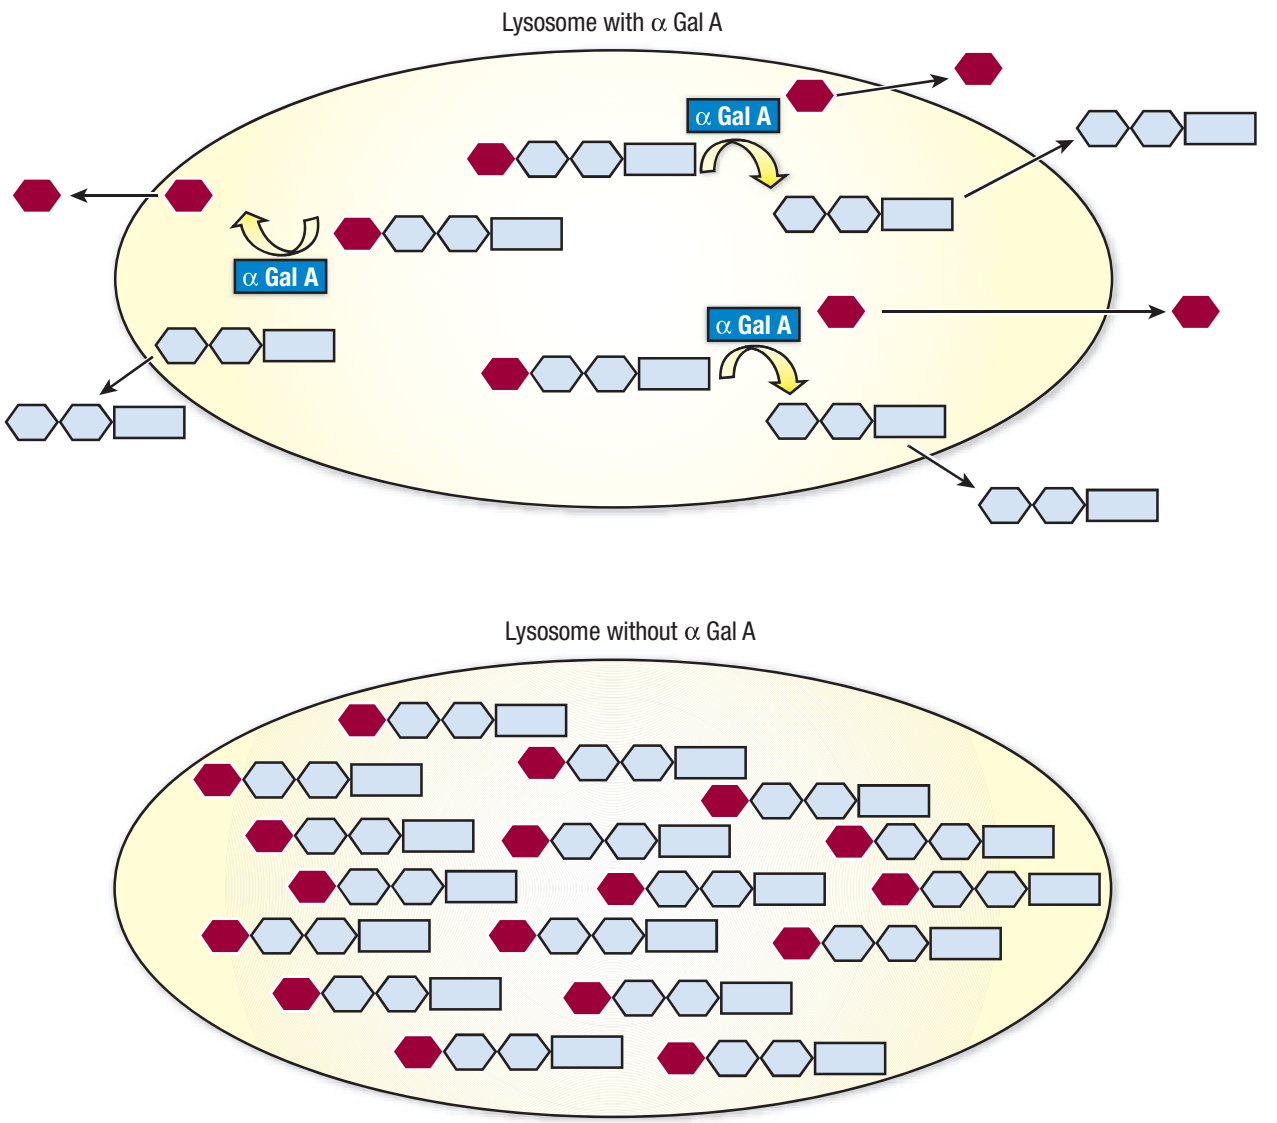


CUTANEOUS FINDINGS

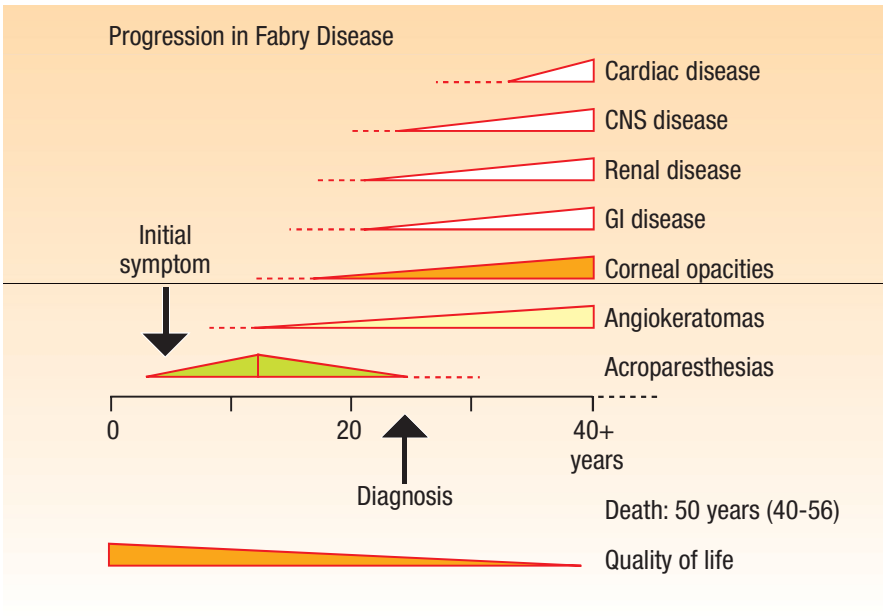
Angiokeratomas

Angiokeratomas (AKs) are the most obvious and one of the most frequent clinical features of Fabry disease.[3,11] These lesions usually become evident between the age of 5 and adolescence, but significantly later in heterozygous females.[12] AKs usually present as clustered red to black papules that measure up to 1 cm in diameter, do not blanch with pressure, and often show a verrucous surface (Figs. 136-4 and 136-5).[4,13] They typically localize symmetrically in the bathing trunk area (buttocks, lower abdomen, groin, umbilicus, upper thighs) (Figs. 136-6 and 136-7, see eFigs. 136-6.1 and 136-6.2 in on-line edition; see Fig. 136-5), elbows, waist, and extensor surfaces of arms, as well as along the spine, suggesting a role for trauma in their occurrence (Koebner phenomenon). AKs are occasionally found on the hands (see eFig. 136-7.1 in on-line edition), feet, ears, and axillae, and rarely on the face, upper chest or back.[12,14] The number of lesions and their extent increases progressively with time.[3] The presence or extent of cutaneous involvement does not always correlate with systemic morbidity.[15]

Female patients usually show scattered, single AKs, often in an atypical distribution (upper chest or patches in a dermatomal distribution on the upper



▲ **FIGURE 136-2** Deficit of α-galactosidase A (α Gal A) results in the accumulation of the substrate inside the lysosome.



▲ **FIGURE 136-3** Natural history of Fabry disease: Acroparesthesias, angiokeratomas, corneal opacities, and gastrointestinal symptoms are often the first manifestations. Diagnosis is usually delayed and occurs around the second decade. CNS = central nervous system; GI = gastrointestinal.

or lower limbs).[16] In one series, 83 percent of hemizygous males had generalized AKs, but 80 percent of heterozygous females had isolated AKs.[3]

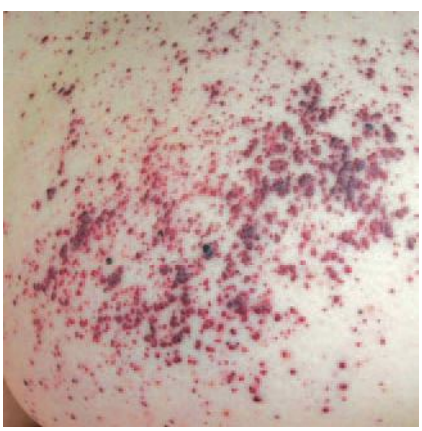
Hypohidrosis

Hypohidrosis is usually present by childhood or adolescence, leading to dry skin, intolerance to heat and exercise, and fever of unknown origin. It has been linked to peripheral nerve damage and/or lipid deposits in the small blood vessels surrounding eccrine glands and in the eccrine cells, as well as to abnormal nerve function due to an ischemic process.[17] By electron microscopy, marked degeneration of the secretory and myoepithelial cells of the sweat glands is demonstrable. The ability to sweat is not affected by the extent of the deficiency of α-galactosidase A.[18] Hyperhidrosis has also been reported in some patients.[19]

▲ **FIGURE 136-4** Multiple red pinpoint papules (angiokeratomas).

Oral Mucosal Lesions

AKs are found both periorally and intraorally, are mostly present in the anterior buccal mucosa, and can occasionally be present elsewhere (soft palate, tonsillar pillars, retromolar pads, and gingiva). They may appear telangiectatic (see eFig. 136-7.2 in on-line edition). Fissures and erythematous fungiform papillae have been described on the dorsal surface of the tongue.[20] Other mucosal findings include a cobbled tongue, glossitis, cheilitis granulomatosa, punctate



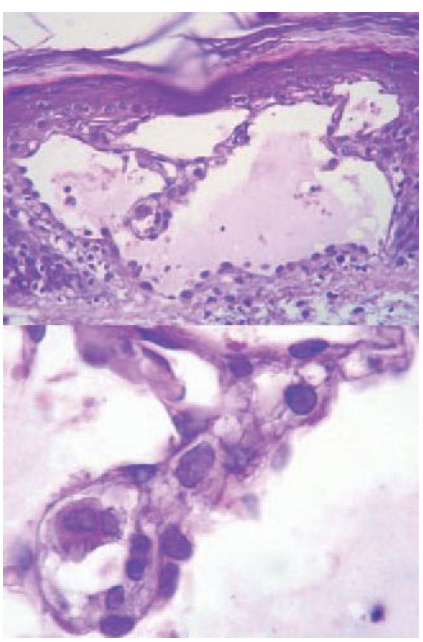
▲ **FIGURE 136-5** Larger magnification of multiple red to black angiokeratomas with a verrucous surface.

▲ **FIGURE 136-6** Angiokeratomas over the lower abdomen of a male patient with complete phenotypic expression.

angiectasis, and a twofold increase in the prevalence of cysts/pseudocysts of the maxillary sinuses.[20] There may be increased vascular tortuosity of the conjunctival vessels (see eFig. 136-7.3 in on-line edition). Although many patients complain of xerostomia, the salivary glands appear to be normal.

Other Mucocutaneous Features

Lymphedema of the legs has been frequently described and is thought to be due to the deposition of Gb3 in lymphatics (see eFig. 136-7.4 in on-line edition).[21] Although not as striking as in



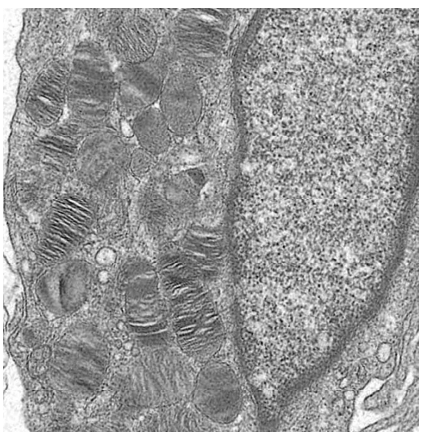
▲ **FIGURE 136-7** Light microscopy: Very dilated capillaries surrounded by an acanthotic epidermis. Larger magnification reveals cytoplasmic vacuoles inside endothelial and perithelial cells. (Used with permission from Dr. Gabriel Casas.)

other lysosomal diseases, some male patients have subtle dysmorphic facial features.[22] It is likely that these features become more pronounced over time together with the storage material, as patients with residual enzyme have less pronounced features. They tend to show periorbital fullness, prominent lobules of the ears, bushy eyebrows, recessed forehead, pronounced nasal angle, generous nose, prominent supraorbital bridge, broad alar base, and coarse features.[1,12,23] Alterations of the density of body hair have also been described.[19]

Histopathology

By light microscopy, AKs are characterized by a thin epidermis overlying a dermis with dilated blood vessels. Older, fully developed AKs may show hyperkeratosis (see Fig. 136-7). Endothelial, perithelial, eccrine, and smooth muscle cells are filled with cytoplasmic vacuoles containing glycosphingolipid that can be seen with toluidine stains. To preserve vacuolar contents (which are cleared by routine fixation), fixed tissue can be frozen or fixed with 1 percent calcium formol.

Characteristic electron-dense concentric or lamellar (zebra-like) inclusion bodies with a pattern of alternating (every 4 to 6 nm) light- and dark-staining bands are evident ultrastructurally under the electron microscopy (Fig. 136-8), in the endothelium, smooth muscle cells of the blood vessels, erector pilorum muscle cells, and dermal macrophages. These inclusion bodies can also be recognized in clinically normal skin.[24,25] The electron-dense lamellar (zebra-like) inclusions are strikingly prominent in the eccrine sweat glands.[17]



▲ **FIGURE 136-8** Electron microscopy. Osmiophilic lamellar bodies in a larger magnification reveals zebra bodies in a cutaneous endothelial cell. (Used with permission from Dagmar Foedinger, MD.)

Electron microscopy and immunoelectron microscopy using anti-Gb3 antibodies are useful tools when other diagnostic tests are not conclusive.[26]

NON-CUTANEOUS FINDINGS (Table 136-1, see Fig. 136-3)

Neurologic Findings (See Table 136-1)

ACROPARESTHESIAS Burning pain and tingling of the extremities is the most constant (80 percent to 90 percent) and early (in the first decade) clinical feature of Fabry disease in male patients. Female carriers report numbness or increased sensitivity of the extremities later in life.[12] Pain is described as feeling like pins and needles on the hands and feet, radiating proximally. It is constant or can be intermittent, triggered by changes of environmental or body temperature, exercise, or emotional stress.[18] Lipid accumulation within intradermal nerve fibers with degeneration of small unmyelinated nerve fibers and reduction of intraepidermal innervation can be seen ultrastructurally.[13,27,28] With time, patients often note a reduction in the intensity and frequency of acroparesthesias due to the complete destruction of the nerve fibers.

CEREBROVASCULAR DISEASE (See Table 136-1) Ischemic or hemorrhagic strokes occur early in life (average onset of 34 years in hemizygotes and 40 years in heterozygotes) and are, after renal failure, the most devastating and life-limiting event. Fabry disease should be considered as a differential diagnosis in young patients with cryptogenic stroke, for it has shown to affect nearly 1.5 percent of these patients.[29] Strokes lead to death in 55 percent of male and 40 percent of female patients.[13] A higher incidence of venous and arterial intravascular thrombosis, as well as increased levels of soluble intercellular adhesion molecule 1, P-selectin, and plasminogen activator inhibitor, and decreased thrombomodulin levels, have been detected.

OTHERS (See Table 136-1) Depression and dementia often occur in patients as they grow older. Some authors also report an increased frequency of suicidal ideation and suicide.[30,31] Sexual activity is often affected by the presence of AKs of the genital region or genital pain, leading to decreased self-esteem and libido. Autonomic dysfunction may include abnormalities in tears and saliva formation, cerebrovascular reactivity, cardiac rhythm, gastrointestinal motility, pain perception, and peripheral edema.[31] In contrast to other lysosomal storage diseases, mental retardation is not an early problem; however, older patients complain of dizziness, cephalalgia, and abnormal muscle reflexes.

TABLE 136-1
Non-Cutaneous Findings

- Renal
  - Chronic renal failure
- Cardiovascular
  - Hypertension
  - Coronary vascular disease
  - Left ventricle hypertrophy
  - Valve disease
  - Arrhythmias
  - Elevated high-density lipoprotein
- Neurologic/psychiatric
  - Acroparesthesias
  - Cerebrovascular disease
  - Dementia
  - Depression
  - Increased suicide ideation
- Ocular
  - Cornea verticillata
  - Conjunctival vessel aneurysms
  - Increased tortuosity of retinal vessels
  - Fabry cataract
- Gastrointestinal
  - Diarrhea
  - Nausea
  - Vomiting
  - Postprandial flank pain
  - Malabsorption
- Others
  - Hearing loss and tinnitus
  - Hypothyroidism
  - Obstructive airway disease
  - Osteopenia and osteoporosis
  - Anemia

Renal Manifestations (See Table 136-1)

Proteinuria develops around adolescence with gradual deterioration of renal function and the development of end-stage renal disease by around the third to fifth decade.[4] Characteristic maltese cross-shaped birefringent lipid globules can be found in the urine or the urinary sediment under polarizing microscopy (see eFig. 136-8.1 in on-line edition). A renal variant of Fabry disease has been described.[32,33] Patients have decreased, but not absent, α-galactosidase A activity and develop end-stage renal disease at ages similar to that of classically affected patients, but lack other characteristic manifestations.[34]

Cardiac Manifestations (See Table 136-1)

Cardiac involvement is a constant feature.[35] It is thought to be due to the deposition of Gb3 in myocardium, valves, and the conduction system,[27] although other mechanisms might contribute.[35,36] Deposition may manifest as left ventricular hypertrophy, mitral valve collapse, and arrhythmias, as well as coronary artery disease (angina, myocardial infarction, and electrocardiogram abnormalities).[27,37] An interesting finding in Fabry disease is their unusual lipoprotein phenotype, showing elevated high-density lipoprotein cholesterol, normal low-density lipoprotein cholesterol and triglycerides, and a borderline increase in total cholesterol.[38] Some patients with low residual α-galactosidase A levels and cardiac manifestations have a milder and later-onset phenotype than typical affected patients (cardiac variant).[34,39]

Ocular Findings (See Table 136-1)

The most characteristic and common ocular finding is cornea verticillata (opacities characterized by one or more lines radiating from near the center of the cornea), which occurs in 94 percent of male and 70 percent of female patients.[40] Conjunctival vessel aneurysms, increased tortuosity of retinal vessels (especially of the posterior pole) (see eFig. 136-7.3 in on-line edition), papilledema, optic atrophy, anterior cataracts, and lenticular changes can also be found.

Gastrointestinal Manifestations (See Table 136-1)

Episodic diarrhea, nausea, vomiting, postprandial flank pain, and malabsorption are the most common gastrointestinal complaints. Other gastrointestinal signs (pancreatic insufficiency, achalasia, and jejunal diverticulosis) have also been described. All these symptoms may relate to the deposition of glycosphingolipid in intestinal small vessels and in autonomic ganglia. Many patients consider gastrointestinal symptoms to be the most debilitating features of the disease, especially during childhood.[13]

Other Non-Cutaneous Manifestations (See Table 136-1)

Tinnitus and high-frequency sensorineural hearing loss are also common manifestations of Fabry disease, with a prevalence of around 50 percent. The severity of the hearing loss is thought to be closely related to the renal function impairment.[41]

Although Gb3 deposits in many endocrine glands, the function of most endocrine organs seems to be intact, with normal production of gonadotropins and sex hormones, as well as normal fertility rates.[42] The exception is a much higher incidence of sub-clinical hypothyroidism in both male and female patients.[43]

Some patients can develop severe obstructive airway disease. Spirometry studies show a reduced forced residual volume and increased mean residual capacity. Older patients may also show reduced Vmax25 (25 percent of vital capacity) and diffusing capacity. Osteopenia and osteoporosis are complications that likely result from malabsorption of vitamin D, reduction of physical activity because of pain, chronic renal failure, and, possibly, decreased osteoblastic activity because of endothelial glycosphingolipid accumulation.[44] Anemia often occurs, largely related to the impaired renal function, heart failure, and chronic inflammation.[45]

Quality of Life (See Fig. 136-3)

The severe clinical manifestations (affecting kidney, gastrointestinal system, heart, and brain), the presence of sometimes visible AKs, as well as the debilitating pain and hypohidrosis, affect patient well-being, physical and social functioning, work, and the ability to carry out daily activities.[46]

DIAGNOSIS

The definitive diagnosis of Fabry disease is usually delayed, with a mean time between the onset of symptoms and diagnosis of 15 years.[47] Although clinical and histopathologic findings might lead to suspicion of Fabry disease,[48] the diagnosis must be confirmed by the demonstration of deficient α-galactosidase A activity in tears, plasma, serum, or leukocytes and in dried blood spots on filter paper,[3]

as well as the presence of Gb3 in urinary sediment, plasma, and cultures of fibroblasts in hemizygous and some heterozygous patients. Female patients have variable, and, occasionally, even normal levels of enzyme activity. Thus, identification of a pathogenic mutation is required to confirm diagnosis.[18]

Biopsy of tissues, such as skin and kidney, demonstrates the presence of lipid deposition and multilamellated myelin bodies in electron micrographs (see Fig. 136-8).[13] As Gb3 deposition starts in utero,[49] prenatal diagnosis can be performed from chorionic villi or culture of amniotic cells, where low α–galactosidase A activity can be demonstrated.[50]

DIFFERENTIAL DIAGNOSIS (Boxes 136-1, 136-2, and 136-3)

The discomfort is often mistaken for rheumatoid arthritis, rheumatic fever, erythromelalgia, Raynaud disease, or simply as "growing pains."[13,51]

The clinical diagnosis of AKs may be difficult. They may resemble petechiae, pyogenic granulomas, or eruptive angiomas; older lesions with a verrucous surface may be misdiagnosed as warts, condylomas, or even melanoma.[52] The AKs from Fabry disease should also be differentiated from other AKs,[53] particularly angiokeratoma of Fordyce, angiokeratoma of Mibelli, the solitary papular angiokeratoma, and angiokeratoma circumscriptum (Table 136-2).

AKs have also been described in several other lysosomal storage disorders (Table 136-3).[54] In addition to the distinct enzyme deficiency in each of these storage diseases and other clinical features, AKs from Fabry disease can be

differentiated by electron microscopic examination by the characteristic electron-dense, lamellar (zebra-like) inclusions within endothelial and other cell types.[55] Widespread AKs have been also described in a 29-year-old patient with tuberous sclerosis,[56] a 12-year-old patient suffering from juvenile dermatomyositis,[57] two infants with neonatal lupus erythematosus, and co-existing with a familial cerebral cavernous angioma syndrome. Generalized AKs without an associated metabolic disorder have been also described (see eFig. 136-8.2 in on-line edition).

PROGNOSIS AND CLINICAL COURSE

Life-span reduction in patients with Fabry disease has been calculated to be 20 years for male patients and 15 years for female heterozygotes. Unless the patient undergoes hemodialysis or renal transplantation, death most often is due to uremia (see Fig. 136-3).

TREATMENT (Box 136-4)

The many different debilitating symptoms of Fabry disease demand a multidisciplinary approach that involves the primary caregiver, as well as experienced nephrologists, cardiologists, dermatologists, and neurologists.

Palliative Therapies

AKs can be treated with cryotherapy, electrocoagulation, or excisional surgery. However, the treatment of choice is laser therapy (neodymium YAG, pulsed dye, KTP 532nm, copper, argon, candela V, or beam laser).[19,58] Pain is the most disturbing and early symptom, and can sometimes be partially managed with diphenylhydantoin, carbamazepine, or gabapentin. Nonsteroidal anti-inflammatory drugs are not only ineffective, but also contraindicated because they can affect renal function. Narcotics are also best avoided, given the chronic nature of the disease and the high risk of addiction. Patients should be encouraged to identify and try to avoid their personal precipitating stimuli if possible.

For the primary or secondary prevention of stroke and other vascular pathologies, such as retinal artery occlusion, anti-platelet and anticoagulant therapy might be needed.[59]

Metoclopramide and pancrelipase are used to reduce gastrointestinal symptoms. Hypertension must be controlled, as it significantly affects three of the most affected organs, the kidney, brain, and heart. Special attention should also be paid to renal function, because renal dysfunction is the most frequent and serious late complication. For maintaining a good cardiac functioning, antiarrhythmics, artificial pacemakers, and even cardiac transplant might be required.

If an engrafted kidney has normal α-galactosidase A activity, it will metabolize the glycosphingolipids and remain free of Gb3 deposition through life.[4] Allograft kidneys from Fabry carriers, however, should be avoided because they may function correctly initially, but over time may become less effective; furthermore, the carrier female donor is at risk for the development of renal disease and may suffer for having only one kidney.

Specific Therapeutics: Enzyme Replacement Therapy

One enzyme preparation, agalsidase β (Fabrazyme), has been approved and is available in the United States and Europe; another, agalsidase alfa (Replagal), is available only in Europe. Several clinical trials have shown enzyme replacement therapy (ERT) to be effective in reducing the amount of stored tissue glycolipids.[60–62] Additionally, the therapy

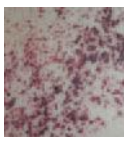
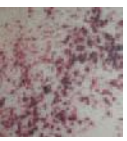
  - α-Galactosidase A (Replagal)



reduces pain episodes, stabilizes or improves renal function in patients with a mild renal disease, and reduces excess cardiac mass, gastrointestinal symptoms, and hypohidrosis. Gb3 deposition in the skin has also been reduced by the ERT, suggesting that periodic ultrastructural examination of skin might be useful to monitor response to therapy.[24,63] Whether or not ERT will positively impact on mortality is still unknown.[64] When to start ERT is still controversial,[65] especially among female and patients with milder variants.[66] Experts recommend that ERT should be provided in the second decade in male patients or as soon as symptoms are observed.[39,67] Adverse events to date have only been infusion related (hives, pruritus, fever, and rigors) and respond to premedication and a decrease in infusion rate.



New Treatments

A new strategy for treating this disease is chaperone-based enzyme enhancement therapy (phase II clinical trial by Amicus Therapeutics). This novel therapy consists of small molecules that rescue misfolded/mistrafficked enzymes from the lysosomes and transport them to the endoplasmic reticulum. The principal benefit of this therapy is that it can be administered orally and can cross the blood-brain barrier.[68] Chaperone-based ERT is useful only for patients with some residual enzyme.

Substrate deprivation (inhibition of an early step in the synthesis of glycosphingolipids)[14] and the infusion of galactose are other therapeutic options that are still in the research state.

Gene therapy and hematopoietic cell transplantation are still being developed.[69]

Genetic Counseling

All families that have a member with Fabry disease should have an opportunity to receive genetic counseling. Given the X-linked nature of Fabry disease, female patients have a 50 percent chance of transmitting the gene both to their sons and daughters while male patients will have no affected sons and 100 percent of daughters are affected. The genotype-phenotype variability should also be stressed especially among patients with subtle manifestations.[70]

CHAPTER 137

Lipoid Proteinosis

Jonathan A. Dyer

EPIDEMIOLOGY

Lipoid proteinosis (LP) is also known as *hyalinosis cutis et mucosae* (Online Mendelian Inheritance in Man #247100) and is a very rare genodermatosis. Only about 300 cases have been reported in the literature. However, it is relatively common in the Namaqualand area of Northern Cape Province in South Africa (frequency of 1 in 300 population). To date, all South African LP patients studied have carried the same mutation (Q276X), likely contributed by a German settler who arrived in 1652 (founder effect).[1]

ETIOLOGY AND PATHOGENESIS

LP is inherited in an autosomal recessive fashion and is caused by mutations in the gene encoding extracellular matrix protein-1 (ECM-1). Although it was given this name because of its discovery among various connective tissue proteins in a murine stromal cell line, ECM-1 likely has broader functions. ECM-1 is known to inhibit bone mineralization, contribute to epidermal differentiation, and stimulate angiogenesis.[2]

ECM-1 is present both in the epidermis and as a secreted protein in the dermis. There are three splice variants, with ECM-1a encoded by the full gene, ECM-1b lacking exon 7, and ECM-1c containing an additional exon 5a. ECM-1a is widely expressed, whereas ECM-1b is expressed only in tonsils, keratinocytes, and the upper respiratory tract. ECM-1c is also expressed in the skin. The function of ECM-1 is unknown, although it has been shown to interact with perlecan, a heparin sulfate proteoglycan present in basement membranes. The ECM1 gene is located next to the epidermal differentiation complex on chromosome band 1q21. This localization, along with expression of ECM-1a in basal keratinocytes but ECM-1b in terminally differentiated keratinocytes, suggests a role in keratinocyte differentiation. Both ECM-1a and ECM-1b may stimulate blood vessel endothelial cell proliferation and promote angiogenesis in chicken embryo.[3] Abnormalities of the cutaneous vasculature are described in LP.[4]

Mutations in ECM1 in LP lead to loss of function of ECM-1. The majority of mutations occur in exon 7, with frameshift mutations leading to ablation of the ECM-1a transcript but not that of ECM-1b, which typically lacks exon 7. The majority of mutations outside of exon 7 occur in exon 6 and are nonsense or

LIPOID PROTEINOSIS AT A GLANCE

- Rare worldwide occurrence, with the greatest incidence (1 in 300) in the Namaqualand region of South Africa.
- Autosomal recessive disorder with variable phenotype, even within families.
- Caused by defects in extracellular matrix protein-1.
- Hoarseness is the most frequent finding.
- Skin fragility and blistering occur in some affected children; blisters heal as infiltrated lesions with scar-like appearance.
- Progressive development of infiltrated papules and plaques is seen, especially on the elbows and extensor aspects of the arms and lower legs.
- Beaded papules on the eyelid margin (moniliform blepharosis) are a classic finding but are not always present.
- Calcification of the temporal lobes and amygdala may lead to neurologic and/or psychiatric symptoms.
- Some patients have airway compromise from upper airway infiltration.
- Periodic acid-Schiff–positive, diastase-resistant thickening is seen at the dermal-epidermal junction, perivascularly, and along adnexal epithelia with hyaline material in the dermis.
- Electron microscopy reveals deposited dermal material and excess basement membrane material around blood vessels with irregular duplication of the lamina densa at the dermal-epidermal junction.
- No effective treatment exists. Laser ablation/dermabrasion of papules is helpful in some cases.

frameshift mutations. Patients with exon 7 mutations may have a slightly milder phenotype than those with non–exon 7 mutations with regard to respiratory and skin (but not neurologic) manifestations.

The second tandem repeat of ECM1, encoded by exon 7, binds fibulin-1, an extracellular component of most basement membranes. Thus, ECM-1a binds to fibulin, whereas ECM-1b, lacking exon 7, does not bind fibulin.[5] Given the differential expression of ECM-1 isoforms in skin, the ability to bind fibulin-1 may be important in keratinocyte differentiation. Antibodies to ECM-1 have now been detected in patients with lichen sclerosus et atrophicus (see Chap. 63), which suggests that this disorder represents an acquired form caused by antibody-induced ECM-1 loss.[6]

CLINICAL FINDINGS

The most reliable clinical signs for diagnosing LP are a hoarse voice and thickened sublingual frenulum, which prevents patients from protruding the tongue—thus the clinical admonition, "Listen to them talk and have them stick out their tongues." Secondary features include beaded eyelid papules, infiltration and warty papules of the skin around the elbows and extensor forearms, and mild alopecia. Increased scarring and photoaging of sun-exposed skin may be seen. Scars or scar-like lesions are present in areas of minor trauma but are not increased at sites of surgery or vaccination.[1] An algorithm outlining an approach to the patient with suspected LP is shown in Fig. 137-1.

History

Cutaneous Lesions

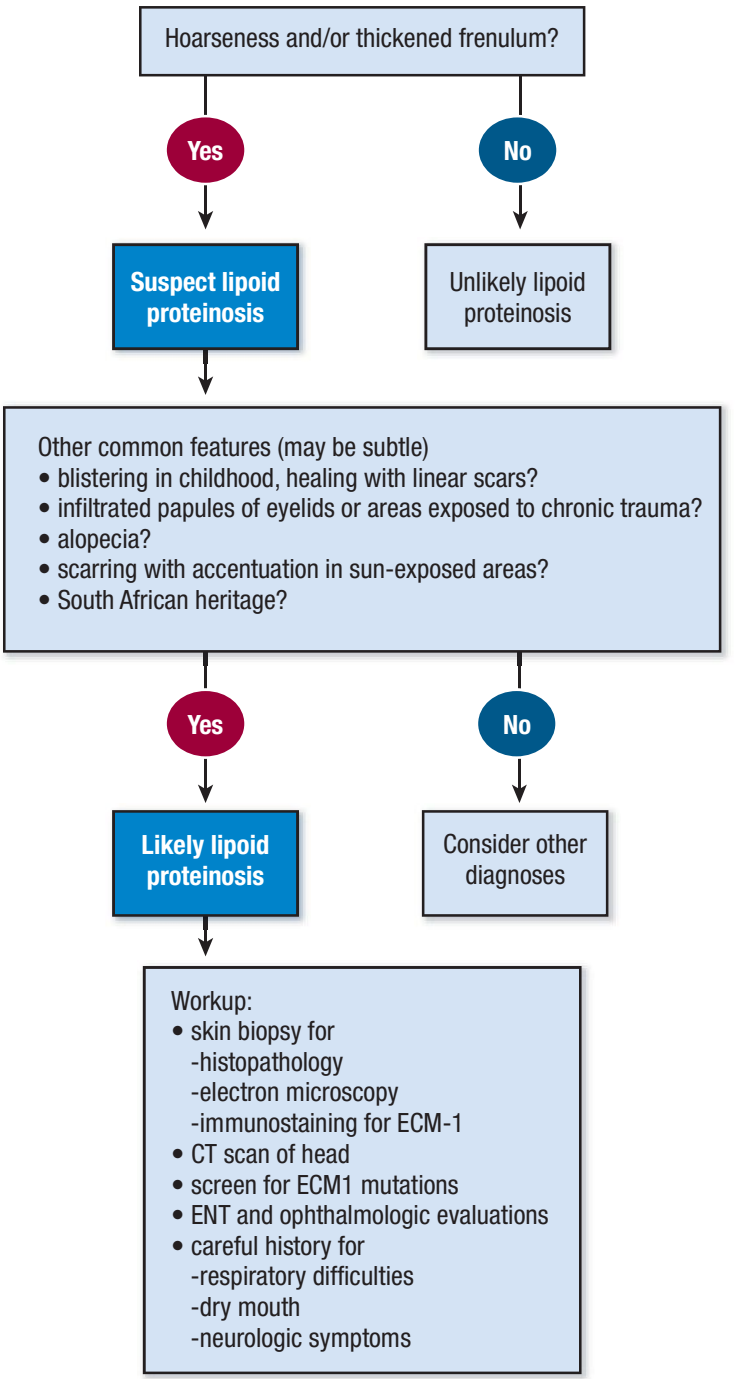
The phenotypic features of LP are quite variable, even within families. This is well demonstrated in studies of South African patients, all of whom share the same mutation yet exhibit highly variable phenotypes. The variable expressivity can lead to difficulty in diagnosis of affected patients. The earliest finding in LP is hoarseness from vocal cord infiltration, which occurs at birth or in the first few years of life. Initially, this may be noted as a faint or weak cry and is one of the most striking and consistent features. Hoarseness may progress during the lifetime of a patient. Dysphagia may occur from involvement of the upper aerodigestive tract and esophagus.[1,8,9]

Skin lesions usually develop in the first years of life, although the timing of their onset is variable. Importantly, two stages of skin lesions may be noted. A long-neglected and underappreciated clinical feature of LP is the erosions that can develop during childhood. Blistering can be extensive enough to mimic epidermolysis bullosa. The associated vesicles (and rarely bullae) are typically noninflammatory and heal slowly with hemorrhagic crusting and resultant scarring (Fig. 137-2). Scars may be linear and resemble pseudoporphyria on the face. In some patients, blistering is worse during warmer weather. Skin fragility and easy wounding with minor trauma or friction are noted. Spontaneous development of extra-facial pustular lesions has also been noted. Shedding of sheets of skin, which leaves red oozing areas, has also been described.

The skin lesions of the second stage are better recognized. Although beaded papules along the eyelid margins (moniliform blepharosis) (Fig. 137-3) are considered a classic clinical finding, they are variable and may be subtle. Other cutaneous stigmata include generalized skin thickening with a waxy, yellow appearance as well as areas of distinct papules and nodules. Areas subject to repeated friction or trauma, such as the elbows, halluces, and extensor aspects of the arms and lower legs, may develop overlying hyperkeratosis, which may be quite striking and verrucous (Fig. 137-4). The scarring usually begins during childhood and is often worst on the face. It may follow trauma or occur spontaneously, yet no tendency to excessive scarring is noted after surgery or vaccination. Pock-like or acneiform scarring is well described in LP, especially on the face and extremities.[10] Some areas may resemble solar elastosis (see Fig. 137-3). Flexural lichenification may also be seen, and patients with LP have been misdiagnosed as having atopic dermatitis.[8] Some patients report increased photosensitivity, and, in some patients, sun-exposed areas exhibit the greatest amount of scarring. Significant pruritus, alterations in the ability to sweat, and an abnormal pain sensation have been noted. Alopecia may occur, although it is variable in severity. Nails are normal.[9]

Related Physical Findings

The mucosa of patients with LP exhibits infiltration and thickening. Early in life, oral erosions may be noted. Thickening of the lingual frenulum leads to inability to protrude the tongue (Fig. 137-5). The pharynx, tongue, soft palate, tonsils, and lips are typically involved. Laryn-



▲ **FIGURE 137-1** Approach to the patient with possible lipoid proteinosis. CT = computed tomography; ECM-1 = extracellular matrix protein-1; ENT = ear, nose, and throat.

▲ **FIGURE 137-2** Lipoid proteinosis. Early bullous lesion with typical hemorrhagic crust healing with scarring. (From Dyer JA, Yu QC, Paller AS: "Free-floating" desmosomes in lipoid proteinosis: An inherent defect in keratinocyte adhesion? *Pediatr Dermatol* **23**:1, 2006, with permission.)

geal and pharyngeal involvement may be severe enough to trigger respiratory difficulty, and tracheostomy has been required in rare cases. Shortness of breath or worsening of respiratory difficulties as well as swelling of the salivary glands (submandibular and parotid) may be triggered by upper respiratory tract infections. Xerostomia and dental caries may be seen.[9,11] Dental abnormalities (absent permanent upper lateral incisors) have also been described. Parotitis from infiltration of Stenson's duct and subsequent blockage can occur.

Central nervous system involvement is a well-recognized, but variable, feature of LP. Amygdala dysfunction has been described, which leads to abnormal perception and appraisal of fear. More recent studies have demonstrated subtle differences between LP patients and normal controls in the judgment of facial expression and emotion, in memory for negative and positive pictures, and in odor-figure association tests. Because of the frequent bilateral amygdala damage, LP has been used as a model disorder for the investigation of the function of the amygdala.[12] Neurologic and psychiatric findings include seizures, memory deficits, social and behavioral changes, paranoid symptoms, mental retardation, and aggressiveness. Severe generalized dystonia has also been reported.

The ocular examination may reveal drusen-like fundal lesions.[13] Eyelid infiltration may induce corneal ulcers due to abnormal eyelash positioning, and alopecia of the eyebrows and eyelashes can occur. The abnormal deposition of hyaline material has been detected histopathologically in many internal organs, although this is typically asymptomatic.[14]

▲ **FIGURE 137-3** Lipoid proteinosis. Beaded papules along margin of the eyelids (moniliform blepharosis). Note increased severity of yellowish, waxy lesions in sun-exposed areas. (Used with permission from O. Braun-Falco, Munich.)

LABORATORY TESTS

Light microscopic evaluation of lesional sections reveals deposition of amorphous eosinophilic material at the dermal-epidermal junction, perivascularly, and along adnexal epithelia. There is deposition of hyaline material in the dermis, often perpendicular to the basement membrane (Fig. 137-6). The hyaline material is periodic acid-Schiff positive and diastase resistant, with a composition similar to that of basement membrane. Often arranged in concentric, "onion-skin" layers around vessels, these layers include type III and type IV collagen as well as laminin. Electron microscopy reveals irregular duplication of the lamina densa at the dermal-epidermal junction. Cytoplasmic vacuoles are noted in dermal fibroblasts.[15] The presence of lipids varies and is considered a secondary phenomenon due to lipid adherence to glycoproteins present in the hyaline material rather than a primary defect of LP.

The histologic features of the early bullous lesions of LP have only recently been described. Acantholysis of keratinocytes apparently is the cause.[16] Electron microscopy suggests an abnormality of desmosomal attachment, with "free-floating" desmosomes noted in bullous lesions. These preliminary findings require confirmation; however, given the pattern of expression of ECM-1 in the epidermis, a role in keratinocyte cell–cell adhesion appears plausible.[17]

Three-dimensional analysis of the cutaneous vasculature in LP shows enlarged vessels in the mid- and deep dermis with an orientation parallel to the dermal-epidermal junction. The dermal papillary plexus also lacks capillary loops. As in lichen sclerosus et atrophicus, the subcutaneous plexus and transverse connecting vessels are atretic or poorly formed.[4] Such vascular abnormalities may reflect a disturbance of ECM-1 function during angiogenesis.

SPECIAL TESTS

Computed tomographic scans of the brain reveal bilateral anterior medial temporal lobe calcifications, often bean-shaped, and especially within the amygdala, in 50 percent to 75 percent of LP patients.[12]

Histopathologic evaluation of these lesions shows amorphous masses of calcium and bone along with multiple haphazardly arranged small blood vessels with wall calcification and gliotic adjacent tissue. The cortex and white matter show isolated blood vessels occluded by fibrin, parietal calcification, small perivascular infarctions, and demyelination.[18] Immunohistochemical staining of skin biopsy specimens may show absence or attenuation of ECM-1. This may prove to be a valid diagnostic test, not only to aid in diagnosis in mild cases but also potentially to direct molecular investigations.[19]

DIFFERENTIAL DIAGNOSIS

See Box 137-1.

PROGNOSIS AND CLINICAL COURSE

The prognosis of LP is variable. Often, there is progressive worsening of cutaneous features, with clearance during childhood of blistering lesions and progressive development of infiltrative lesions. The hoarseness and mucosal lesions also may

▲ **FIGURE 137-4** Hyperkeratotic papular lesions on the dorsal hands (**A**) and interdigital web and sides of the fingers (**B**), and verrucous nodular lesions on the knee (**C**).

▲ **FIGURE 137-5** Restricted mobility of the tongue due to infiltration of the frenulum is seen in most patients with lipoid proteinosis. Note discoloration of the lips as well. (Used with permission from O. Braun-Falco, Munich.)

progress with time. Although some patients have experienced respiratory complications from upper respiratory tract infiltration that have, in rare cases, led to early mortality, most patients have a normal life span. It is important to recognize the impact of LP on the quality of life of affected patients. The disfiguring nature of the skin lesions, along with the abnormal voice, significantly impact the interactions of LP patients with others. Patients have increased difficulty holding jobs.[1]

▲ **FIGURE 137-6** Extensive deposition of periodic acid-Schiff–positive, diastase-resistant hyaline material in the dermis of a scar-like lesion of lipoid proteinosis.

TREATMENT

Many agents, including topical and systemic corticosteroids, oral dimethyl sulfoxide,[20] and intralesional heparin, have been investigated and used in the treatment of LP. None of these agents has demonstrated any sustained benefits. Given the apparent photo-exacerbation of lesions in a subset of LP patients, photoprotection seems reasonable, although there are no data confirming any benefit. Early intervention for developmental problems is important, and management of other stigmata by the appropriate specialists is warranted. Various surgical modalities such as dermabrasion and CO_2 laser procedures have been used to treat cutaneous lesions. CO_2 laser surgery for vocal cord lesions and eyelid papules has been helpful.[21,22]

PREVENTION

Prenatal genetic testing in families at risk is theoretically possible using DNA-based analysis.

Box 137-1

Differential Diagnosis of Lipoid Proteinosis

CLINICAL

Most Likely

- Erythropoietic protoporphyria (EPP) or pseudoporphyria (clinically and histologically)—in EPP most changes are in sun-exposed areas, whereas in lipoid proteinosis they are present in non–sun-exposed sites as well; EPP has no beading of the eyelids.
- Variegate porphyria—especially in South Africa
- Epidermolysis bullosa—hoarseness with blistering (infancy)
- Impetigo—childhood blisters and erosions

Consider

- Scarring from acne
- Scleromyxedema
- Amyloidosis
- Residual lichenification from atopic dermatitis

HISTOPATHOLOGIC

- Erythropoietic protoporphyria
- Diabetic microangiopathy
- Amyloidosis
- Lichen sclerosus

CHAPTER 138

Cutaneous Mineralization and Ossification

John S. Walsh
Janet A. Fairley

CALCIUM

Calcium is involved in many physiologic processes. It is key to skeletal muscle and myocardial contraction, neurotransmission, and blood coagulation. In addition, it is the primary mineral in the bony skeleton. On the cellular level, its diverse functions include transmission of information into and between cells, regulation of plasma membrane potential, and exocytosis. Only over the last 20 years has its effect on skin been fully appreciated. Calcium regulates major functions in the epidermal keratinocytes including proliferation, differentiation, and cell-cell adhesion.[1–6]

REGULATORY HORMONES

At least three regulatory hormones control the ionic calcium concentration in serum: parathyroid hormone (PTH), calcitonin, and 1,25 dihydroxyvitamin D_3 [$1,25(OH)_2D_3$].

PTH is an 84-amino acid, single-chain polypeptide that is synthesized in the parathyroid glands. Under normal conditions, a decrease in the serum concentration of ionized calcium results in an increase in PTH production, whereas an increase in the serum concentration of ionized calcium results in a decrease in PTH production. In the kidney, PTH increases renal tubular reabsorption of calcium and increases renal clearance of phosphate. PTH also acts directly on the bone to increase the plasma calcium concentration. It does this acutely by mobilizing calcium from bone into the extracellular fluid. Osteocytes and osteoblasts are the presumed target cells for this effect. PTH also stimulates osteoclastic bone resorption, possibly by stimulating osteoblasts to release factors that activate osteoclasts. PTH together with a decreased plasma phosphate concentration stimulates 1α-hydroxylase activity in the kidney, causing an increase in the plasma concentration of $1,25(OH)_2D_3$. $1,25(OH)_2D_3$ increases intestinal absorption of calcium.

Calcitonin is a 32-amino acid polypeptide that is produced by parafollicular or C cells of the thyroid gland. Calcium is the primary stimulant for calcitonin secretion. Calcitonin lowers the serum calcium concentration, primarily through osteoclast inhibition, but whether it plays a major role in serum calcium metabolism outside of the neonatal period in vivo is unclear.

Vitamin D_3, or cholecalciferol, is a secosteroid formed by the opening of the β ring of 7-dehydrocholesterol. In humans, this formation occurs in the basal layer of the epidermis. First there is an ultraviolet B–mediated conversion of 7-dehydrocholesterol to previtamin D_3. Previtamin D_3 then undergoes thermal isomerization to form vitamin D_3. To become biologically active, vitamin D_3 must first be hydroxylated at carbon position 25 in the liver and then at carbon position 1α by the enzyme 1α-hydroxylase in the kidney. 1α-hydroxylase is tightly regulated. PTH and calcitonin increase its activity, whereas calcium, phosphate, and $1,25(OH)_2D_3$ inhibit it.[7]

$1,25(OH)_2D_3$, similar to PTH, increases the concentration of plasma calcium. Its primary action is to stimulate the active transport of calcium across the intestine. $1,25(OH)_2D_3$ also increases the plasma calcium concentration by mobilizing calcium from bone.[8] The simultaneous presence of PTH appears to be necessary for this effect.

$1,25(OH)_2D_3$ also plays a major role in the growth and differentiation of tissues, including skin.[9] Receptors for $1,25(OH)_2D_3$ are present on epidermal keratinocytes, pilosebaceous structures, and in the dermis.[10–13] In human keratinocyte cultures, $1,25(OH)_2D_3$ causes a dose-dependent decrease in proliferation, an increase in morphologic differentiation, and an increase in terminal differentiation markers.[14] Cultured human keratinocytes can also convert $25(OH)D_3$ to $1,25(OH)_2D_3$, suggesting that the epidermis may regulate its own growth and differentiation by endogenously produced $1,25(OH)_2D_3$.[14] The mechanism by which $1,25(OH)_2D_3$ may induce differentiation of epidermal cells may be through calcium, because calcium is required for terminal differentiation of keratinocytes. $1,25(OH)_2D_3$ may facilitate calcium entry into cells and, through induction of calcium-binding proteins, facilitate the ability of calcium to regulate various cellular processes.

ABERRANT CALCIFICATION AND OSSIFICATION

Despite the careful regulation of serum calcium, calcification and ossification of cutaneous and subcutaneous tissues may occur.[15] Calcification is the deposition of insoluble calcium salts; when it occurs in cutaneous tissues it is known as *calcinosis cutis*. Ossification is the formation of true bony tissue by the deposition of calcium and phosphorus in a proteinaceous matrix as hydroxyapatite crystals. Cutaneous calcification may be divided into four major categories: dystrophic, metastatic, idiopathic, and iatrogenic. Dystrophic calcification is the most common type of calcinosis cutis and occurs as a result of local tissue injury. Although calcium and phosphate metabolism and serum levels are normal, local tissue abnormalities, such as alterations in collagen, elastin, or subcutaneous fat may trigger calcification. The internal organs usually remain unaffected. Metastatic calcification is the precipitation of calcium salts in normal tissue secondary to an underlying defect in calcium and/or phosphate metabolism. The calcification may be widespread and, in addition to the skin, affects predominantly blood vessels, kidneys, lungs, and gastric mucosa. All patients presenting with signs of metastatic calcification should receive a calcium and phosphate metabolic evaluation. Idiopathic calcification occurs without identifiable underlying tissue abnormalities, abnormal calcium, and/or phosphate metabolism. Cutaneous calcification also may be iatrogenic. Cutaneous ossification most commonly occurs secondary to local tissue alteration

CUTANEOUS MINERALIZATION AT A GLANCE

- Results from the deposition of calcium salts in the dermis, subcutaneous tissue, or vascular endothelium when the local calcium concentration exceeds its solubility in the tissue.
- Clinically, may be categorized as dystrophic, metastatic, idiopathic, or iatrogenic.
- Pathology shows aggregates of calcium that stain with Alizarin red S or von Kossa stains.

or pre-existing calcification. Any calcifying disorder of the skin may ossify secondarily. On rare occasions, primary cutaneous ossification may occur without underlying tissue abnormalities or pre-existing calcification.

DYSTROPHIC CALCIFICATION

Connective Tissue Diseases

Dystrophic calcification frequently occurs in connective tissue diseases.[16] Scleroderma and CREST syndrome (calcinosis cutis, *R*aynaud phenomenon, *e*sophageal dysfunction, *s*clerodactyly, *t*elangiectasia) are notable examples that are frequently associated with calcinosis cutis (Fig. 138-1; see Chap. 158). In these disorders, nodules and plaques of calcium deposits may occur in the skin, subcutaneous tissue, muscle, or tendons. The calcium deposits most commonly occur on the upper extremities, especially on the fingers and wrists, but may occur in any area subject to trauma or motion. As the calcifications enlarge, they may ulcerate and exude a chalky material.

Dystrophic calcification also occurs in dermatomyositis (see Chap. 157). It is more commonly associated with juvenile rather than adult-onset dermatomyositis, occurring in 44 percent to 70 percent of children as opposed to 20 percent of adults.[17] The calcification tends to occur 2 to 3 years after disease onset and most frequently appears on the elbows, knees, shoulders, and buttocks.[18] The calcium deposits may be painful and can ulcerate. They also may exude a chalky material, form sinuses, and become chronically infected. Calcium salt deposition may become quite extensive, progressing along fascial planes of skin and muscle, forming an "exoskeleton," and leading to significant morbidity and mortality. Calcinosis cutis in dermatomyositis is difficult to treat; however, if the patient survives long enough, the calcified nodules may improve spontaneously.

Although uncommon, calcinosis cutis has been described in all clinical subsets of lupus erythematosus.[19–22]

There is no standard treatment for dystrophic calcification. A diet low in calcium and phosphate along with aluminum hydroxide has been reported to arrest or facilitate regression of the calcified nodules.[23] Disodium etidronate has also been used with some success.[24] Several series report long-term treatment with diltiazem improves the calcinosis in some patients.[25,26] Other reported treatments include warfarin, colchicine, probenecid, and bisphosponates.[16,27] Occasionally, calcium deposits must be removed surgically to clear sinus tracts, ulcers, or chronic infections.

▲ **FIGURE 138-1** Dystrophic calcification in CREST syndrome (*c*alcinosis cutis, *R*aynaud phenomenon, *e*sophageal dysfunction, *s*clerodactyly, *t*elangiectasia).

Panniculitis

Pancreatic enzyme panniculitis (see Chap. 68) is a lobular panniculitis that commonly demonstrates dystrophic calcification. It occurs in patients with pancreatitis or pancreatic adenocarcinoma and is presumably caused by the action of liberated pancreatic enzymes on subcutaneous fat. The fatty acids formed by lipolysis may combine with calcium and form calcium soap.

In subcutaneous fat necrosis of the newborn, erythematous, well-defined nodules and plaques occur during the first few weeks of life over the cheeks, back, buttocks, and extremities.[28,29] The affected infants are generally otherwise healthy, and the nodules and plaques usually clear spontaneously. Occasionally, the lesions calcify, and in a small subset of patients symptomatic hypercalcemia may develop, sometimes several months after birth.

Inherited Disorders

Dystrophic calcification occurs in patients with pseudoxanthoma elasticum (PXE; see Chap. 139). PXE is a hereditary disorder of elastic tissue characterized by progressive calcification of elastin fibers, primarily within the skin, Bruch's membrane of the retina, and the cardiovascular system. The cause of PXE was recently identified as a mutation in the ABC-C6 gene.[30] This gene is thought to play a critical role in transmembrane transport. Most patients with PXE have normal calcium-phosphate metabolism, but a few have been identified who have abnormal calcium, phosphate, and/or vitamin D metabolism. Patients in this subset may develop metastatic calcification in the form of calcified or ossified tumors, calcification of the falx cerebri, and arterial calcification.[31–33]

Ehlers-Danlos syndrome (EDS; see Chap. 139) is a group of inherited disorders of fibrillar collagen metabolism. Mutations in the collagen genes or enzymes that regulate collagen biosynthesis have been determined to underlie a number of EDS sub-types.[34–36] The skin characteristically shows hyperelasticity and fragility with formation of pseudotumors and large gaping scars. Subcutaneous calcified nodules, termed *spheroids* may appear, and are thought to represent calcified ischemic fat lobules.[37,38] Calcification of healing surgical incisions has also been reported in patients with EDS.[39]

Dystrophic calcification has been observed in patients with porphyria cutanea tarda (see Chap. 132).[40,41] Sclerodermoid plaques with dystrophic calcification have occurred on the preauricular area, scalp, neck, and dorsa of the hands. Ulceration with trans-epidermal elimination of sheets of calcium is also rarely reported.

Other genetic disorders in which calcification may occur include Werner syndrome and Rothmund-Thomson syndrome (see Chap. 140).[42,43]

Cutaneous Neoplasms

Dystrophic calcification occurs in association with a variety of benign and malignant cutaneous neoplasms. Often the neoplasms also show ossification in the surrounding stroma.

Pilomatricomas (see Chap. 119) are the most common cutaneous neoplasms that manifest calcification and ossification. Approximately 75 percent of pilomatricomas show calcification and 15 percent to 20 percent show ossification.[44,45] Ossification usually occurs within the connective tissue adjacent to the shadow cells, probably through metaplasia of fibroblasts into osteoblasts. Activating mutations in the adherens junction protein β-catenin have been identified in some pilomatricomas.[46]

A large number of other neoplasms may be associated with calcification and ossification, including: pilar cyst, basal cell carcinoma, intradermal nevi (probably as a result of inflammation or folliculitis), desmoplastic malignant melanoma, atypical fibroxanthoma, pyogenic granuloma, hemangioma, neurilemmoma, trichoepithelioma, and seborrheic keratoses.[47–51] Mixed tumors (chondroid syringomas) may also show calcification and ossification. However, unlike other neoplasms, the ossification occurs within the tumor via ossification of the chondroid cells, much like endochondral bone formation occurring in the epiphyses of bones.

Infections

Infectious agents may produce enough cutaneous damage to cause dystrophic calcification. Parasitic infections that may result in calcinosis cutis include onchocerciasis (*Onchocerca volvulus*) and cysticercosis (*Taenia solium*).[52,53] Calcinosis cutis has also been reported as a complication of intrauterine herpes simplex infection.[54]

Other

Dystrophic calcification has been reported in a variety of settings where local tissue injury occurs, such as in scarring caused by burns, trauma, neonatal heel sticks (sub-epidermal calcified nodule), surgery, and keloids.[55–59]

METASTATIC CALCIFICATION

Chronic Renal Failure

Metastatic calcification most commonly occurs in chronic renal failure and takes the form of either benign nodular calcification or calciphylaxis. In chronic renal failure, decreased clearance of phosphate results in hyperphosphatemia. In addition, the impaired production of $1,25(OH)_2D_3$ results in a decrease in calcium absorption from the intestine and decreased serum calcium levels. The hypocalcemia results in increased PTH production and secondary hyperparathyroidism. Elevated levels of PTH cause bone resorption and mobilization of calcium and phosphate into the serum, leading to normalization of the serum calcium concentration but marked hyperphosphatemia. If the solubility product of calcium and phosphate is exceeded, metastatic calcification may occur. In benign nodular calcification, the calcifications typically occur at periarticular sites, and their size and number tend to correlate with the degree of hyperphosphatemia. The lesions disappear with normalization of calcium and phosphate levels.

Calciphylaxis is a life-threatening disorder characterized by progressive vascular calcification, soft tissue necrosis, and ischemic necrosis of the skin (see Chap. 151).[60] Clinically, it presents as firm, extremely painful, well-demarcated, violaceous plaques associated with soft tissue necrosis and ulceration (Fig. 138-2). The lesions may occur anywhere, but the lower extremities are most frequently involved. The mortality rate is estimated to be approximately 80 percent. Histopathologically, there is medial calcification of small and medium-sized arteries with intimal hyperplasia, primarily in dermal and subcutaneous tissues. Calciphylaxis occurs almost exclusively in patients with a history of chronic renal failure and prolonged secondary hyperparathyroidism. However, there exist rare reports of the occurrence of calciphylaxis in the absence of renal failure.[61] Most of the patients reported are female, and there may be an association with obesity and poor nutritional status.[62,63]

The pathogenesis of calciphylaxis is unknown. Experiments in a rat model have suggested that calciphylaxis may be triggered by exposure to a sensitizing agent (PTH, dihydrotachysterol, or vitamin D) followed by a challenging agent (metal salts, albumin, or corticosteroids).[64] However, the clinical description and histopathology of the animal lesions differ from the human disease. Protein C dysfunction has also been described in a subset of patients with calciphylaxis, but this more likely is a mark for a coagulation defect that predisposes this group to calciphylaxis.[65] More recently, it has been proposed that glycoproteins that regulate vascular fibrosis and calcification are involved in the pathogenesis of this disorder.

The current therapy of calciphylaxis involves attempts to normalize the calcium-phosphate product and meticulous wound care. Normalizing methods include low calcium dialysis, use of phosphate binders that combine calcium acetate and magnesium carbonate, sodium thiosulfate, and parathyroidectomy.[60] Parathyroidectomy may increase survival.[66] Aggressive management of wound infections and judicious use of débridement may help lower the incidence of sepsis and death in these patients.

Hypervitaminosis D

Chronic ingestion of vitamin D in supraphysiologic doses (50,000 to 100,000 units/day) may produce hypervitaminosis D.[67] The initial signs and symptoms of hypervitaminosis D are attributable to hypercalcemia and hypercalcuria, and include weakness, lethargy, head-

▲ **FIGURE 138-2** Calciphylaxis. The lesions develop as violaceous plaques that may progress to necrotic ulcers, as shown in this patient.

ache, nausea, and polyuria. Metastatic calcification may also occur.

Milk-Alkali Syndrome

Milk-alkali syndrome is characterized by excessive ingestion of calcium-containing foods or antacids, leading to hypercalcemia.[68] Complications other than the acute manifestations of hypercalcemia include irreversible renal failure, nephrocalcinosis, and subcutaneous calcification, occurring predominantly in periarticular tissues.

Tumoral Calcinosis

Tumoral calcinosis (TC) is a disorder characterized by the deposition of calcific masses around major joints, such as hips, shoulders, elbows, and knees. The masses are intramuscular or subcutaneous and may enlarge to sizes causing significant impairment of joint function. Usually the overlying skin is normal, but associated ulceration and calcinosis cutis may occur. It generally occurs in otherwise healthy adolescents. Tumoral calcinosis may be either sporadic or familial. The familial type may be associated with hyperphosphatemia or normophosphatemia. Inactivating mutations in either the GALNT3 or FGF23 genes may lead to hyperphosphatemic TC.[69–71] GALNT3 encodes a glycosyltransferase (N-acetylgalactosaminyltransferase 3 or ppGalNAc-T3) that initiates mucin-type O-glycosylation. It is hypothesized that FGF23, an important regulator of phosphate homeostasis, must be glycosylated by ppGalNAc-T3 to function properly. The defect in normophosphatemic TC is unknown. Surgical excision is the treatment of choice, but phosphate deprivation has met with some success.

Other Disorders

Other systemic disorders associated with hypercalcemia and/or hyperphosphatemia are reported to cause metastatic calcification. These include neoplasms associated with bony destruction, such as lymphoma, leukemia, multiple myeloma, and metastatic carcinoma.[72–74] Sarcoidosis may also be associated with metastatic calcification.[75]

IDIOPATHIC CALCIFICATION

Calcified nodules characterize idiopathic calcification of the scrotum. The lesions usually appear in otherwise healthy males and tend to increase in size and number with time.[76] Eventually, they may break down and exude a chalky material. Controversy exists over the etiology of this disorder. Many believe idiopathic calcification of the scrotum is truly idiopathic; others maintain that calcified scrotal nodules are inflamed or ruptured epidermoid cysts that undergo dystrophic calcification.[77–79] Excision of the lesions is the treatment of choice, although patients may continue to develop nodules at other sites. Idiopathic calcification of the penis, vulva, and breast has also been reported.[80,81]

Sub-epidermal calcified nodules appear on the exposed areas of the head and the extremities.[82] They may be congenital or acquired and typically appear as hard, 3- to 10-mm solitary lesions, although multiple lesions may occur. Some investigators believe the lesions represent calcified sweat gland hamartomas.[83]

Reports have described the appearance of milia-like idiopathic calcinosis cutis on the dorsa of hands and forearms of patients with Down syndrome.[84–86] Some of the calcifications are associated with syringomas.

IATROGENIC CALCIFICATION

Cutaneous calcification may be iatrogenic. Calcinosis cutis is a complication of intravenous calcium chloride and calcium gluconate therapy.[85] Calcified nodules may appear at sites of extravasation, probably as a result of an elevated tissue concentration of calcium and tissue damage. Minor trauma and prolonged contact with calcium salts can lead to calcinosis cutis in a variety of settings.[86,87] It has occurred in patients undergoing electroencephalography with saturated calcium chloride electrode paste.[88] Cutaneous calcification of skin graft donor sites after the application of calcium alginate dressings has also been reported.[89] Transient deposits of calcium in the skin and other soft tissues have also been reported after liver transplantation.[90] It is hypothesized that these transient deposits are caused by the large amounts of calcium- and citrate-containing blood products used during surgery, combined with metabolic abnormalities in the perioperative period.

PRIMARY OSSIFICATION

Primary ossification of cutaneous and subcutaneous tissues rarely occurs without any underlying tissue abnormality or pre-existing calcification. In addition to miliary osteoma of the face, there are four well-described ossifying syndromes[93]: fibrodysplasia ossificans progressiva (FOP), Albright hereditary osteodystrophy (AHO), progressive osseous heteroplasia (POH), and plate-like osteoma cutis. Other primary ossification disorders reported in the literature, such as isolated osteoma or widespread osteoma, probably are variants of the described ossifying syndromes or represent a group of poorly described primary ossification disorders.

Fibrodysplasia Ossificans Progressiva

FOP is an autosomal-dominant syndrome characterized by the progressive ossification of deep connective tissues leading to significant morbidity and mortality.[94] Ossification is of the endochondral type, and involvement of the skin occurs as a result of direct extension from underlying tissues. Dysmorphic great toes are a characteristic feature of FOP. Other features include abnormal phalanges of the hands, deafness, baldness, and mental retardation. Although the genetic defect remains unknown, linkage analysis studies have identified potential loci at 4q27–31.[95] Genes involved in the bone morphogenesis protein-signaling pathways are located in these regions.

Albright Hereditary Osteodystrophy, Progressive Osseous Heteroplasia, and Plate-Like Osteoma Cutis

AHO, POH, and plate-like osteoma cutis are three closely related syndromes that are characterized by intramembranous bone formation in skin. Mutations in the gene encoding for the α-subunit of the stimulatory G protein of adenyl cyclase (GNAS1), a negative regulator of bone formation, have been identified in all three of these disorders.[93,96–99] In addition, families have been described in which some members have plate-like osteoma cutis whereas other members have POH.[100] Several families have demonstrated an "imprinting" effect; inheritance of an inactivating mutation in GNAS1 from the father results in POH, whereas inheritance from the mother leads to AHO.[102] In addition, different splice variants are expressed solely by maternal or paternal alleles.

AHO is an autosomal-dominantly inherited syndrome characterized by the

▲ **FIGURE 138-3** Progressive osseous heteroplasia. The appearance of the skin in progressive osseous heteroplasia can be subtle, but the lesions have a distinctive textural change that feels like rice grains in the skin.

ossification of cutaneous and subcutaneous tissues in childhood. AHO generally follows a limited course, and significant deformity and physical impairment are rare. Patients typically have brachydactyly, dimpling over the metacarpophalangeal joints (Albright's sign), obesity, round or moon facies, short stature, and mental retardation. Most patients have a deficient end-organ response to PTH or "pseudohypoparathyroidism" with hypocalcemia, hyperphosphatemia, and elevated levels of PTH. Other patients have "pseudo-pseudohypoparathyroidism" with normal serum levels of calcium and phosphorus.[93]

POH is characterized by progressive ossification of skin and deep tissues during infancy or childhood.[102,103] Most reported patients are female, although a small number of male patients have also been described. Ossification usually begins in the dermis and progresses to involve deeper tissues, such as muscle, as well as overlying skin. Skin involvement has been described as a papular eruption resembling "rice grains" and having a "gritty" consistency (Fig. 138-3). Unlike AHO or FOP, there are no associated dysmorphic features. Secondary orthopedic problems, such as limb-length discrepancy or ankylosis of the joint, arise if the cutaneous ossification is severe enough to limit motion.

Plate-like osteoma cutis is currently used to describe patients with a more limited, nonprogressive form of cutaneous ossification.

Miliary osteoma cutis of the face most commonly occurs as multiple small, firm nodules on the faces of young women with a history of acne vulgaris. There are, however, reports of multiple miliary osteoma cutis in older patients without acne vulgaris or other underlying skin disease.[104]

CHAPTER 139

Heritable Disorders of Connective Tissue with Skin Changes

Mario E. Lacouture
Amy S. Paller

Inherited disorders of connective tissue comprise a clinically and genetically diverse group of conditions affecting primarily the skin, joints, and, often, the cardiovascular system. The severity of the skin phenotype depends on the type of mutation and the role of the affected protein on dermal structure and function (see Chap. 61). Although genetic testing for most patients is not available commercially at this time, a listing of research laboratories that conduct testing can be found at http://www.genetests.com. Some inherited connective tissue disorders are characterized by hyperextensible skin, whereas others show cutaneous laxity. Yet other disorders have specific cutaneous changes that reflect the alternations in the dermis, such as the striae in Marfan syndrome and the cutaneous papules of pseudoxanthoma elasticum.

EHLERS-DANLOS SYNDROMES

The Ehlers-Danlos syndromes (EDSs) are a heterogeneous group of disorders characterized by hypermobile joints, hyperextensible skin, and fragile tissues that are extremely susceptible to trauma.[1–3] As many as 1 in 5000 individuals may be affected by some form of the disease.[4] The seven sub-types of EDS have been categorized based on clinical[5] and corresponding molecular pathogenetic findings in collagen types I, III, and V, or processing enzymes[6] (Table 139-1). These collagen types are all fibrillar types of collagen with cross-banding that are expressed in different locations in the skin and in other tissues (see Chap. 61 for distribution). Pathogenic alterations of fibrillar collagens in EDS result from deficient collagen-processing enzymes, haploinsufficiency, or mutations in collagen α chains.[7] A uniform finding in all types of EDS is generalized joint hypermobility, which can be assessed clinically according to the Beighton scale (Table 139-2).[8]

Classical Type

EPIDEMIOLOGY The classical form of EDS is one of the most common, occurring in 1 in 10,000 to 20,000 infants.[9]

ETIOLOGY AND PATHOGENESIS The classical type of EDS is characterized by an alteration in type V fibrillary collagen and is inherited in an autosomal dominant (AD) fashion. Mutations in *COL5A1* and *COL5A2* have been shown to cause this variant[10,11] in up to 50 percent of cases.[12–15] The abnormal allele leads to dominant-negative effects or haploinsufficiency, depending on the mutation.[16,17] At least one other locus is involved, because several families are discordant for linkage to both *COL5A1* and *COL5A2*.[13,18] A few patients have shown mutations in *COL1A1*, a gene more commonly mutated in osteogenesis imperfecta (OI; see Osteogenesis Im-

EHLERS-DANLOS SYNDROMES AT A GLANCE

- Combined incidence of almost 1 in 5000 persons.
- Seven sub-types.
- Most commonly autosomal dominant (classical and hypermobile types).
- The gene encoding collagen V is most often affected.
- Cutaneous features include soft, velvety skin that bruises easily and wounds that heal as thin, atrophic, gaping scars.
- Extracutaneous manifestations include hypermobile joints with frequent dislocations, problems with pregnancy and delivery, and, less commonly, cardiovascular manifestations, particularly aortic root dilatation.
- Information for patients and professionals at http://www.ehlers-danlos.org and http://www.ednf.org.

perfecta).[19,20] Whereas *COL5A1* is located on the long arm of chromosome 2q31, the *COL5A2* gene resides on the long arm of chromosome 9q34.2-34.3. Although collagen V is not abundant in skin, tendons, or ligaments, the clinical phenotype attests to its important structural role.

Ultrastructural findings show thickened collagen fibrils in skin,[21] with an approximate 25 percent increase in diameter, underscoring the function of collagen V in limiting fibril diameter, as shown in vitro.[22] This effect is thought to be due to the negative charge of the amino terminus of α1(V), conferred by abundant tyrosine residues, which inhibits fibril growth.[7] Another hallmark of classical EDS is the presence of rare composite fibrils also known as "collagen cauliflowers."[23] These abnormalities are present in less than 5 percent of fibrils, suggesting that other factors may be responsible for the severe clinical phenotype, such as the arrangement of collagen fibrils in tissue. This disorganized arrangement of collagen fibrils and their interaction with other extracellular matrix (ECM) proteins is thought to cause the altered biomechanical properties of EDS skin.[24]

CLINICAL FINDINGS Classical EDS is characterized by joint laxity, hyperextensibility of skin, and poor wound healing. The skin manifestations can vary in severity from mild to severe; milder forms were previously termed the "mitis" type, or type II, EDS. The skin is soft, velvety, and can be stretched easily (Fig. 139-1). It is not lax, except in late stages. Skin hyperextensibility should be determined at the volar surface of the forearm or some other site that is not subjected to mechanical forces or scarring. Approximately 50 percent of patients with Ehlers-Danlos of the classic and hypermobile types can touch the tip of their nose with their tongue (Gorlin's sign), in contrast to 10 percent of individuals who do not have EDS (Fig. 139-2).

The dermis is fragile and easily bruised. The shins show persistent discoloration, often beginning in early childhood (Fig. 139-3). When the skin splits from trauma, it is relatively painless and does not bleed excessively, but the wounds tend to gape. The wound margins tend to retract, heal slowly, and often become infected. Dehiscence is common, and complete wound breakdown

TABLE 139-2
Beighton Criteria for Joint Hypermobility

1. Passive dorsiflexion of the fifth finger > 90 degrees
2. Passive apposition of the thumbs to the flexor aspect of the forearm (Beighton sign)
3. Hyperextension of the elbow > 10 degrees
4. Hyperextension of the knees > 10 degrees
5. Ability of the palms to completely touch the floor during forward flexion of the trunk with knees fully extended

Numbers 1–4 are scored for each side, so that a maximal score of two is possible if both left and right sides show criteria; number 5 is scored as 1. A score of ≥ 5/9 is hypermobile.

TABLE 139-1
The Ehlers-Danlos Syndromes: Clinical Sub-Types and Associated Defects

VILLEFRANCHE TYPE/(OMIM)	CLINICAL FEATURES	INHERITANCE	PROTEIN/(GENE DEFECT)
Classical/(130000 and 130010)	Hyperextensible skin; easy bruising; wide, atrophic scars; hypermobile joints	AD	Collagen type V/(*COL5A1*, *COL5A2*)
Hypermobility/(130020)	Smooth, velvety skin; joint hypermobility	AD/AR	Unclear for most; collagen type III; tenascin XB/(*COL3A1*; *TNXB*)[a]
Vascular/(130050)	Thin, translucent skin with easy bruising; arterial and visceral rupture; typical facies	AD	Collagen type III/(*COL3A1*)
Kyphoscoliosis/(225400 and 229200)	Atrophic scars, easy bruising; neonatal hypotonia; scoliosis; ocular rupture; marfanoid habitus	AR	Lysyl hydroxylase/(*PLOD1*)
Arthrochalasia/(130060)	Hyperextensible and fragile skin; severe joint hypermobility; congenital hip dislocation	AD	Collagen type I/(*COL1A1*; *COL1A2*)
Dermatosparaxis/(225410)	Severely fragile, sagging, redundant skin; hernias and premature rupture of fetal membranes	AR	Procollagen I N-peptidase/(*ADAMTS2*)
Other types[a]			
Progeroid variant[190]/(130070)	Wrinkled, loose facial skin, curly fine hair, scanty eyebrows and eyelashes	AR	Due to mutations in galactosyltransferase

AD = autosomal dominant; AR = autosomal recessive; OMIM = Online Mendelian Inheritance in Man.
[a]Few reported cases.

▲ **FIGURE 139-1** Classical Ehlers-Danlos syndrome. Dermal elasticity is demonstrated. Unlike cutis laxa, the skin returns to original shape after stretching.

may require repeated suturing or healing by secondary intention (Fig. 139-4). Alternatively, the skin may appear to hold the stitches well initially, but the wound may fall apart after sutures are removed. Scars after trauma or surgical procedures are thin, papyraceous (having the consistency of paper), and may stretch considerably after healing (see Figs. 139-3 and 139-4). The more severely affected individuals have scars with a characteristic "fish mouth" or "cigarette paper" appearance. Thin, atrophic, darkly pigmented scars form as a consequence of intradermal or subdermal hematomatas, and occur mainly at pressure points. Molluscoid pseudotumors, fleshy lesions associated with scars, are present at the extensor surfaces of joints, in the foot, and on the shins. Spheroids are well-defined, mobile, subcutaneous indurated nodules that occur at sites of recurrent trauma and can be confused with subcutaneous granuloma annulare. Affected persons

▲ **FIGURE 139-2** Classical Ehlers-Danlos syndrome (EDS). Gorlin's sign is the ability to touch the tip of the nose with the tongue and is described in approximately 50 percent of patients with Ehlers-Danlos, in contrast to 10 percent of individuals who do not have EDS.

▲ **FIGURE 139-3** Classical Ehlers-Danlos syndrome. Chronic discolored scars on the shin and ankle after repeated trauma. This is often associated with firm subcutaneous nodules that can be confused with subcutaneous granuloma annulare. Note the widened scar at the knee area.

may have pressure-induced herniation of subcutaneous fat on the wrists or on the medial or lateral aspect of the heels, evident when the patient is standing (piezogenic pedal papules). Hiatal hernia, postoperative hernias, and anal prolapse have been noted as manifestations of the tissue hyperextensibility and fragility.[25]

Musculoskeletal features seen in classical EDS include joint hyperextensibility in all patients and a fairly high frequency of scoliosis and pes planus.[26] Patients tend to have "double-jointed" fingers and frequent sprains or subluxation of larger joints (Fig. 139-5), either spontaneously or after slight trauma. Affected individuals complain of chronic joint and limb pain despite normal skeletal radiographs.[27] The joint hypermobility can lead to the onset of osteoarthritis in the third or fourth decade. Muscle hypotonia and delayed gross motor development have been described.

Dyspareunia and sexual dysfunction have been reported,[28] and the signs of classical EDS may be aggravated by pregnancy. Forty percent of affected individuals and 21 percent of babies of affected mothers are born prematurely, typically between 32 and 37 weeks, owing to premature rupture of fetal membranes or infection of the chorioamnionic membrane.[29,30] Fetuses with classical EDS may exhibit retarded growth, hernias, and joint dislocations. A significant number of individuals with EDS have abnormal cardiac echocardiographic parameters, showing aberrant vessels and incompetent valves.[31] Aortic root dilatation has been described in 29 percent of patients with the classical and hypermobile forms of EDS,[27,32] especially in the former, and may lead to rupture. The most commonly affected site is the sinus of Valsalva. Initial screening of all EDS patients by echocardiography is recommended.[32] Aortic valve incompetence, aortic rupture, and dissection occur far less commonly than in Marfan syndrome. β Blocker therapy with agents such as atenolol has been attempted in individual cases, but too few data exist to determine whether therapy is indicated or effective. Mitral valve prolapse (MVP) occurs no more frequently than in the general population.[31]

▲ **FIGURE 139-4** Classical Ehlers-Danlos syndrome. After suturing for a laceration, the wound dehisced with secondary infection and marked widening. Note the evidence of former sutures at the lower border, now 3 weeks after the injury and treatment with antibiotics. Scars tend to stretch further in the 6 months after closure.

▲ **FIGURE 139-5** Classical Ehlers-Danlos syndrome. Hyperextensibility of digits is demonstrated.

The diagnosis is confirmed by clinical examination, family history, and the identification of mutations in *COL5A1* or *COL5A2*, a test not commercially available.

Hypermobile Type

EPIDEMIOLOGY Hypermobile EDS, as the classical type, is a relatively common type of EDS, affecting 1 in 10,000 to 1 in 15,000 individuals.[9]

ETIOLOGY AND PATHOGENESIS The underlying molecular abnormality for this form of EDS has not been clearly defined. However, mutations in two genes have been found in a few cases: *COL3A1* (responsible for type III collagen)[33] and *tenascin-XB* (which encodes tenascin-X [TNX])[34] (see Chap. 61). TNX is a glycoprotein with a structure comprised of a cysteine-rich N-terminal domain and epidermal growth factor (EGF)–like repeats, followed by a number of fibronectin type III–like domains and a carboxy-terminal fibrinogen–like domain. Most cases are AD, although patients with *tenascin-XB* mutations show autosomal recessive inheritance.[6] EDS of the hypermobile type has been associated with congenital adrenal hyperplasia, owing to recombinational events in the gene encoding TNX. This aberration leads to deletions in *CYP21*, which results in congenital adrenal hyperplasia and decreased TNX messenger RNA (mRNA) and protein in fibroblasts and skin of affected individuals, causing EDS.[7]

CLINICAL FINDINGS The diagnosis of hypermobile EDS is made on the basis of clinical criteria and family history. Predominant features include generalized joint hypermobility, with recurrent dislocations and arthralgias. Hyperextensibility of both large and small joints is present, although predominantly the shoulders, hips, patellae, temporomandibular joints, and digits are affected.[3] As in the classical form of EDS, scoliosis and pes planus are common. Musculoskeletal pain is a prominent, debilitating feature in many patients; temporo-mandibular joint disorder is seen with increased prevalence,[35] and complex regional pain syndrome has been described, likely due to stretch injury to nerves traversing hypermobile joints and increased fragility of nerve connective tissue.[36] Chronic pain is frequently compounded by secondary depression.[37] Individuals with hypermobile EDS have mildly hyperextensible or soft, velvety skin, but near-normal scarring and no molluscoid pseudotumors. Patients with TNX deficiency tend to be intermediate in severity between the classical and more common hypermobile forms. Electron microscopic evaluation of skin biopsies show increased degeneration of elastic fibers when compared with controls.[38] A significant number of individuals with both the classical form and the hypermobile form have dilatation or rupture of the ascending aorta, or both.[31]

Vascular Type

EPIDEMIOLOGY Vascular type EDS is the most clinically significant due to arterial or major organ rupture. It affects approximately 1 in 100,000 to 200,000 individuals.[9]

ETIOLOGY AND PATHOGENESIS The vascular form of EDS is an AD disorder[39] caused by dominant-negative mutations in the gene for *COL3A1*,[40] which is located on chromosome 2q24.3-q31.[41] More than 320 mutations of this gene have been identified, most of which are either exon-skipping or missense, and disrupt the triple-helical structure.[25] Genotype-phenotype correlations have not been demonstrated.[25] Collagen III is a homotrimer, so the mutant pro α1(III) chain will be incorporated into almost all fibrils, leading to abnormalities of secretion and intracellular accumulation.[42] Collagen III is an important component of vascular walls and the upper dermis. Decreased collagen III leads to dermal atrophy and weakening of vessels.[43] Testing for this form of EDS can be reliably accomplished by analysis of type III procollagen and collagen chains harvested from cultured dermal fibroblasts or genetic testing.

CLINICAL FINDINGS The four major hallmarks of vascular-type EDS are distinctive facial features; thin, translucent skin; bruising/hematomas; and rupture of vessels or viscera, or both.[25,39] Patients with this condition often have short stature and a characteristic thin nose; thin upper lip; small earlobes; and a sunken, pigmented appearance around the eyes. The skin is thin and easily bruised; unlike in the classical or hypermobile types, hyperextensibility is minimal to absent. Individuals are prone to forming large and frequent hematomas with minimal to no trauma, including after inflation of a blood pressure cuff. Papyraceous scars are present over bony prominences. In fair-skinned individuals, subcutaneous vasculature is easily visible beneath the skin (Fig. 139-6).

▲ **FIGURE 139-6** Vascular Ehlers-Danlos syndrome. The venous pattern is apparent in a fair-skinned individual. (In order to enhance visibility of the venous network, the image was colorized.)

Affected individuals are at high risk for life-threatening rupture of the medium-sized arteries, particularly of the mesenchymal arteries in the abdomen, the splenic and renal arteries, and the descending aorta.[43] The aortic disease in this form is more prevalent than that found in the other forms of EDS and is different in its location. Rupture or dissection of the aorta, or both, when it occurs, is usually at or distal to the mid-aortic arch and extends distally. Arterial rupture generally occurs in the third, fourth, and fifth decades, and is the major cause of reduced life span in patients with this disorder. Dissection and rupture of aorta or arteries is usually not preceded by dilatation, in contrast to the rupture in Marfan syndrome and other forms of EDS.[32]

Patients are also at increased risk for stroke. Pregnancies are high risk, as arterial or uterine rupture in the peripartum period may lead to maternal death in 12 percent to 25 percent of cases[43,44]; vaginal or perineal tears can occur, and wounds after cesarean section frequently dehisce.[9]

Kyphoscoliotic Type

EPIDEMIOLOGY Characteristics of the kyphoscoliotic type of EDS have been described in fewer than 60 reported cases worldwide and are evident at birth.[9]

ETIOLOGY AND PATHOGENESIS The kyphoscoliotic type is the only type of EDS that is always inherited in an autosomal recessive fashion. It is caused by a deficiency of procollagen-lysine, 2-oxoglutarate 5-dioxygenase (PLOD1 or lysyl hydroxylase),[45] an enzyme that adds hydroxyl groups to lysines in collagen in an X-lys-gly se-

quence. The gene coding for this enzyme is located on chromosome 1p36.3-36.2. All patients with the kyphoscoliosis form of EDS have decreased hydroxylysine content in dermal tissues.[46] Many of the cross-links that normally occur between adjacent collagen monomers within a fibril begin as chemical modifications of hydroxy lysyl residues. Therefore, although hydroxylysine-deficient collagen is efficiently secreted from cells, it is not capable of normal cross-linking.[47] The deficiency is highly tissue- and collagen type–specific, apparently affecting only type I and III collagens.[48] Hautula and co-workers[49] reported homozygosity for an intragenic duplication of exons 9 to 15 in two patients, which appears to be the only common mutant allele, with an allele frequency of 19.1 percent in families with kyphoscoliotic EDS.[50] There appears to be a rare subtype that is clinically indistinguishable but has normal lysyl hydroxylase activity and normal hydroxy lysyl content in skin.[51]

CLINICAL FINDINGS Patients show joint laxity, kyphoscoliosis, and hypotonia.[52] Ocular fragility with microcornea, which was observed in the original reports, is found in only a minority of patients. Skin fragility, easy bruisability, and dermal hyperextensibility occur to some extent in most patients, although they are much less prominent features than in patients with the classical form of EDS. Individuals with the kyphoscoliosis form of EDS, like those with the vascular form, are at risk of having a potentially catastrophic arterial rupture. Most patients have radiologically detectable osteopenia, but pathologic fractures are rare. They can also exhibit a marfanoid habitus.

Although enzymatic testing for lysyl hydroxylase activity in cultured fibroblasts is available as a diagnostic test, measurement of the ratio of urinary excretion of total urinary hydroxy lysyl pyridinoline and lysyl pyridinoline has become widely used to screen for this disorder. Affected individuals demonstrate a narrow range of deoxypyridinoline-pyridinoline ratios that are at least one order of magnitude greater than age-matched controls.[53,54] This method shows great promise in providing a rapid, inexpensive diagnostic test for this type of EDS.

Arthrochalasia Type

EPIDEMIOLOGY Arthrochalasia-type EDS is rare; approximately 30 cases have been reported.[9]

ETIOLOGY AND PATHOGENESIS This rare form of EDS is caused by mutations in the type I collagen (*COL1A1* or *COL1A2*) genes that result in the loss of exon 6 sequences from the mature mRNA.[55–57] The molecular mechanism is almost always a mutation that disrupts the splice acceptor or splice donor sequences 5′ or 3′ to exon 6, causing removal of that exon (also known as *exon skipping*) during processing of mRNA. This alteration leads to failure of cleavage of the amino-terminal propeptides and subsequent lack of intermolecular cross linking of type I collagen. Thus, type I collagen is the major structural protein affected in connective tissues in EDS VII. This rare AD form is the combination of what was formerly called *types VIIA* and *VIIB*; the former type VIIC is now the dermatosparaxis type (see Dermatosparaxis Type) based on differences in the clinical phenotype and molecular pathogenesis.

CLINICAL FINDINGS Patients present with bilateral congenital hip dislocations, extreme multiple joint laxity, and recurrent subluxations of both large and small joints that are difficult to repair surgically.[58] Thoracolumbar scoliosis, short stature, and muscle hypotonia are common features. Congenital dislocation of the hip is a hallmark of the arthrochalasia form, although it also occurs in the classical and the vascular forms. Cutaneous features include tissue fragility and widened scars; these findings are less prominent than in the classical form of EDS.[59]

Electron micrographs of collagen fibrils from skin of a patient with this disorder show abnormal collagen fibrils that are irregular in outline and vary widely in diameter. Confirmation of the diagnosis is accomplished by electrophoretic demonstration of pNα1(I) or pNα2(I) chains extracted from dermal collagen or harvested from cultured skin fibroblasts. Direct demonstration of exon 6 skipping in complementary DNAs of *COL1A1* or *COL1A2* can be performed, followed by mutation analysis.[57]

Dermatosparaxis Type

EPIDEMIOLOGY The dermatosparaxis type of EDS is well defined in cattle[60] and is the rarest form of EDS, with fewer than 10 reported cases.[9]

ETIOLOGY AND PATHOGENESIS The biochemical defect that results in this autosomal recessive form of EDS is the failure to cleave the amino-terminal propeptide of type I collagen due to deficiency of type I procollagen N-peptidase.[60,61] Homozygosity or compound heterozygosity of mutant alleles in the *ADAMTS-2* gene lead to this alteration.[62] In skin, procollagen metabolites that contain the N-propeptides are present, and cultured dermal fibroblasts secrete procollagens in which the N-propeptide, but not the C-propeptide, is retained.

CLINICAL FINDINGS Dermatosparactic EDS is characterized by extreme skin fragility, easy bruising, large fontanels, blue sclerae, puffy eyelids, micrognathia, umbilical hernia, and short fingers.[63] Orofacial features include micrognathia, malocclusion, and hyperkeratotic gingival hyperplasia.[64] The deciduous teeth show abnormal molars and severe enamel attrition. There may also be agenesis, microdontia, discoloration, dysplastic roots, and tooth pulp obliteration in permanent teeth. The striking dermal fragility and sagging, redundant skin are the cutaneous hallmarks; although the skin is lax, it is not extensible. Large umbilical/inguinal hernias, internal organ rupture, and premature rupture of membranes have been described. Diagnosis can be made by electrophoresis, demonstrating procollagen α1(I) and α2(I) chains from collagen type I extracted from dermis in the presence of protease inhibitors or from fibroblasts.[6]

Other Types of Ehlers-Danlos Syndromes

Treatment and Prevention

The most productive avenue of therapy for EDS involves a triad of anticipatory guidance, pain management, and physical therapy. Regular evaluation by a physician familiar with EDS is strongly recommended. Early intervention is key, along with appropriate education.[72–74]

Avoidance of injury is critical, including making homes safe to prevent falls and avoiding contact sports. Gentle skin care should be encouraged, using mild soaps and non-adherent bandages. Sun protection is critical to prevent the skin thinning and loss of dermis associated with ultraviolet radiation–induced damage. When injuries occur that disrupt skin integrity, sutures should be placed. In addition to supplemental absorbable sutures within the wound, retention sutures tied at a distance from the incision may help. Adhesive strips may be used to support the skin during scar formation, but must be

retained for long periods. Given the problems with skin infection, prophylactic anti-staphylococcal antibiotics should be considered. Scar revision is often requested at the knees and elbows but may require grafting. Early adolescence is often the optimal time for this surgery, because subsequent traumatic events are less likely. Pseudotumors are more easily removed from the elbows and knees than those over the heels.

With the exception of congenital dislocation of the hip, joint dislocations in EDS either spontaneously resolve or can usually be corrected by closed reduction. Orthopedic procedures designed to reduce ligamentous laxity and therefore prevent recurrent dislocations include bracing or fusion of joints.

Avoidance of standing or working on hardened floors for long periods and the wearing of supportive, cushioned shoes reduces foot, knee, hip, and back pain. Nonsteroidal anti-inflammatory drugs (NSAIDs) may bring temporary relief; none are demonstrably superior. The relevant issue is the best-tolerated drug at the least cost. Other medications that may be used include fixed combination products (NSAID/opioid) or single-entity opioids and tricyclic antidepressants. There is some evidence that a subset of patients with the kyphoscoliotic type of EDS may respond to hydralazine and ascorbic acid.[75] Hydrotherapy and behavioral or cognitive coping strategies, or both, may also be tried to improve pain. Physical therapy, particularly directed at strengthening the shoulder girdle, has lowered the frequency of shoulder dislocations in individuals with chronic or recurrent dislocation. A regular exercise program may be helpful for strengthening muscles, helping to stabilize the joints, and relieve stress. Swimming and lifting weights are noncontact sports that have been tolerated well by many patients. Some patients use orthopedic devices such as orthotics and braces.

Pregnant women with EDS should be referred to high-risk obstetric practices when possible because of increased pregnancy risks. The extremely friable arteries of vascular-type EDS are very difficult to repair.[76]

MARFAN SYNDROME

Epidemiology

Marfan syndrome is a generalized connective tissue disease affecting approximately 1 in 5000 to 10,000 individuals,[77,78] with no racial, gender, or geographic predilection. Whereas most affected individuals will have a family history of the disease, approximately 25 percent will not, suggesting de novo mutations.[79]

Etiology and Pathogenesis

Routine histopathologic examination of biopsies do not show significant changes. However, ultrastructurally the dermis of Marfan patients demonstrates abnormal collagen fibrils with varied thickness, whirl- and wave-formed disarray, and twisted fibrils with flower-like shapes with zigzagged margins, similar to EDS.[38] In addition, the ratio of collagen I–collagen III content is decreased.[38]

Marfan syndrome is typically an AD disorder caused by heterozygous mutations in the gene for fibrillin 1 (FBN1),[80] localized to 15q21.1. More than 500 mutations in the *FBN1* gene have been reported that span the entire coding region of the gene (65 exons). Some, but not all, mutations result in the classical features of Marfan syndrome, and a few genotype-phenotype correlations are possible. Most missense mutations in the EGF domains result in the classic form of the disease. Patients with dramatic structural rearrangements, such as exon skipping (approximately 10 percent of the total), have comparatively severe forms of the disease.[81] Patients with mutations that lead to premature stop codons and reduced mRNA transcripts from the mutant allele have a surprisingly wide range of clinical severity, which is unlike the clear differences seen between OI patients with dominant-negative mutations and loss-of-function mutations (null alleles). The only established genotype-phenotype correlation is that of severe neonatal onset with mutations clustered in the middle of the *FBN1* gene.[82]

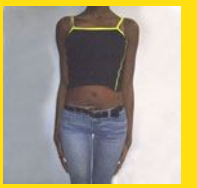
FBN1 is a major constitutive element of ECM microfibrils throughout the body. It is abundant in tissues affected in Marfan syndrome—the ascending aorta, suspensory ligament of the lens, periosteum, and the skin. Fibrillin plays a major role in the normal functioning of microfibrils, which are critical structural components of many tissues. The fibrillin molecule is spanned by cysteine-rich repeats interspersed with latent transforming growth factor-β (TGF-β)–binding protein-like and EGF-like motifs.[82]

Genetic alterations in *FBN1* produce a spectrum of clinical abnormalities well beyond the classic Marfan phenotype, the so-called *fibrillopathies*.[83] The spectrum includes the severe neonatal Marfan phenotype at one end, extending to isolated aortic root dilatation or marfanoid skeletal features lacking cardiovascular involvement or ectopia lentis at the other. Other phenotypes that can result from mutations in *FBN1* include: the mitral, aortic, skin, and skeletal manifestations (MASS) phenotype; bicommissural aortic valve with ascending aortic aneurysm; Shprintzen-Goldberg syndrome; MVP syndrome; familial ectopia lentis; isolated marfanoid habitus, and Weill-Marchesani syndrome.[78]

Mutations in the *FBN2* gene on chromosome 5q23[84] can result in an AD disorder that resembles neonatal Marfan syndrome, especially in its skeletal manifestations—congenital contractural arachnodactyly (Beals syndrome).[85] It is characterized by multiple flexion contractures (especially elbow, knee, and finger joints), arachnodactyly, severe kyphoscoliosis, crumpled pinnae, and muscular hypoplasia. Aortic root dilatation and the ocular manifestations of Marfan syndrome do not tend to be associated.

Heterozygous mutations in the TGF-β receptor 2 on chromosome 3p24.2-25 have also been described in a subset of patients[86] with prominent aortic dilatation but without ocular abnormalities.[87]

MARFAN SYNDROME AT A GLANCE



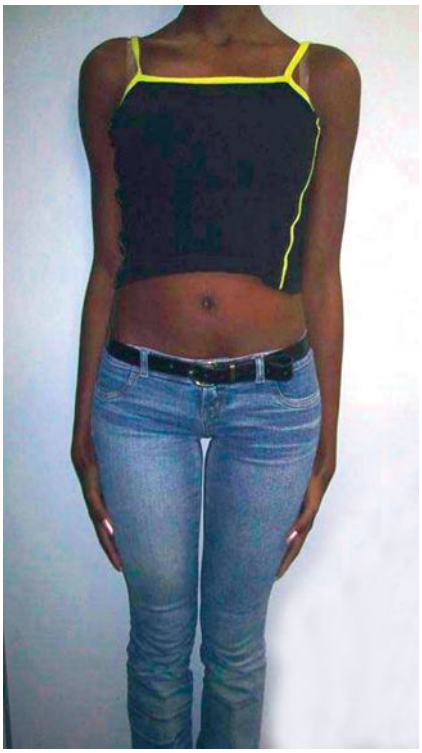
- Incidence: 1 in 5000 to 10,000 (Online Mendelian Inheritance in Man #154700).
- Autosomal dominant inheritance with mutations in fibrillin 1 (*FBN1*; chromosome 15q21.1).
- Cutaneous features include striae distensae (two-thirds of patients), inguinal or incisional hernias, and, rarely, elastosis perforans serpiginosa.
- Extracutaneous manifestations include hyperextensible joints, upward lens displacement, skeletal abnormalities, and cardiac aberrations, such as aortic aneurysm and rupture.
- Information for patients and professionals at http://www.marfan.org.

Clinical Findings

Marfan syndrome is a generalized disorder of connective tissue that has primary manifestations in the skeletal, ocular, and cardiovascular systems.[79] Patients with Marfan syndrome may have major abnormalities primarily in three organ systems: in the eye—most characteristically dislocation of the lenses; in the skeletal system—excessive length of extremities, loose-jointedness, kyphoscoliosis, and anterior chest deformity; and in the cardiovascular system—most characteristically aortic aneurysm and mitral valve redundancy.[83] Skin manifestations consist of striae distensae, a common finding, and elastosis perforans serpiginosa (see Chap. 67), a rare finding.

Virtually all patients with Marfan syndrome have myopia as the result of an abnormally long anterior-posterior axis of the orbit and relatively flat corneas.[88] In addition, approximately 70 percent of affected patients have ectopia lentis, with the lens usually displaced upward. In an examination after the dilation of the pupil, the margin of the lens is usually visible in the lower part of the pupil. Dislocation of the lens into the anterior chamber or trapping of the lens in the pupil sometimes occurs, and acute glaucoma may result. Detection of mild ectopia lentis requires full dilation of the pupils and slit-lamp examination for redundancy of the suspensory ligament of the lens. Therefore, clinical exclusion of ectopia lentis in an individual suspected of having Marfan syndrome must include a slit-lamp examination after dilation of the pupils. Strabismus and cataracts may also develop.

The skeletal features, particularly the long, narrow extremities, figured prominently in Marfan's initial description in 1896 of the syndrome that now bears his name. Patients with Marfan syndrome are usually taller than their same-sex siblings. There is skeletal disproportion, with the most consistent and reliable measure being an abnormally low ratio of the upper segment (height minus lower segment) to the lower segment (measured from the pubic symphysis to the floor) (Fig. 139-7). The arm span (fingertip to fingertip when expanded) is usually longer than the height by several centimeters. These discrepancies may be magnified by associated kyphoscoliosis. The ribs appear to undergo the same excessive longitudinal growth, as do the bones of the extremities. Depression of the sternum (pectus excavatum) or projection (pectus carinatum) or an asymmetric deformity of the anterior chest results.



▲ **FIGURE 139-7** Marfan syndrome. Frontal view of teenage girl with Marfan syndrome. Note the tall stature, arachnodactyly, abnormally low ratio of the upper segment to lower segment, and long arms.

Joint hyperextensibility is present in some, but not all, patients with Marfan syndrome. Flat-footedness, hyperextensibility at the knees (genu recurvatum) and elbows, and occasional dislocation of joints are manifestations of the loose-jointedness. Because of joint hyperextensibility and long, narrow extremities, the patient is often able to touch his or her umbilicus with the right hand passed around the back and approaching the umbilicus from the left. A relatively narrow palm of the hand with a long thumb and hyperextensibility is the basis of Steinberg's sign, in which the thumb propped across the palm extends well beyond the ulnar margin of the hand.

The cardiovascular manifestations of Marfan syndrome are by far the most clinically significant and account for the overwhelming majority of morbidity and mortality associated with this disorder. The two major cardiovascular manifestations are MVP and aortic root dilatation. MVP is a consequence of the redundancy of the valve leaflets, the stretching of the chordae tendineae, and dilatation of the valve annulus. The prevalence of MVP in Marfan syndrome increases with age and is present in approximately 75 percent of individuals.[79] MVP can occasionally be associated with abnormal electrocardiograms, regurgitation, and cardiac arrhythmias that can lead to sudden death.[89]

Dilatation of the proximal aorta is progressive and, in some cases, may even occur in utero. Dilatation is often first seen in the sinuses of Valsalva, but is often discontinuous and unpredictable.[90] Patients with Marfan syndrome should be monitored on a yearly basis, as aortic complications of Marfan syndrome do not occur in aortas that are normal for age or in adults in aortas less than 40 mm in diameter. The aortic pathology of Marfan syndrome is almost always in the proximal (ascending) aorta; distal pathology is usually a result of forward progression of a dissecting lesion. Premature death in Marfan syndrome is a result of its cardiovascular complications: proximal aortic dilatation associated with aortic valve incompetence, aortic rupture, or aortic dissection.[89] Other manifestations of this syndrome include a high-arched palate and crowding of the anterior teeth, emphysema, spontaneous pneumothorax, and dural ectasia.

Cutaneous lesions develop in approximately two-thirds of patients with Marfan syndrome and represent minor diagnostic signs in the revised 1996 Ghent criteria.[91] These include striae distensae (more prominent during adolescence and on the buttocks, thighs, breasts, abdomen, and thighs) and inguinal or incisional hernias.[89,92] Histology reveals abnormal elastic fibers with a moth-eaten appearance and collapsed, distorted adipocytes.[93]

The large size of the gene, along with the absence of mutational hot spots and the heterogeneity of these mutations preclude sensitive testing for *FBN1* mutations.[94,95] Clinical assessment remains the current diagnostic method, but in individuals with a familial phenotype, mutational or linkage analysis may yield positive results.[76]

Treatment

Management of patients with Marfan disease should be multi-disciplinary, targeting each affected organ system.

Prevention

Patients with aortic dilatation are encouraged to avoid caffeine, stressful circumstances, and vigorous exercise. Contact sports or heavy lifting should be avoided.[88] Early use of either a valve-

saving aortic repair or composite graft placement is now prudent because of significant improvements in the success of these procedures and the well-known difficulties in managing an acute aortic dissection in Marfan patients. To prevent pneumothorax, patients should avoid smoking and activities that involve rapid changes in pressure such as flying or scuba diving.[98]

HOMOCYSTINURIA

Epidemiology

The incidence of homocystinuria varies from 1 in 344,000 worldwide[101] to a much greater incidence of 1 in 65,000 in Ireland.[102] It is the second most common treatable aminoaciduria after phenylketonuria.

Etiology and Pathogenesis

Patients with homocystinuria have primary hepatic deficiency of cystathionine β-synthase (CBS), a pyridoxine-dependent enzyme in the methionine transsulfuration pathway,[103,104] resulting in high plasma levels of the toxic amino acid L-homocysteine.[105] A minority of patients have an acquired (dietary) deficiency of cobalamin or heritable disorders that prevent conversion of dietary cobalamin to its biologically active forms; rarely, some have defects that cause decreased availability of 5-methyltetra-hydrofolate, which is also required in the metabolism of methionine.

By definition, homocystinuria is a biochemical abnormality, not a specific disease entity. By far the most common cause of this condition is a deficiency of the enzyme CBS because of recessive mutations in its gene. The *CBS* gene is located at chromosome 21q22.3.[106] More than 92 disease-causing mutations have been described.[105] Molecular analysis of the *CBS* locus has identified several mutant alleles in patients with homocystinuria. Substitution of serine for glycine at amino acid position 370 (G370S) is the most common mutation in northern European populations, and the T191M point mutation is found frequently in Spanish and South American patients.[107] Another common mutation in Europe (I278T) has prognostic significance, as it indicates responsiveness to pyridoxine,[108,109] in contrast to the lack of response in most patients with G370S or T191M mutations. Most patients are compound heterozygotes for rare mutant alleles.[110]

HOMOCYSTINURIA AT A GLANCE

- Incidence: 1 in 65,000 to 344,000 (Online Mendelian Inheritance in Man #236200).
- Autosomal recessive inheritance, mutations in cystathionine β-synthase, chromosome 21q22.3.
- Cutaneous features include malar flush, fair and thin skin and hair, and livedo reticularis.
- Extracutaneous manifestations include downward lens displacement, osteoporosis, mental retardation, thromboembolism, and severe hyperhomocysteinemia.
- Information for patients and professionals at http://www.pku-allieddisorders.org and http://www.hcusupport.com.

The pathogenesis of the connective tissue abnormalities, including ectopia lentis, osteoporosis, and the vertebral and thoracic abnormalities, may be related to elevated homocystine levels, which inhibit cross-linking of collagen. The mechanism for decreased cross-linking in vivo is unknown. It might be in the earliest step in cross-linking, which is catalyzed by lysyl oxidase, or in later steps, which serve to mature the cross-links. Ultrastructurally, elastic fibers from affected patients show an elastic matrix with lucent and dense stripes and numerous abnormal elastic microfibrils.[38] The biologic basis for mental retardation and psychiatric disturbance in patients with homocystinuria is also unknown.

Patients with combined methylmalonic aciduria and homocystinuria [cblC; Online Mendelian Inheritance in Man (OMIM) #277400] are also at risk for the same neurologic, ophthalmologic, and cardiac abnormalities as in CBS, presumably related to the high levels of homocysteine.[112,113] The most frequent hereditary abnormality of vitamin B_{12} (cobalamin, cbl) metabolism, cblC results from mutations in *MMACHC*. Features often manifest during infancy, but late-onset disease occasionally occurs and is primarily characterized by neurologic deterioration.

Clinical Findings

The major clinical manifestations of CBS deficiency include ocular, skeletal, vascular, and central nervous system abnormalities.[114] These include ectopia lentis, osteoporosis, mental retardation, and thromboembolism. By the age of 10 years, 82 percent of patients develop ectopia lentis, and by 15 years, 50 percent have radiographic signs of osteoporosis.[115]

The cutaneous manifestations include malar flush, thin hair and skin, and cutis reticulata. A prominent malar flush has been reported in many patients, which is most easily seen after vigorous exercise or after cold exposure. This malar flush was also found to be more frequent in pyridoxine responders, although the difference was not significant, likely due to the small sample of patients.[114] The dermis is usually fair and thin, and livedo reticularis is commonly seen on the extremities. In patients with deep venous thromboses, collateral venous channels are visible through the skin. Hair is often thinned and fair. Treatment may cause hair to darken.

Treatment

Therapeutic modalities include pyridoxine, in combination with folic acid and vitamin B_{12}; methionine-restricted, cystine-supplemented diet; and betaine. Approximately one-half of patients with clinical CBS deficiency respond to very high doses of pyridoxine (250 to 500 mg/day) with decreases of methionine in plasma and virtual elimination of homocysteine from urine.[103,117] In these patients, pyridoxine treatment, if initiated in infancy, significantly reduces the risk of thrombosis, grand mal seizures, and mental retardation. Increases in responsiveness are likely caused by increased production of pyridoxal-5′-phosphate, the active form of vitamin B_6 that is the cofactor for CBS. Sensitivity to pyridoxine may be predicted by the specific CBS mutation,[103] is constant in affected siblings, and only occurs in the presence of residual CBS activity. Betaine is a methyl donor agent that lowers homocysteine through remethylation of methionine.[118] Increase in methionine levels is a potential risk of betaine therapy and led to cerebral progressive cerebral edema in a child with CBS deficiency[119]; betaine should be used as an adjunct to other therapies, particularly to dietary restriction of methionine.

PSEUDOXANTHOMA ELASTICUM

Epidemiology

The disease prevalence is estimated at 1 in 25,000 to 100,000 persons and occurs

PSEUDOXANTHOMA ELASTICUM

AT A GLANCE

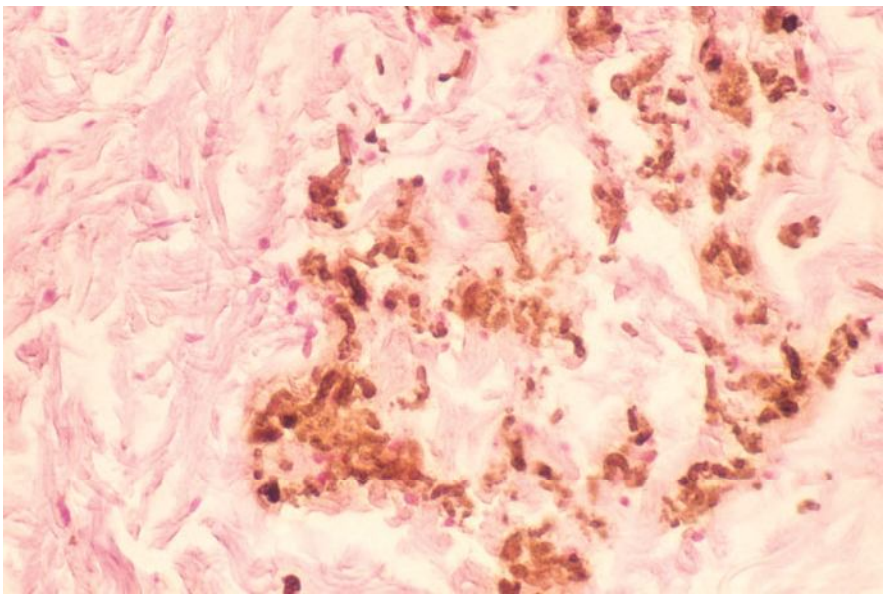
- Incidence: 1 in 25,000 to 100,000 (Online Mendelian Inheritance in Man #177850 and #264800).
- Autosomal recessive inheritance, occasional pseudo-dominant.
- Mutations in multidrug resistance associated protein (MRP6), encoded by (*ABCC6*) on chromosome 16q13.1.
- Cutaneous features include yellow, flat papules in the neck, flexures, and periumbilical areas. Less frequent skin lesions include acneiform lesions, elastosis perforans serpiginosa, reticulate pigmentation, and granulomatous nodules.
- Extracutaneous manifestations include angioid streaks, visual impairment, *peau d'orange* retinal hyperpigmentation, cardiovascular disease, and bleeding.
- Histopathology shows swollen, clumped, fragmented elastic fibers and calcium deposits in the mid and deep reticular dermis. Alterations easily visualized with calcium (i.e., von Kossa) and elastic (i.e., Verhoeff-van Gieson or orcein) stains.
- Information for patients and professionals at http://www.pxe.org and http://www.napxe.org.

twice as frequently in females.[120] Pseudoxanthoma elasticum (PXE) has been reported in all ethnic groups, with an average age of initial manifestation of 13.5 years.

Etiology and Pathogenesis

PXE, also known as *Grönblad-Strandberg syndrome*, is characterized by progressive calcification and fragmentation of elastic fibers in various tissues, including skin (particularly flexural sites), eye (angioid streaks and retinal defects), and cardiovascular system (hypertension, gastrointestinal bleeding, and vascular disease).

At the histologic level, PXE is known to be caused by progressive calcification and fragmentation of elastic fibers. Elastic fibers in the deep and reticular dermis show a swollen, clumped, and fragmented appearance with calcium deposits (Fig. 139-8). Interspersed are more normal-appearing elastic fibers, which may also stain blue because of their high calcium content. These changes are also present in fibers of other organs, including blood vessels, Bruch's membrane of the eye, and the heart. Dermatopathologic findings are more easily seen with the use of calcium (von Kossa's) or elastic (Verhoeff-van Gieson) stains. As evidenced with electron microscopy, calcification occurs in a centripetal fashion within the fiber.[121] Affected skin also reveals deposits of other ECM components associated with elastic fibers such as fibronectin, vitronectin, and proteoglycans.[122] Some patients also show increased levels of urinary and skin glycosaminoglycans.[123]

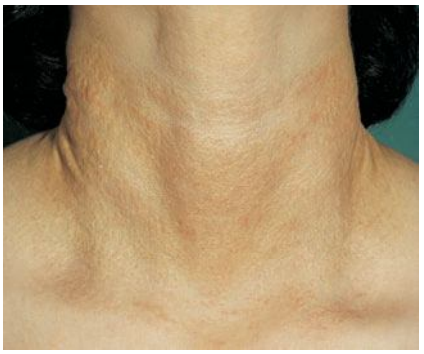


▲ **FIGURE 139-8** Pseudoxanthoma elasticum, elastic tissue stain. The elastic fibers show marked degeneration: They are swollen, tortuous, and irregularly clumped.

The gene responsible for PXE has been localized to chromosome 16p13.1, and it encodes an adenosine triphosphate–binding cassette (ABC) subfamily C member 6 (*ABCC6*) transporter.[124–127] The *ABCC6* gene is a member of a family of 48 genes, some of which have also been associated with other dermatologic conditions (for example, *ABCA12* with lamellar ichthyosis and harlequin ichthyosis)[128] (see Chap. 47). The gene consists of 31 exons spanning 75 kb and encodes the 165-kd transmembrane multidrug resistance–associated protein 6 (MRP6), which is a transporter protein. MRP6 expression in liver and kidneys is low in PXE, suggesting a metabolic origin with secondary tissue involvement in this disease.[129]

More than 60 mutations have been detected in *ABCC6*, of which more than 90 percent result in recessive inheritance and less than 10 percent in dominant fashion (likely pseudo-dominant forms of PXE with milder manifestations),[126,129–131] most of which are inactivating mutations. Although most mutations appear to be unique variants, two disease-causing alleles occur frequently in apparently unrelated individuals. *R1141X* has been found predominantly in Europe at a frequency of 28.4 percent (overall, 18.8 percent). *ABCC6del23–29* occurs at an overall frequency of 12.9 percent and is most prevalent in patients from the United States (28.4 percent). These results suggest that *R1141X* and *ABCC6del23–29* might be derived regionally from founder alleles.[125] Molecular studies can be performed to confirm the clinical diagnosis and to help recognize asymptomatic patients with a positive family history.

The precise function of the ABCC6 transporter is unknown, and the genotype-phenotype relationship between *ABCC6* mutation and pathologic changes in PXE tissues remains to be elucidated. Abnormalities in the attachment and proliferation of cultured fibroblasts from the dermis of affected patients suggest a functional role for ABCC6.[132] However, recent studies support the concept that a circulating factor in the serum of affected individuals interferes with the normal assembly



▲ **FIGURE 139-9** Pseudoxanthoma elasticum. Papules on the neck. There is a distinct yellowish hue. Loose, thickened skin with a pebbled appearance on the neck.

of elastic fibers. PXE fibroblasts cultured with normal human serum deposit structurally normal elastic fibers, but normal and PXE fibroblasts deposit abnormal aggregates of elastic fibers when maintained in the presence of serum from PXE patients.[133]

Clinical Findings

PXE usually involves the skin, Bruch's membrane of the eye, and vascular tissues.[134] Cases with involvement of other systems have occasionally been reported, including urinary tract and pulmonary tissues. The mortality and morbidity of PXE is dependent on the extent of extracutaneous involvement, especially the extent of vascular disease.

Typically, yellowish papules giving a "plucked chicken" or "cobblestone" appearance in flexural skin begin in childhood[120] (Fig. 139-9). These 1- to 5-mm symmetric papules may form a reticulated pattern but often coalesce to form plaques that have also been compared with "Moroccan leather." However, their presence is usually not noted until adolescence or even later adulthood because of their asymptomatic nature. These papules are generally first seen on the lateral areas of the neck. Additional commonly involved areas include the antecubital, popliteal, inguinal, neck, axillae, and periumbilical regions, as well as oral, vaginal, and rectal mucosae. Involvement may be progressive, and the disease may ultimately involve the entire skin, although severe involvement is rare. In time, the skin may become soft, lax, wrinkled, and hang in folds, particularly in the neck, axillae, and groin. Prominent horizontal and oblique mental creases (separating the lower lip from the chin) before 30 years of age are highly specific. Patients usually present to their physicians with these lesions because of cosmetic concern. Careful complete physical examination is warranted, and a skin biopsy of scars or flexural skin should be performed, as abnormal histologic findings may be present in the absence of visible cutaneous lesions.[135] The differential diagnosis of the skin lesions of PXE is listed in Box 139-1.

Once they appear, the skin defects of PXE usually remain unchanged throughout life. Elastosis perforans serpiginosa

Box 139-1

Differential Diagnosis of the Skin Lesions of Pseudoxanthoma Elasticum (PXE)

DISORDER	MORPHOLOGY	DISTRIBUTION	ASSOCIATIONS	DIFFERENTIATION
Dermatofibroma lenticularis[191]	Asymptomatic, flat-topped yellowish papules and nodules, which, when grouped, form large plaques several centimeters in diameter	Often proximal extremities, truncal; symmetric; may be more widespread	Osteopoikilosis, fractures in Buschke-Ollendorff syndrome [due to LEMD3 (MAN1) mutations][191]	Clinical; biopsy shows increased elastic tissue
Localized acquired cutaneous PXE[192]	Asymptomatic, coalescing yellow macules and papules, occasional reticulate or checkered pattern; lax, redundant areas	Neck, axillae, groin, flexural surfaces, areas exposed to saltpeter fertilizer (calcium-ammonium-nitrate)	Older age, exposure to saltpeter fertilizer in Norwegian farmers, uremia	Histology shows fragmented, thickened, mineralized elastic fibers in mid and deep reticular dermis
Perforating periumbilical PXE[193]	Asymptomatic or pruritic, erythematous lesions that progress to hyperpigmented plaques, with central atrophy, a red, scaly border, and peripheral hyperkeratotic papules, sometimes expressing elastotic debris	Periumbilical or breast area	Multiparity, ascites, abdominal surgery; uremia and hyperphosphatemia in chronic renal failure	Histopathology shows elimination of basophilic, elastotic debris through channels in addition to thickened and mineralized elastic fibers in mid and deep reticular dermis
Long-term penicillamine therapy[194]	Varied presentations; may resemble pseudoxanthoma elasticum, elastosis perforans serpiginosa, cutis laxa, and anetoderma	Similar to those seen in idiopathic forms of disease (i.e., neck and flexures for PXE, flexures in elastosis perforans serpiginosa)	Use of D-penicillamine	Histopathology shows thickened elastic bundles with prominent lateral protrusions ("bramble-bush"), granulomatous dermal inflammation, infrequent calcification, and trans-epidermal elimination of elastic fibers
Actinic damage to neck[154]	Numerous small, asymptomatic, discrete, white papules	Neck	Middle aged to elderly individuals	Histology shows elastolysis and fibrosis in papillary and mid-reticular dermis
Papular elastorrhexis[154]	Asymptomatic, firm, non-follicular 1- to 5-mm whitish papules on trunk and upper extremities	Chest, abdomen, shoulders, back, proximal extremities	Rarely familial occurrence	Loss of elastic tissue in reticular dermis (relative increase in fibrillar component) and fragmentation, with occasional perivascular mixed infiltrate

may co-exist with PXE, and perforating disease may occur, with transdermal elimination of calcium (see Chap. 67).[136] Hyperpigmented, reticulated macules, telangiectasias of the lips, and acneiform and granulomatous lesions may also occur.[136,137]

The characteristic ocular defects of PXE are angioid streaks of the retina, characterized by reddish-brown curvilinear bands that radiate from the optic disk. Angioid streaks result from calcification of the elastic fibers in Bruch's membrane of the retina, with cracking and fissuring in its outer portion, the lamina elastica. Approximately 85 percent of the patients with PXE may have those lesions identified on routine ophthalmologic examination.[121,134] The angioid streak is usually present bilaterally and is often first noted between the ages of 20 and 40 years, typically many years after the onset of cutaneous lesions. The streaks may progress slowly or remain stationary for years. Angioid streaks are often mistaken for blood vessels, though they are irregular and generally wider. They are not unique to PXE and may be present in EDS, Marfan syndrome, lead poisoning, sickle cell anemia, thalassemia,[138] Paget disease of bone, acromegaly and other pituitary disorders, and familial hyperphosphatemia.[134] The most common retinal feature associated with angioid streaks is the presence of "*peau d'orange*," a mottled fundus appearance that usually precedes the appearance of the streaks. These are small, relatively symmetric, drusen-like, flat, yellow, and, occasionally, confluent lesions in the retinal pigment epithelium. Leopard spotting of the posterior pole of the retina is another early sign. Fibrovascular ingrowth in the retina may result in retinal hemorrhages and lead to a risk of retinal detachment and vision loss that increases with each hemorrhage.[139] Other retinal changes include salmon patches (typically a healing subretinal hemorrhage), black dots (pigmentation after focal hemorrhage), and "pearls" (tiny white foci after subretinal or pigment epithelial hemorrhage, or a focal scar). The most visually devastating complication is disciform degeneration of the central visual area. Peripheral vision is generally spared.

Cardiovascular complications occur primarily in affected adults, but occasionally occur in children.[140,141] Calcification of the elastic media of blood vessels with subsequent intimal proliferation leads to a variety of physical findings and to serious complications of PXE. Intermittent claudication is the most common cardiovascular manifestation and the one that presents the earliest. In adults, peripheral pulses are often severely diminished. Angina pectoris or abdominal angina may become incapacitating. Hypertension, caused by renal artery involvement, is three times more common in patients with PXE than in the general population. Severe coronary artery disease may cause early myocardial infarction. MVP has a higher prevalence in PXE than the general population and is almost always accompanied by a murmur.[142] Cerebral artery involvement has also been reported. Seizures occur more frequently than in the general population because of the cerebral involvement.[143] Subarachnoid hemorrhage has been a major cause of death.

Gastrointestinal hemorrhage, apparently caused by the fragility of calcified submucosal vessels, is the most significant vascular complication of PXE, and it is usually gastric in origin. Hemorrhage may occur early in the disease progression and is often the presenting sign, beginning without warning in the second to fourth decade of life. Approximately 10 percent to 15 percent of patients with PXE have a gastrointestinal hemorrhage at some point in their lives. Lung involvement has been seen, but rarely. Bleeding may occur in the urinary tract, and the patient presents with hematuria.[144] Pregnancy is uncomplicated and thus not contraindicated in these patients, but there is an increased risk of miscarriage in the first trimester, and multiple pregnancies may aggravate the disease course.[145]

TABLE 139-3
Monitoring Studies for Patients with Pseudoxanthoma Elasticum

STUDY	REASON
Complete blood cell count	Occult blood loss; iron-deficiency anemia
Calcium, phosphate	Rare reports of hypercalcemia and hyperphosphatemia
Fasting lipids	Hyperlipidemia aggravates risk of cardiovascular disease
Urinalysis	Hemorrhage from urinary tract
Fecal test for blood	Occult blood loss from GI hemorrhage
Eye examination	To detect angioid streaks, retinal hemorrhage, early retinopathy
Endoscopy	If evidence of GI bleeding
Echocardiography	If murmur, angina, or personal or family history of coronary artery disease
Doppler blood pressure (ankle, brachial)	To investigate claudication or if decreases peripheral pulses
Computed tomography of head	If focal neurologic problems or evidence of cerebral hemorrhage
Radiographs	If seeking calcifications

GI = gastrointestinal.

Treatment

Tissue alterations in PXE patients are irreversible, so most efforts are directed toward minimizing complications. Early diagnosis of this disease allows early recognition of ocular and cardiovascular manifestations, thus reducing potential major complications. Surgical excision of the sagging skin seen late in the disease can be corrected by surgical excision if desired.[146] Fillers or autologous fat injections may improve the appearance of the mental creases.

Prevention

Prevention or minimization of complications in patients with PXE through education is of critical importance. Providing information on support groups is extremely important (PXE International, Inc., at http://www.pxe.org and National Association for Pseudoxanthoma Elasticum, or NAPE, at http://www.napxe.org). Recommended testing for patients with PXE is reviewed in Table 139-3. A healthy diet and exercise regimen are key components to minimizing the extent of the cardiovascular disease. Diet should be low in calcium (60 to 1200 mg/day)[147] and lipids, and medications to control these should be introduced if diet and exercise alone are not sufficient. Medications that decrease coagulation, such as NSAIDs and aspirin, should be avoided.

Patients and family members should be monitored by an ophthalmologist regularly for funduscopy, as early eye changes often precede skin changes.[148] Patients should be instructed to self-test with an Amsler grid, which can find early evidence of retinal hemorrhage. Changes can be confirmed by intravenous fluorescein angiography. Patients should avoid heavy lifting, straining, and head trauma, as in weight lifting or head-contact sports, to decrease the risk

of retinal hemorrhage. This early detection allows for the use of laser photocoagulation to minimize vision loss. Although early attempts to treat with laser photocoagulation were disappointing, more recent studies show Verteporfin photodynamic therapy every 3 months for the choroidal neovascularization to be promising.[149]

Regular cardiologic monitoring is also important. Prophylactic antibiotics should be prescribed before any dental procedure or surgical procedures if mitral valve insufficiency is present to prevent bacterial endocarditis. Intermittent claudication can be treated by weight reduction and exercises that stimulate collateral blood vessel development, and tobacco use should be prohibited. Patients should be monitored carefully for gastrointestinal bleeding. Depending on its severity, hospitalization, blood transfusion, endoscopic treatment, and surgery with partial gastrectomy may be necessary to manage bleeding. Appropriate referrals for urologic, pulmonary, and neurologic consultation should be made based on concerns and physical findings.

CUTIS LAXA (GENERALIZED ELASTOLYSIS)

Epidemiology

Few cases reported.

Etiology and Pathogenesis

Cutis laxa (CL) describes a group of disorders that share loose, redundant skin as a feature. Most cases are inherited in an AD, autosomal recessive, or X-linked manner,[150–153] but acquired cases have also been described.[154]

Because of histologic abnormalities in elastin quantity or structure in virtually all forms of CL, investigations into the molecular pathogenesis have focused on genetic mutations that result in alterations in the structure or processing of elastin in the ECM. The genetic heterogeneity of CL reflects the fact that several genes are required for normal elastin biosynthesis and function.[155] Decreased synthetic activity of skin fibroblasts and qualitative and quantitative abnormalities of elastic fibers been reported.[156,157]

Elastin gene mutations that result in abnormal tropoelastin and abnormal elastic fibers result in AD CL (OMIM #123700).[150,158] Elastin is one of several matrix components responsible for the properties of reversible deformability in many tissues, including the skin, lungs, and large blood vessels. The human elastin gene (*ELN*) is 45 kb in length and has been mapped to 7q11.2.[159] Elastin initially is synthesized as individual tropoelastin molecules that are aligned on a network of elastic fibers. This alignment is stabilized by the formation of intermolecular cross-links that are mediated by the copper-dependent enzyme lysyl oxidase.

Type I autosomal recessive CL (OMIM #219100) is frequently fatal and is caused by mutations in the fibulin-5 gene (*FBLN5*, also known as *EVEC* or *DANCE*),[160] which is critical for elastic fiber development.[161] Mutations in FBLN5 can rarely lead to AD disease. The molecular basis for type II CL, (also known as *CL with joint laxity and developmental delay*; OMIM #219200),[152] remains elusive, but lysyl oxidase deficiency is also found in these patients.[158,162,163] A girl with CL in association with severe aortic dilatation and arachnodactyly has recently been described and found to have a mutation in the fibulin-4 (*FBLN4*) gene[164] (Fig. 139-10).

Mutations in the gene encoding ATP7A, a member of the P-type adenosine triphosphatase family responsible for copper transport, have been described in the X-linked type of CL, which is allelic to Menkes syndrome.[158] ATP7A mediates copper transport from the gastrointestinal tract, efflux of excess copper from cells, and delivery of intracellular stores of copper to cuproenzymes.

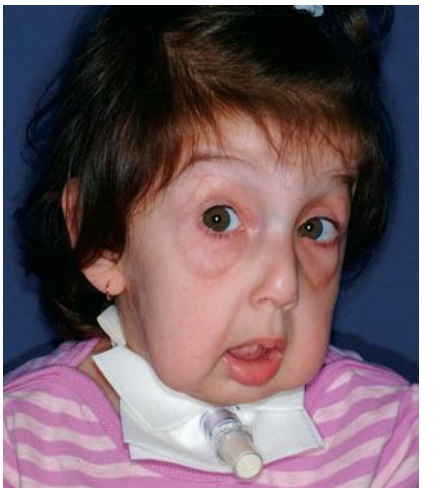
Acquired forms of this disease are present after skin inflammation and structural damage of elastic fibers. Increased neutrophil elastase is found in affected skin and is presumed to disrupt elastic fiber integrity.[165] A recent report described heterozygous mutations in *FBLN5* and *ELN* in an adult with "acquired" CL and aortic root aneurysm after a toxocara infection; predisposition to inflammatory damage by the missense mutations is theorized.[166]

Clinical Manifestations

The clinical presentation of CL shows considerable heterogeneity.[167,168] Congenital onset is generally indicative of an autosomal recessive or X-linked form of CL; later onset is consistent with either a heritable or acquired form. In both inherited and acquired forms, internal organs can be involved. As a rule, the AD form

CONGENITAL CUTIS LAXA AT A GLANCE

- Inheritance may be autosomal dominant [Online Mendelian Inheritance in Man (OMIM) #123700), autosomal recessive (OMIM #219100 or #219200), or X-linked recessive (also known as *occipital horn syndrome* (OMIM #304150).
- Mutations in elastin (*ELN*) or fibulin-5 (*FBLN5*) in autosomal dominant; in fibulin-5 (*FBLN5*, *EVEC*, *DANCE*) or fibulin-4 (*FBLN4*) in autosomal recessive; a copper transport adenosine triphosphatase (*ATP7A*) in the X-linked type.
- Cutaneous features include pendulous, inelastic skin, with an aged facies.
- Extracutaneous manifestations may include pulmonary emphysema, aortic aneurysm, pulmonary artery and valve stenosis, hernias, gastrointestinal diverticula, joint laxity, low serum ceruloplasmin, and bilateral exostoses of the occiput (or occipital horn syndrome).
- Histopathology shows sparse and fragmented elastic fibers, better visualized with stains (i.e., Verhoeff-van Gieson or orcein).
- Information for patients and professionals at http://www.orpha.net/nestasso/cutislax/.



▲ **FIGURE 139-10** Cutis laxa due to fibulin-4 mutation. The facial skin hangs in loose folds, giving the appearance of premature aging. Note the prominent periorbital vessels. The tracheostomy was placed for diaphragmatic eventration and respiratory difficulty.

of CL has primarily skin involvement, and is thus largely a cosmetic problem with a good prognosis.

The autosomal recessive and X-linked forms are often associated with more severe multisystem complications that include emphysema, diaphragmatic hernia, and gastrointestinal and genitourinary diverticula. Type I autosomal recessive CL is associated with severe cardiorespiratory complications and early death from cor pulmonale. Type II is a less severe recessive form, characterized by growth retardation, developmental delay, and ligamentous laxity. X-linked CL is characterized by mild joint laxity, bladder diverticula, hernias, and cranial occipital exostoses or horns. Many cases of acquired CL have developed after a febrile illness and/or inflammatory skin diseases such as lupus erythematous, urticaria, eczema, erythema multiforme, vesicular eruption, amyloidosis, and angioedema, as well as reactions to penicillin and D-penicillamine.[154,169] CL may also be associated with amyloidosis and plasma cell dyscrasias.

CUTANEOUS FEATURES In all forms of CL, the skin gives the appearance of being too large for the rest of the body (see eFig. 139-10.1 in on-line edition). CL may affect any portion of the body, but it often causes attention when it is present with loose appearance around the face, neck, shoulders, and thighs. At birth, the skin may be noticeably soft, loose, and hyperextensible. It tends to sag in the areas where the skin is normally loose, for example, around the face and eyes (see Fig. 139-10). In contrast to the skin of EDS, it returns very slowly to its normal position after being stretched; skin fragility, easy bruisability, joint hypermobility, and poor wound healing are not usually associated with CL. The skin may be excessively wrinkled and appears prematurely aged. Children with severe CL may have characteristic facial features known as the "bloodhound" look—an aged appearance with sagging jowls (see Fig. 139-10).

Biopsy sections of clinically affected skin show a reduced number of elastic fibers in the dermis, with the remaining fibers being fragmented, shortened, clumped, or granular. Calcifications are not present. CL can also be an acquired condition and present diffusely or localized, giving individuals the characteristic "bloodhound-like" facies.[170] It is more common in adults, although children may also be affected. In more than one-half of cases, the disorder is preceded by a urticarial eruption, which may respond to dapsone, but progression will be unaffected.[171] Common associated findings include hiatal hernias, aortic aneurysm and rupture, intestinal and genitourinary diverticula, and emphysema. Some cases with cardiovascular or pulmonary involvement may be fatal.[172] Moreover, associated systemic conditions include multiple myeloma, lymphoma, sarcoidosis, amyloidosis, and α_1-antitrypsin deficiency.[154] Histology shows initial inflammation with concurrent loss of elastic fibers.

EXTRACUTANEOUS FEATURES The X-linked form of CL is known as *occipital horn syndrome* because of occipital exostoses. Characteristic facial features include inverted lower eyelids, a hooked nose, inverted nostrils, a short columella, and a long upper lip. The cry of an affected infant may be hoarse, and a low-pitched voice is often associated redundancy of the vocal cords. Diagnostic skeletal features of this condition can be identified radiologically and include short flat clavicles, fused carpal bones, and the occipital horns, which may not be present until a few years of age. This is the only form of CL with joint laxity.

The autosomal recessive forms of CL are often associated with severe internal complications, such as genitourinary and gastrointestinal diverticula. Chronic diarrhea is a widely reported complication, and secondary kidney damage may result from diverticula causing urinary tract obstruction. The most serious complications are diaphragmatic hernia and emphysema, which may lead to cor pulmonale and death in the first few years of life, especially in patients with *FBLN5* mutations. Rare cardiovascular features include aortic dilatation with secondary cardiomegaly and congestive heart failure. Rectal prolapse, diaphragmatic atony, pneumothorax, peripheral pulmonary stenosis, and aortic dilatation have also been reported. Facial features include down-slanting palpebral fissures, broad/flat nose, and large ears.

Several multisystemic disorders have features that have been called "cutis laxa," and must be considered in the differential diagnosis listed in Box 139-2.

Box 139-2

Differential Diagnosis of Cutis Laxa

SYNDROMES	FEATURES
DeBarsy syndrome[195]	Cutis laxa, mental retardation, cloudy corneas, athetoid posturing, dislocations, aged appearance
Lens-Majewski hyperostotic dwarfism (OMIM #151050)[196]	Skin hyperplasia, joint laxity, progeroid features, skeletal abnormalities, generalized osteosclerosis
SCARF syndrome (OMIM #312830)[197]	Skeletal abnormalities, cutis laxa, craniostenosis, ambiguous genitalia, retardation, facial abnormalities
Congenital hemolytic anemia and pulmonary emphysema (OMIM #235360)[198]	Hemolytic anemia, pulmonary emphysema, cutis laxa
Costello syndrome (faciocutaneoskeletal syndrome (OMIM #217040), mutations in the HRAS oncogene[199,200] (Fig. 139-11)	Wrinkly skin, redundant skin of palms, soles and fingers and neck. Deep palmar creases with mildly hyperkeratotic palms and soles. Postnatal growth retardation, early feeding difficulties, mental retardation, coarse facies, thick lips and ear lobes, macroglossia, aged appearance, hyperextensible fingers and papillomas not infrequent: acanthosis nigricans, sleep apnea, cardiac abnormalities, increased risk of tumors, especially rhabdomyosarcoma, neuroblastoma[199]
Wrinkly skin syndrome (may be a variant of cutis laxa with growth and developmental delay) (OMIM #219200) linked to 2q32[201]	Wrinkling of skin (hands, feet, abdomen), hyperextendibility of joints (hands), dysmorphism, failure to thrive, developmental delay

OMIM = Online Mendelian Inheritance in Man; SCARF = skeletal abnormalities, cutis laxa, craniostenosis, psychomotor.

Treatment

Surgical correction of redundant skin folds, rectal prolapse, or any hernias is temporarily beneficial and can be undertaken without major complication. Botulinum toxin has also been used to improve facial cosmesis.[173] There is no known medical treatment to prevent disease progression in the inherited

▲ **FIGURE 139-11** Costello syndrome. Note the coarse facial features, hypertrophic lower gingival, and papillomatosis of the right cheek, eyelids, and lips.

forms. Regular evaluation of internal organ involvement is important in prevention and management of major complications. Dapsone has been used to control the acute swelling of affected skin that precedes acquired CL, consistent with the suspected role of neutrophil elastase.[174]

OSTEOGENESIS IMPERFECTA

Epidemiology

The incidence of OI varies depending on type: I (1 in 20,000 to 30,000); II (1 in 60,000); III (1 in 70,000); IV (rare); V, VI, and VII (very rare).[175]

Etiology and Pathogenesis

Primary osteopenia and fractures are the hallmarks of OI.[176] Decreased bone mass is a consequence of mutations in either *COL1A1* or *COL1A2*, both of which encode the polypeptide chains forming the collagen type I molecule.[177–179] Type I collagen is the most abundant protein in skin and bone. It provides tensile strength and interacts with other matrix proteins. As a result, OI osteoblasts show abnormal expression of thrombospondin, proteoglycans, hyaluronan, decorin, and fibronectin.[180] The mineral phase is also affected, and bones from OI patients have higher average mineralization density than controls. Although the severe forms of OI were once assumed to be autosomal recessive, almost all cases of OI are now known to result from mutations in a single allele. Germline mosaicism has been shown to explain the lack of parental involvement in some cases of OI with affected siblings, and uniparental disomy has also been described. Glycine residues, which are normally present at every third position, are critical for triple helical conformation of type I collagen. Thus, point mutations in glycine have profound effects on molecular structure. Frameshift and null mutations lead to early termination and nonsense-mediated mRNA decay; as a result, only normal collagen is produced, but at a decreased rate, and a mild phenotype results.

OSTEOGENESIS IMPERFECTA AT A GLANCE

- Combined incidence of 1 in 12,000 people (Online Mendelian Inheritance in Man #166200 and #166240 type I; #166210 type II; #259420 type III; #166220 type IV; #166220 type V).
- Seven sub-types (ranging from mild, nondeforming (type I) to severe perinatal lethal (type II).
- Most commonly autosomal dominant inheritance.
- The gene encoding procollagen I is most often affected.
- Cutaneous features include hyperextensible skin and blue sclerae.
- Extracutaneous manifestations include increased fractures, dentinogenesis imperfecta, ligament laxity, triangular facies, short stature, hearing impairment, and wormian bones.
- Information for patients and professionals at http://www.oif.org.

Clinical Findings

The most notable finding in OI patients is the development of multiple fractures throughout life.[181] Whereas type I tends to be mild, type II tends to be lethal in the perinatal period, with fractures in utero. Type III individuals survive birth but have severely deforming fractures, with a short triangular face and severe scoliosis. Types IV to VII are moderately deforming and rare.[180] Individuals with OI type I (relatively milder type) have very blue sclerae (Fig. 139-12) that stays

▲ **FIGURE 139-12** Osteogenesis imperfecta (OI). Blue sclerae are the most characteristic mucocutaneous feature of patients with mild OI.

intensely blue throughout life, in contrast to the sclerae in OI type III and OI type IV, which may also be blue at birth and during infancy, but tends to fade by later childhood or adolescence. Other abnormalities include limb deformities, dentinogenesis imperfecta, short stature, triangular face, scoliosis, and hearing loss (> 50 percent of individuals).[182,183] Just as in the bone, the cutaneous findings in the skin of OI patients reflect the decreased type I collagen,[184,185] and cultured skin fibroblasts from affected individuals show decreased or abnormal type I procollagen molecules, a finding often used as a diagnostic tool. The skin is stiffer and less elastic than normal, as documented using the suction cup technique.[186] Histologic analysis shows a relative increase of argyrophil and elastic fibers when compared to collagen.

Treatment

Therapy for OI involves a multi-disciplinary approach. Orthopedic surgeons, physical therapists, and rehabilitation personnel are the primary providers of care. Careful mobility is encouraged, and surgical repairs and support are frequently employed, giving patients a more active lifestyle.[187] More recently, remarkable success has been attributed to the use of potent antiresorptive bisphosphonates. Intravenous and oral administration of these agents has been shown to decrease bone pain, increase muscle strength, enhance well-being, and increase bone mineral density. However, these preliminary results are currently being further investigated in randomized clinical trials.[188] Transplantation of adult mesenchymal stem cells is currently under investigation as a means to correct bone fragility, and HLA-mismatched mesenchymal stem cells have led to

clinical improvement when transplanted into an affected fetus at 32 weeks gestational age.[189]

CHAPTER 140

Hereditary Disorders of Genome Instability and DNA Repair

Thomas M. Rünger
John J. DiGiovanna
Kenneth H. Kraemer

Because the genome is the basic control for cellular function, maintaining genome stability is important for the continued function of cells, tissues, and organisms. DNA is the carrier of genetic information. Its structure is regularly threatened by damaging agents that include oxidative stress, ultraviolet (UV) and x-radiation, and chemical agents. Although much damage is repaired, failure to maintain genomic integrity may lead to abnormal cell function or cell death. If the cell divides, progeny may accumulate additional damage and this progressive accumulation of damage can lead to malignancy (see Chap. 109).

This chapter describes the relevant skin disorders with genome instability and the underlying defective mechanisms of DNA repair or DNA maintenance (Table 140-1). All of these exhibit prominent cutaneous abnormalities that involve dermatologists in their diagnosis and management. Most, but not all, are also characterized by an increased risk of malignancies. This demonstrates that the maintenance of genome integrity is of utmost importance for the prevention of malignant transformation. As malignant transformation requires the accumulation of several mutations in specific genes of a single cell, a mutator phenotype is often regarded a prerequisite for carcinogenesis, because without genome instability it would be exceedingly unlikely that all of those mutations occur in a single cell.[1–4] The same genes that are affected in the hereditary genome instability disorders can also confer genome instability to individual cells when impaired through acquired mutations, thereby playing an important role early in spontaneous carcinogenesis.

In addition, although these heritable diseases are rare (on the order of 10^{-5} or 10^{-6}), carriers of the affected genes may comprise several percent of the general population. These individuals are usually free of clinical symptoms, as most of these disorders are characterized by autosomal recessive inheritance. However, epidemiologic studies suggest that heterozygote carriers may have an increased risk of neoplasia as well.

Spontaneous genome instability is present in Bloom syndrome (BS), ataxia telangiectasia, and Fanconi anemia (FA) as manifested by increased chromosome breakage in primary blood or skin cells. On the other hand, genome instability is present in cells from patients with xeroderma pigmentosum (XP) only after exposure to DNA-damaging agents such as UV radiation or other carcinogens such as benzo[*a*]pyrene, which is present in cigarette smoke. In XP, many of the severe disease manifestations such as cancer and corneal scarring leading to blindness are the result of the interplay between genetic risk and environmental exposure. For example, XP patients who avoid UV radiation dramatically reduce or eliminate the probability of developing skin cancer and blindness.

HEREDITARY DISORDERS OF GENOME INSTABILITY AND DNA REPAIR AT A GLANCE

- Genome instability characterizes a large group of inherited disorders with prominent cutaneous abnormalities; many have an increased cancer risk.
- Genome instability is caused by impaired repair and/or maintenance of DNA.
- Xeroderma pigmentosum is a prototype with impaired repair of environmentally induced DNA damage and a greatly increased frequency of sunlight-induced cancers.
- Although these disorders are rare, heterozygote carriers of affected genes, which may comprise several percent of the general population, may carry an increased cancer risk as well.

In some of the disorders discussed here, genome instability is caused by an impaired ability to repair damage to DNA introduced by certain physical or chemical agents. Cells are equipped with different DNA repair pathways

TABLE 140-1
Hereditary Disorders of Genome Instability and DNA Repair

	Clinical Features				Mechanisms		
Disorder	Cutaneous	Neoplasia	Other	Inheritance	Cellular Abnormalities	Affected Gene(s)	Impaired Function
Disorders of genome instability with defective DNA repair							
XP	Photosensitivity, poikiloderma (hyper- and hypo-pigmentation, atrophy, telangiectasia), skin cancers	BCC, SCC, melanoma, central nervous system tumors	Sensorineural deafness, progressive neurologic degeneration, primary loss of neurons (some patients)	Autosomal recessive	Increased UV-induced cell killing and mutagenesis	*XPA, XPB, XPC, XPD, XPE, XPF, XPG*, or DNA polymerase eta	Nucleotide excision repair: global genome and transcription-coupled DNA repair; translesional DNA synthesis (XP-variant)
Cockayne syndrome (CS)	Photosensitivity	No increased incidence	Typical facial features (deep-set eyes, loss of subcutaneous fat), pigmentary retinal degeneration, postnatal growth failure, sensorineural deafness, progressive neurologic degeneration, primary dysmyelination, brain calcifications	Autosomal recessive		*CSA* or *CSB*	Nucleotide excision repair: transcription-coupled DNA repair only
XP-CS	Same as XP	BCC, SCC	Neurologic changes of CS	Autosomal recessive	Same as XP	*XPB, XPD,* or *XPG*	Nucleotide excision repair: global genome and transcription-coupled DNA repair
TTD	Brittle hair, photosensitivity, ichthyosis, collodion membrane	No increased incidence	Congenital cataracts, developmental delay, primary dysmyelination, recurrent infections	Autosomal recessive	Increased UV-induced cell killing	*XPB, XPD, TTD-A,* or *TTDN1*	Nucleotide excision repair: transcription-coupled pathway of nucleotide excision repair
HNPCC/MTS	Sebaceous tumors (benign and malignant), keratoacanthomas	Low-grade cancers of the colon, endometrium, stomach, small intestine, hepatobiliary system, upper urethral tract, larynx and ovary; sebaceous carcinoma, BCC with sebaceous differentiation	—	Autosomal dominant	High level of microsatellite instability in tumors	*hMSH2* (MTS, HNPCC1), *hMLH1* (MTS, HNPCC2), *PMS1* (HNPCC3), *hPMS2* (HNPCC4), *hMSH6* (HNPCC5), *TGFBR2* (HNPCC6), or *hMLH3* (HNPCC7)	Mismatch repair
Other Disorders of Genome Instability							
Bloom syndrome	Photosensitivity, malar erythema, café-au-lait macules	Most cancer types; in particular leukemias, lymphomas, carcinomas of the breast and gastrointestinal tract	Immune deficiency, growth retardation, unusual facies, male infertility and female subfertility, type 2 diabetes	Autosomal recessive	Spontaneous chromosome breakage and rearrangements, increased sister chromatid exchanges, quadriradial chromosomes	*BLM*	A RecQ DNA helicase, recombination, replication

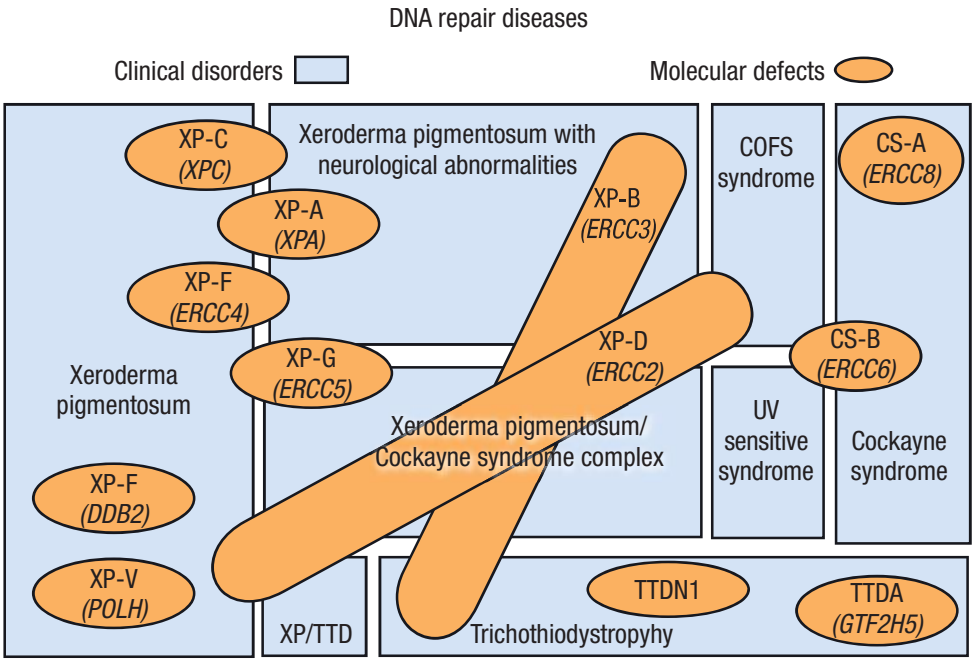
Werner syndrome	Graying of hair, skin atrophy, leg ulcers, melanomas	Sarcomas, thyroid cancers, meningiomas, melanomas (acral lentiginous, and mucous membrane melanomas)	Premature aging (atherosclerosis, diabetes mellitus, osteoporosis, cataracts)	Autosomal recessive	Chromosomal instability, accelerated telomere shortening	*WRN*	A RecQ DNA helicase, transcription, DNA repair (DSBR, SSBR, recombination), DNA replication, telomere maintenance
Rothmund-Thomson syndrome	Photosensitivity, poikiloderma, alopecia	Osteosarcomas, cutaneous SCC, and others	Skeletal abnormalities, growth deficiency, juvenile cataracts, osteoporosis	Autosomal recessive	Chromosomal instability in response to ionizing radiation	RECQL4 (some patients)	A RecQ DNA helicase
Fanconi anemia	Café-au-lait macules	Myeloid leukemias, SCC of head and neck	Aplastic anemia, pancytopenia, growth retardation, thumb and other bone abnormalities	Autosomal recessive	Increased sensitivity to DNA cross-linking agents	*FANCA, FANCB, FANCC, FANCD1/BRCA2, FANCD2, FANCE, FANCF, FANCG, FANCI, FANCJ, FANCL*	DNA damage signaling, recombination repair
AT	Telangiectasias	T-cell leukemias, lymphomas	Progressive cerebellar ataxia, immune defects, hypogonadism, increased acute toxicity of therapeutic x-ray	Autosomal recessive	Increased spontaneous and x-ray–induced chromosome breakage, increased sensitivity to killing by ionizing radiation, impaired cell cycle arrest and/or apoptosis in response to DNA damage	*ATM*	DNA damage signaling (control of cell cycle, apoptosis), repair of DNA double strand breaks
AT-like disorder	Similar to AT	Similar to AT	Similar to AT, but no ocular telangiectasias	Autosomal recessive	Increased spontaneous and x-ray–induced chromosome breakage, increased sensitivity to killing by ionizing radiation, impaired DNA strand break repair	*LIG4*	DNA ligase 4, strand break repair
Nijmegen breakage syndrome	Café-au-lait macule, vitiligo	B- and T-cell lymphomas, rhabdomyosarcoma, neuroblastoma	Immune defects, growth retardation, microcephaly, mental retardation, characteristic facies	Autosomal recessive	Increased spontaneous and x-ray–induced chromosome breakage, increased sensitivity to killing by ionizing radiation	*NBS1*	Nibrin (p95), which is part of the MRE11-RAD50-NBS1 complex, DNA damage signaling, recombination, DNA double-strand break repair, cell cycle checkpoint

(continued)

TABLE 140-1
Hereditary Disorders of Genome Instability and DNA Repair (Continued)

	Clinical Features				Mechanisms		
Disorder	**Cutaneous**	**Neoplasia**	**Other**	**Inheritance**	**Cellular Abnormalities**	**Affected Gene(s)**	**Impaired Function**
Seckel syndrome	Café-au lait macules	Leukemia	Proportionate dwarfism, microcephaly, mental retardation, characteristic facies (receding forehead, narrow face, large beaked nose, micrognathia), immune deficiency, pancytopenia	Autosomal recessive	Spontaneous and mitomycin C–induced chromosome instability, sensitivity to killing by UV and DNA cross-linking agents	*ATR*	Ataxia telangiectasia– and RAD3-related protein, DNA damage response, cell cycle checkpoints
Dyskeratosis congenita	Poikiloderma, nail dystrophy, skin cancer	Mucosal leukoplakia leading to cancer of anus or mouth, Hodgkin disease, pancreatic adenocarcinoma	Stenosis of lacrimal duct, anemia, pancytopenia, learning difficulties, deafness, brain calcifications, testicular atrophy, growth retardation	X-linked recessive, autosomal dominant	Increased frequency of chromatid breaks after x-radiation during G_2 phase of cell cycle	*DKC1* X-linked; *TERC* autosomal dominant form	Dyskeratin, involved in cell cycle and nucleolar function, impaired internal ribosome entry site–dependent translation; TERC (associated with telomerase RNA)

AT = ataxia telangiectasia; BCC = basal cell carcinoma; CS = Cockayne syndrome; HNPCC = hereditary non-polyposis colon cancer; MTS = Muir-Torre syndrome; SCC = squamous cell carcinoma; TTD = trichothiodystrophy; UV = ultraviolet; XP = xeroderma pigmentosum.



▲ **FIGURE 140-1** Relationship of clinical disorders and molecular defects in DNA repair diseases. Eight clinical phenotypes of DNA repair diseases have been recognized (*blue rectangles*). Defects in 12 genes have been associated with these clinical phenotypes (*orange ovals*). Mutations in different DNA repair genes can be associated with the same clinical phenotype. On the other hand, different mutations in one DNA repair gene can be associated with different clinical phenotypes. For example, mutations in the XPD (ERCC2) gene have been associated with xeroderma pigmentosum (XP), with XP with neurologic abnormalities, with the XP-Cockayne syndrome complex, with trichothiodystrophy, with XP-trichothiodystrophy, or with COFS (cerebro-oculo-facio-skeletal syndrome). The official names of the genes are in parentheses, whereas the names of the corresponding complementation groups are in caps.

(reviewed in Chap. 109) that repair different types of DNA damage. The nucleotide excision repair (NER) pathway, which processes bulky DNA lesions, including UV-induced DNA photoproducts, is impaired in XP, Cockayne syndrome (CS), and trichothiodystrophy (TTD). Cells from patients with these conditions are characterized by increased killing and mutation formation following exposure to UV light. However, only XP patients have increased cancer risk. The reason for this difference in cancer risk is not known.

Proteins encoded by some of the affected genes in these three disorders are not only involved in DNA repair, but also in transcription and cellular DNA damage responses. Thus, mutations affecting different functions of the same gene appear to play a role in various phenotypes that are not directly linked to DNA repair functions and underlie several overlap syndromes between those three conditions (Fig. 140-1).

XP variant, which is clinically indistinguishable from XP, is a disorder of DNA damage tolerance. Although normal cells can bypass DNA damage during replication (translesional DNA synthesis), cells from XP-variant patients have a defect in this process. The DNA mismatch repair pathway (see Chap. 109) is affected in hereditary nonpolyposis colon cancer (Lynch syndrome) and its subform, Muir-Torre syndrome which has cutaneous features including sebaceous gland tumors. Those are reviewed in Chap. 154.

Helicases are proteins that unwind DNA and are required for a multitude of metabolic processes involving DNA, such as transcription, replication, repair, and more. Two genes involved in NER are helicases that are also part of the basal transcription factor, TFIIH. The XPB (ERCC3) gene product unwinds DNA in the 3′ to 5′ direction whereas the XPD (ERCC2) gene product unwinds DNA in the opposite direction. The RecQ family of DNA helicases is highly conserved in evolution from bacteria to humans.[8,9] Of the five known human RecQ family members, three [BLM, WRN, and RECQL4, which cause BS, Werner syndrome (WS), and Rothmund-Thomson syndrome (RTS) respectively] are mutated in distinct clinical disorders associated with chromosomal instability, cancer predisposition, and/or premature aging.[10]

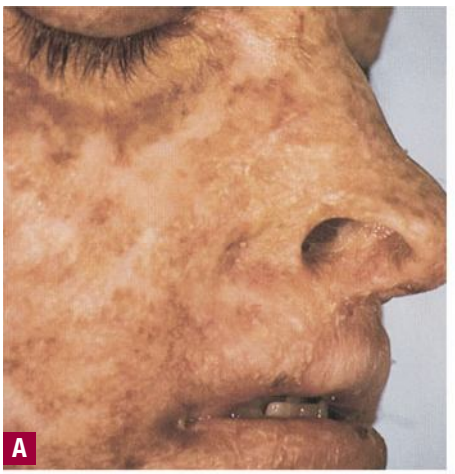
BASC (*B*RCA1-*a*ssociated genome *s*urveillance *c*omplex) is a multi-enzyme complex centered around the BRCA1 protein in the nucleus.[11] It contains important DNA damage response proteins including ATM, ATR, the MRE11-RAD50-NBS1 complex, BRCA1, BLM, FANCD2, and MLH1. These proteins physically interact with each other. Genome instability may result from a defect in any of those and cause the genome instability disorders ataxia telangiectasia (reviewed in Chap. 144), Seckel syndrome, Nijmegen breakage syndrome, hereditary breast cancer, BS, FA, or hereditary colon cancer. BS and FA are reviewed here.

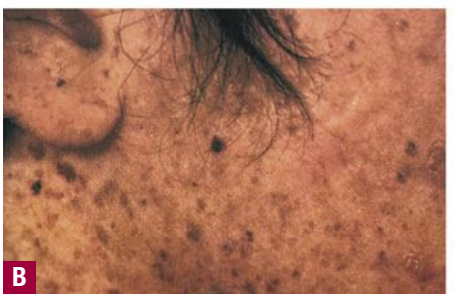
DISORDERS OF DNA REPAIR

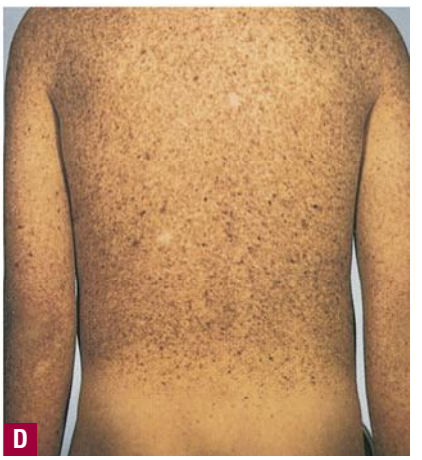
Xeroderma Pigmentosum

XP serves as the prototype heritable disease with increased sensitivity to cellular injury.[11–13] XP is an autosomal recessive disease with sun sensitivity, photophobia, early onset of freckling, and subsequent neoplastic changes on sun-exposed surfaces. There is cellular hypersensitivity to UV radiation and to certain chemicals in association with abnormal DNA repair. Some of the patients have progressive neurologic degeneration.

FREQUENCY XP occurs with an estimated frequency of 1 in 1 million persons in the United States[12] and 1 per 100,000 thousand people in Japan.[15] It is relatively more common in areas such as the Middle East where marriage of close relatives is practiced. Patients have been reported worldwide in all races, including whites, Asians, blacks, and Native Americans.







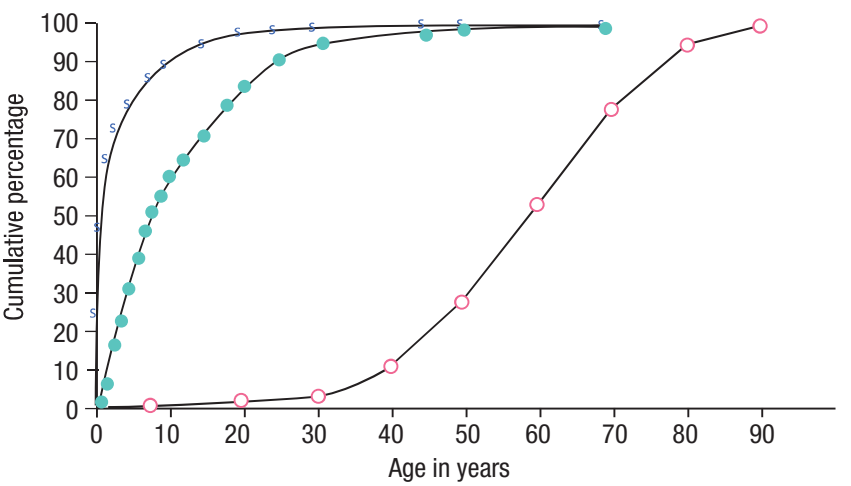
▲ **FIGURE 140-2** Xeroderma pigmentosum. **A.** Pigmentary changes, atrophy, dryness, and cheilitis in a 16-year-old patient. **B.** Cheek of a 14-year-old patient with pigmented macules of varying size and intensity, actinic keratosis, basal cell carcinoma, and a surgical scar. **C.** Corneal clouding, prominent conjunctival blood vasculature, and loss of lashes. **D.** Myriads of pigmented macules of varying size and intensity and scattered achromic areas on the back, with marked sparing of sun-protected buttocks of a 14-year-old patient.

CLINICAL FEATURES ***Skin.*** Approximately one-half the patients with XP have a history of acute sunburn reaction on minimal UV exposure. The other patients tan normally without excessive burning. In all patients, numerous freckle-like hyperpigmented macules appear predominately on sun-exposed skin (Fig. 140-2). The median age of onset of the cutaneous symptoms in XP is between 1 and 2 years (Fig. 140-3).[13] These generally spare sun-protected sites such as the buttocks (see Fig. 140-2D). However, some severely sun-exposed patients may show pigmentary abnormalities in the axillae. Continued sun exposure causes the patient's skin to become dry and parchment-like, with increased pigmentation, hence the name *xeroderma pigmentosum* ("dry pigmented skin"; see Fig. 140-2A). Pre-malignant actinic keratoses develop at an early age (see Fig. 140-2B). The appearance of sun-exposed skin in children with XP is similar to that occurring in farmers and sailors after many years of extreme sun exposure.

Cancer. Patients with XP younger than 20 years of age have a greater than 1000-fold increased risk of cutaneous basal cell carcinoma, squamous cell carcinoma, or melanoma.[11,12,15] The median age of onset of non-melanoma skin cancer reported in patients with XP is 8 years. This 50-year reduction in comparison with the general population is an indication of the importance of DNA repair in protection from skin cancer in unaffected individuals (see Fig. 140-3). Multiple primary cutaneous neoplasms, including melanomas, occur commonly in XP patients.

Review of the world's literature on XP has revealed a substantial number of cases of oral cavity neoplasms, particularly squamous cell carcinoma of the tip of the tongue, a presumed sun-exposed location. Brain (sarcoma and medulloblastoma), central nervous system (astrocytoma of the spinal cord), lung, uterine, breast, pancreatic, gastric, renal, and testicular tumors and leukemia have been reported in a few patients with XP.[11,12,15,16] Overall, these reports suggest an approximate 10- to 20-fold increase in internal neoplasms in XP.

Eyes. Ocular abnormalities are almost as common as the cutaneous abnormalities and are an important feature of XP (see Fig. 140-2C).[13,16] The posterior portion of the eye (retina) is shielded from UV radiation by the anterior portion (lids, cornea, and conjunctiva). Clinical findings are strikingly limited to these anterior, UV-exposed structures. Photophobia is often



▲ **FIGURE 140-3** Xeroderma pigmentosum. Age at onset of clinical symptoms and skin cancers. Age at onset of cutaneous symptoms (generally sun sensitivity or pigmentation) was reported for 430 patients. Age at first skin cancer was reported for 186 patients and is compared with the age distribution for 29,757 patients with basal cell carcinoma or squamous cell carcinoma in the U.S. general population. There is a 50-year reduction in age of onset of skin cancer in the XP patients compared with the U.S. general population. (From Kraemer KH, Lee MM, Scotto J: Xeroderma pigmentosum. Cutaneous, ocular, and neurologic abnormalities in 830 published cases. *Arch Dermatol* **123**:241, 1987, with permission.)

present and may be associated with prominent conjunctival injection. Schirmer's testing frequently reveals reduced tearing leading to dry eyes. Continued UV exposure of the eye may result in severe keratitis, leading to corneal opacification and vascularization. The lids develop increased pigmentation and loss of lashes. Atrophy of the skin of the lids results in ectropion, entropion, or, in severe cases, complete loss of the lids. Benign conjunctival inflammatory masses or papillomas of the lids may be present. Epithelioma, squamous cell carcinoma, and melanoma of UV-exposed portions of the eye are common. The ocular manifestations may be more severe in black patients.[19]

Neurologic System. Neurologic abnormalities have been reported in approximately 30 percent of the patients.[12,15,18] The onset may be early in infancy or, in some patients, delayed until the second decade. The neurologic abnormalities may be mild (e.g., isolated hyporeflexia) or severe, with progressive mental retardation, sensorineural deafness (beginning with high-frequency hearing loss), spasticity, or seizures. The most severe form, known as the *De Sanctis-Cacchione syndrome,* involves the cutaneous and ocular manifestations of classic XP plus additional neurologic and somatic abnormalities, including microcephaly, progressive mental deterioration, low intelligence, hyporeflexia or areflexia, choreoathetosis, ataxia, spasticity, Achilles tendon shortening leading to eventual quadriparesis, dwarfism, and immature sexual development. The complete De Sanctis-Cacchione syndrome has been recognized in very few patients; however, many patients with XP have one or more of its neurologic features. In clinical practice, deep tendon reflex testing and routine audiometry usually can serve as a screen for the presence of XP-associated neurologic abnormalities. In cases where there is clinical evidence of early neurologic abnormalities, a brain magnetic resonance imaging (MRI) may show enlarged ventricles.

The predominant neuropathologic abnormality found at autopsy in patients with neurologic symptoms was loss (or absence) of neurons, particularly in the cerebrum and cerebellum. There is evidence for a primary axonal degeneration in these patients.[19]

LABORATORY ABNORMALITIES ***Cellular Hypersensitivity.*** Cultured cells from patients with XP generally grow normally when not exposed to damaging agents. The population growth rate or single-cell colony-forming ability is reduced to a greater extent than normal, however, after exposure to UV radiation. A range of post-UV colony-forming abilities has been found with fibroblasts from patients, some having extremely low post-UV colony-forming ability and others having nearly normal survival (see Chap. 109).[11,13]

XP fibroblasts are deficient in their ability to repair some UV-damaged viruses or plasmids to a functionally active state.[11,13,19] These host cell reactivation assays have detected an abnormality in every form of XP tested.

UV-irradiated XP fibroblasts are hypermutable compared to normal fibroblasts. This post-UV hypermutability is believed to be the basis of the increased frequency of sunlight-induced somatic mutations that lead to cancer in XP patients.[21]

Chromosome Abnormalities. XP cells generally are found to have a normal karyotype without excessive chromosome breakage or increased sister chromatid exchanges (as seen in Bloom syndrome). After exposure to UV radiation, however, abnormally large increases in chromosome breakage and in sister chromatid exchanges have been observed.[22] The extent of this induced abnormality varies in different patients.

DNA Repair. In 1968, hypersensitivity of cultured XP cells to UV damage was reported by Cleaver[23] to be the result of defective DNA repair. He found defective UV-induced repair replication, indicating a defect in the NER pathway. Most XP cells have a normal response to treatment with x-rays, indicating the specificity of the DNA repair defect. The defective genes for the seven NER-defective forms of XP and the XP variant have been cloned[24] and their functions are being investigated (see Chap. 109).

Complementation Groups. Genetic heterogeneity among the XP DNA repair defects was found by fusing cultured fibroblasts from different patients and defining complementation groups (see Chap. 109). Up to 2006, seven such DNA excision repair–deficient complementation groups have been identified (named *XP-A* to *XP-G*) and the corresponding genes have been identified (see Fig. 140-1).[24] Additional patients with clinical XP but normal NER have been called *XP variants*. Studies of cellular hypersensitivity revealed a slightly increased sensitivity to UV-induced inhibition of cell growth that was potentiated by caffeine. Cells from XP-variant patients have a defect in an error-prone DNA polymerase (pol eta) that bypasses unrepaired DNA damage.[25,26]

Prenatal Diagnosis. Prenatal diagnosis has been reported by measuring UV-induced unscheduled DNA synthesis in cultured amniotic fluid cells[27] and by use of DNA diagnosis of trophoblast cells obtained early in pregnancy.[28]

Drug and Chemical Hypersensitivity. A number of DNA-damaging agents other than UV radiation have been found to yield hypersensitive responses with XP cells. These agents include drugs (psoralens, chlorpromazine), cancer chemotherapeutic agents (cisplatin,[29] carmustine), and chemical carcinogens (benzo[*a*]pyrene derivatives). Presumably, these agents induce DNA damage whose repair involves portions of the DNA repair pathways that are defective in XP.[29]

TREATMENT Management of patients with XP is based on early diagnosis, lifelong protection from UV radiation exposure, and early detection and treatment of neoplasms. Diagnosis rests on recognition of the characteristic clinical features and is confirmed by laboratory tests of cellular hypersensitivity to UV and defective DNA repair (see Chap. 109). Molecular determination of disease-causing mutations may soon move from only being performed in research laboratories to being certified for clinical testing.

Sun Protection. Patients should be educated to protect all body surfaces from UV radiation by wearing protective clothing and UV-absorbing glasses and long hair styles. They should adopt a lifestyle to minimize UV exposure and use sunscreens with high sun protective factor (SPF) ratings (minimum SPF 15) daily. Patients should be examined frequently by a family member who has been instructed in recognition of cutaneous neoplasms. A set of color photographs of the entire skin surface with close-ups of lesions (including a ruler) is often extremely useful to both the patient and the physician in detecting new lesions. A physician should examine patients at frequent intervals (approximately every 3 to 6 months depending on severity of skin disease). Pre-malignant lesions such as actinic keratoses may be treated by freezing with liquid nitrogen, or with topical 5-fluorouracil or imiquimod. Photodynamic therapy, using, for example,

the topical photosensitizer 5-aminolevulinic acid followed by exposure to blue light, is an effective treatment modality for normal patients with multiple actinic keratoses. There are no data on the safety or efficacy of this treatment in XP patients. *Caution is recommended because an abnormal response to photodynamic therapy or other light- or laser-based therapies cannot be excluded in XP cells.* Larger areas have been treated with therapeutic dermatome shaving or dermabrasion to remove the more damaged superficial epidermal layers.[30–33] This procedure permits repopulation by relatively UV-shielded cells from the follicles and glands.

Because cells from patients with XP are also hypersensitive to environmental mutagens such as benzo[*a*]pyrene found in cigarette smoke, prudence dictates that patients should be protected against these agents. One of our patients who smoked cigarettes for more than 10 years died of bronchogenic carcinoma of the lungs at age 35 years and another patient who smoked has developed a lung cancer at age 48 years.[34] Thus, we recommend that XP patients refrain from smoking cigarettes and that parents should protect children with XP from being exposed to second-hand smoke.

Cancers. Cutaneous neoplasms are treated in the same manner as in patients who do not have XP. This involves electrodesiccation and curettage, surgical excision, or Mohs micrographic surgery (see Chaps. 113 and 114). Because multiple surgical procedures are often necessary, removal of undamaged skin should be minimized. Extremely severe cases have been treated by excision of large portions of the facial surface and grafting with uninvolved skin.[31]

Most patients with XP are not abnormally sensitive to therapeutic x-rays, and XP patients have responded normally to full doses of therapeutic x-radiation for treatment of inoperable neoplasms such as an astrocytoma of the spinal cord,[17] a frontal lobe astrocytoma, or recurrent squamous cell carcinoma in the orbit. However, cultured cells from two XP patients were found to be hypersensitive to x-rays,[35,36] so when x-ray therapy is indicated, an initial small dose is advisable to test for clinical hypersensitivity.

Oral isotretinoin has been shown in a controlled study to be effective in preventing new neoplasms in patients with multiple skin cancers.[37] Because of its toxicity (hepatic, hyperlipidemic, teratogenic, calcification of ligaments and tendons, premature closure of the epiphyses), oral isotretinoin should be reserved for patients with XP who are actively developing large numbers of new skin cancers. We found that the effective dose varies among patients and some patients may respond to doses of oral isotretinoin as low as 0.5 mg/kg/day.

A bacterial DNA repair enzyme, den V T4 endonuclease, in a topical liposome-containing preparation, has been reported to reduce the frequency of new actinic keratoses and basal cell carcinomas in XP patients in one research study.[38] As of 2007, this treatment has not yet been approved by the U.S. Food and Drug Administration.

A study treating multiple melanoma in situ lesions with intralesional interferon-α in one XP patient showed localized clearing only of lesions injected with the intralesional interferon-α but not with the control diluent.[39] There are several case reports of XP patients responding to topical treatment with the immune modulator imiquimod (see Chap. 221).[40–43] However, none of these reports long-term follow-up.

Eyes. The eyes should be protected by wearing UV-absorbing glasses with side shields. Methyl cellulose eyedrops can be used to keep the cornea moist. Corneal transplantation has restored vision in patients with corneal opacity from severe keratitis. However, some of these suffered graft rejection due to neovascularization. Neoplasms of the lids, conjunctiva, and cornea are usually treated surgically.[44–46] We are examining the possibility of using a swab to obtain cytologic specimens from the surface of the eye to determine if early neoplasms can be detected or excluded without the need for performing biopsies.

CLINICAL-LABORATORY CORRELATIONS Patients with XP are hypersensitive to UV radiation, as are their cultured cells. Cutaneous and ocular abnormalities are strikingly limited to UV-exposed areas and usually spare such UV-shielded locations as the axillae, buttocks, and retina. The fact that black patients with XP have an increased frequency of skin cancer indicates that a normally functioning DNA repair system provides greater protection against skin cancer than does the natural pigmentation of black skin.

Complementation Groups. At least eight different molecular defects are associated with the clinical abnormalities recognized as XP, as indicated by the existence of seven DNA excision repair–deficient complementation groups (A to G) and the variant form. A discussion of the cloned XP genes and their function can be found in Chapter 109. There is a complex relationship among the DNA repair genes and clinical disease (see Fig. 140-1). Eleven NER genes are associated with at least seven different clinical phenotypes. A clinical phenotype can be associated with defects in each of several genes. Conversely, mutations in one gene can be associated with several different clinical phenotypes. These complex relationships and the roles of DNA repair genes in regulation of transcription and in immune functions are under intense investigation.

COMPLEMENTATION GROUP A. Complementation group A (see Fig. 140-2) contains patients with the most severe neurologic and somatic abnormalities (the De Sanctis-Cacchione syndrome) as well as patients with minimal or no neurologic abnormalities.[12] Long-term follow-up of these patients has revealed a relationship between the genotype and the phenotype. Patients with the most severe disease appear to have truncating mutations in both alleles of the XPA gene leading to no detectible normal protein. In contrast, patients with minimal neurologic abnormalities have splice-site mutations that permit a small amount of normal messenger RNA (mRNA) to be made. This form is seen in the United States, Europe, and the Middle East. It is the most common form of XP in Japan. Approximately 90 percent of Japanese XP-A patients have the same single-base-substitution founder mutation.[47] This finding has served as the basis for development of a rapid diagnostic assay for Japanese XP-A patients (including prenatal diagnosis) using polymerase chain reaction analysis of a small sample of DNA.[33] Heterozygous carriers of this disease-causing mutation who have one mutated allele and one normal allele have been estimated to comprise approximately 1 percent of the Japanese population.[15]

COMPLEMENTATION GROUP B. Complementation group B (Fig. 140-4) is composed of five patients in four kindreds who had the cutaneous abnormalities characteristic of XP (including neoplasms) in conjunction with neurologic and ocular abnormalities typical of CS.[12,48] Another family had two adult sisters with XP without CS who had ocular melanomas and were parents of normal children. Surprisingly, a patient with TTD also was found to have a defect in the *XPB* gene.

▲ **FIGURE 140-4** Xeroderma pigmentosum XP/CS complex. **A.** 28-year-old patient (XP11BE) in XP complementation group B with cutaneous changes of xeroderma pigmentosum, including pigmentary changes and atrophy. She has a beak-like nose and loss of subcutaneous tissue typical of Cockayne syndrome. **B.** The patient is of short stature (less than 4 ft. tall). Her mother, an obligate heterozygote, is clinically normal.

COMPLEMENTATION GROUP C. Patients in complementation group C (see Fig. 140-2), with rare exceptions, have XP with skin and ocular involvement but without neurologic abnormalities.[12,49–54] This is the most common group in the United States, Europe, and Egypt, but has been found rarely in Japan. Most patients have truncating mutations in both alleles leading to undetectable levels of *XPC* mRNA (due to nonsense-mediated message decay). However, a splice lariat branchpoint mutation resulting in as little as 3 percent to 5 percent of normal mRNA resulted in milder clinical symptoms in one family in Turkey.[52] XP-C patients typically do not give a history of severe burning on minimal sun exposure and at times are first diagnosed with the appearance of skin cancer in a child. One XP-C patient was reported to be hypersensitive to ionizing radiation;[36] however, correction of the *XPC* gene defect did not correct the cellular ionizing radiation hypersensitivity, suggesting that more than one gene was defective in this patient.

COMPLEMENTATION GROUP D. Patients in complementation group D have been described with six different clinical phenotypes (see Fig. 140-1). They may have cutaneous XP with late onset of neurologic abnormalities in their second decade of life or XP with no neurologic abnormalities.[12,55] Two XP-D patients have been reported with clinical symptoms of both XP and CS. Cells from patients with a photosensitive form of TTD (without XP) also were assigned to the XP complementation group D. Two patients were reported with combined symptoms of both TTD and XP (one patient had a skin cancer) and mutations in the *XPD* gene.[56] Finally, a patient with cerebro-oculo-facio-skeletal (COFS) syndrome had a mutation in the *XPD* gene.[57]

COMPLEMENTATION GROUP E. Complementation group E was found in one kindred in Europe and several in Japan (see Fig. 140-1).[12,58] These patients had relatively mild cutaneous abnormalities without neurologic involvement.

COMPLEMENTATION GROUP F. Complementation group F patients have been found mainly in Japan.[59,60] Most of these patients have mild clinical symptoms without neurologic abnormalities or skin cancer. However, we recently found two families with adult onset of severe neurodegeneration with mutations in the XPF gene. The residual rate of DNA repair, however, is very low (only 10 percent to 20 percent of normal).

COMPLEMENTATION GROUP G. Thirteen patients in XP complementation group G have been identified in the United States, Europe, and Japan (Fig. 140-5).[61] There is a large variation in clinical features among these patients. Several patients with mutations in the *XPG* gene had clinical features of both XP and severe CS with cachexia and death in the first decade (see Fig. 140-4). Other patients with different mutations in the same gene had no neurologic abnormalities.

XERODERMA PIGMENTOSUM VARIANT. XP-variant cells have normal DNA NER and thus do not fall into any of the complementation groups of cells with defective DNA excision repair (see Fig. 140-2).[13] There is, however, a defect in an error-prone, translesional DNA damage bypass polymerase, pol eta (see Chap. 109).[23,24,62] Most XP-variant patients have clinical XP with no neurologic abnormalities. The cutaneous and ocular abnormalities have been severe in some patients and mild in others.

Heterozygotes. XP heterozygotes (parents and some other relatives) are carriers of the gene for XP but are clinically normal. There is limited epidemiologic evidence to indicate that such persons have an increased risk of developing skin cancer.[7] Most tests of cell function or DNA repair yield normal responses with cells from XP heterozygotes.

PATIENT SUPPORT GROUPS The Xeroderma Pigmentosum Society is an educational, advocacy, and support organization for XP patients and their families: Xeroderma Pigmentosum Society, Inc., Box 4759, Poughkeepsie, NY 12602-4759; website: http://www.xps.org; e-mail: xps@xps.org; telephone: toll-free (877) XPS-CURE (877-977-2873). Another support group is the XP Family Support Group, 8375 Folsom Blvd Suite 201, Sacramento Ca, 95826. Their website is http://www.xpfamilysupport.org/.

A website listing disease-causing mutations in XP and CS genes has been established at http://xpmutations.org/.

Cockayne Syndrome (Including Xeroderma Pigmentosum–Cockayne Syndrome Overlap)

CS is a very rare, autosomal recessive degenerative disease with cutaneous,

▲ **FIGURE 140-5** Severe and mild xeroderma pigmentosum XP-G patients. **A,B.** XP82DC. **C–F.** XP65BE. **A.** Patient XP82DC at 3 years of age has deep-set eyes characteristic of Cockayne syndrome (CS) and irregular lentiginous pigmentation on her face characteristic of XP, indicating XP-CS complex. **B.** Patient XP82DC at 3 years of age has characteristic XP pigmented lesions on her forearms and dorsa of hands along with thin, translucent skin with readily visible veins. The small size of her hands is apparent in comparison with the hands of her mother. **C.** Patient XP65BE at age 6 months experienced severe sunburn on her face with minimal sun exposure. Erythema and swelling are seen on skin of forehead, cheeks, and periorbital area. **D.** Patient XP65BE at age 9 months shows erythema and peeling of skin of malar area of face after sun exposure. **E.** Patient XP65BE at age 4.5 years shows pigmentary changes on her nose, malar area, and other portions of her face. **F.** Patient XP65BE at 4.5 years shows blistering sunburn on her upper thigh. Note spared area above knee where sunscreen was applied. **G.** Patient XP65BE shows minimal pigmentary changes on face and sparing of neck and hand. She used measures to protect her skin from sun exposure. (From Emmert S et al: Relationship of neurologic degeneration to genotype in three xeroderma pigmentosum group G patients. *J Invest Dermatol* **118**:972, 2002, with permission.)

ocular, neurologic, and somatic abnormalities (see Table 140-1).[64,65] A review published in 1992 described 140 cases reported in the literature.[66]

CLINICAL FEATURES In 1936, E.A. Cockayne described a syndrome characterized by cachectic dwarfism, deafness, and pigmentary retinal degeneration with a characteristic "salt and pepper" appearance of the retina.[67] The skin had photosensitivity without the excessive pigmentary abnormalities seen in XP. There was marked loss of subcutaneous fat, resulting in a "wizened" appearance with typical "bird-headed" facies and prominent "Mickey Mouse" ears. Other ocular findings included cataracts and optic atrophy.[68] Neurologic abnormalities, in addition to deafness, include peripheral neuropathy, normal pressure hydrocephalus, and microcephaly. Birth weight and early development are usually normal. The disease onset is usually in the second year of life with slowly progressive neurologic degeneration. Intellectual deterioration may be non-uniform, with some functions preserved better than others. A severe infantile form has been described[69,70] as well as a milder form with late onset. COFS syndrome[57,71,72] with microcephaly and severe mental retardation and CAMFAK syndrome of congenital *ca*taracts, *m*icrocephaly, *fa*ilure to thrive, and *k*yphoscoliosis[73] have some similar features. CS is not associated with an increased incidence of neoplasia.

LABORATORY ABNORMALITIES Clinical laboratory testing often shows sensorineural deafness, neuropathic electromyogram, and slow motor nerve conduction velocity.[12,19,64,66,69,74] The electroencephalogram may be abnormal, and x-ray examination may show thickened skull and microcephaly. Computed tomography may be diagnostically useful in the detection of normal-pressure hydrocephalus and showing calcification of the basal ganglia and other structures (see eFig. 140-5.1 in on-line edition). MRI of the brain shows atrophy and dysmyelination of the cerebrum and cerebellum. Bone age is usually normal. Height and weight are usually well below the third percentile for the age.

Cellular Hypersensitivity. As with XP, cultured cells (fibroblasts or lymphocytes) from patients with CS are hypersensitive to UV-induced inhibition of growth and colony-forming ability.[12,75] Host cell reactivation of UV-damaged adenovirus or plasmids is reduced, although generally to a lesser extent than in XP. There are two complementation groups (A and B) in CS (see Fig. 140-1). Patients with defects in CSA or CSB have similar features.[66] A patient with COFS syndrome was reported with a defect in CSB[73] and another with a defect in XPD.[51]

Prenatal Diagnosis. Prenatal diagnosis of CS has been performed[77] based on the delay in recovery of post-UV RNA synthesis and the increased cell killing by UV radiation.

CLINICAL-LABORATORY CORRELATION

PATIENT SUPPORT GROUP

There is an educational, advocacy, and support organization for helping patients with CS and their families: The Share and Care Cockayne Syndrome Network, Inc., Box 570618, Dallas, TX 75357; website: http://www.cockayne-syndrome.org.

Xeroderma Pigmentosum–Cockayne Syndrome Complex

Approximately one dozen patients with CS have been found to have, in addition, clinical features of XP.[19,48,61] These features include freckling on sun-exposed skin and cutaneous neoplasms (see Fig. 140-5). Cells from these XP-CS patients have reduced DNA excision repair characteristic of XP. Clinically, these patients may be distinguished from XP patients with neurologic abnormalities by the presence of the CS features of pigmentary retinal degeneration, calcification of the basal ganglia, normal-pressure hydrocephalus, and hyperreflexia. Cells from patients with this complex have been found to have mutations in three different XP genes: *XPB, XPD,* and *XPG,*[48,61,75] demonstrating that several different genes are implicated in this disorder (see Fig. 140-1).

Trichothiodystrophy

TTD is an autosomal recessive disorder that is characterized by sulfur deficient, brittle hair and includes a spectrum of clinical phenotypes that may include photosensitivity, ichthyosis, intellectual impairment, short stature, microcephaly, characteristic facial features (protruding ears, micrognathia), and decreased fertility (Fig. 140-6).[78–83] Some patients have immunodeficiency, dystrophic nails, and cataracts. Developmental delay may be associated with dysmyelination,[84] a feature similar to CS; however, patients do not have retinal changes of CS. The spectrum of clinical involvement is broad ranging from only hair to severe multisystem abnormalities (see Fig. 140-6). TTD encompasses patients who have been described as *Amish brittle hair syndrome, Sabinas brittle hair syndrome,* or *Pollitt syndrome*.

In 1980, Price proposed the term *trichothiodystrophy* [derived from Greek tricho (hair) thio (sulfur) *dys* (faulty) *trophe* (nourishment)] recognizing the hair shaft sulfur deficiency as a marker for this symptom complex.[81] Under light microscopy with polarization, TTD hair shafts have a characteristic dark and light banding pattern which gives a "tiger tail" appearance (see Fig. 140-6E). In addition, they usually have hair shaft abnormalities including trichoschisis (a clean transverse break through the hair) (see Fig. 140-6G), trichorrhexis nodosa-like defects, and ribboning (see Fig. 140-6H).[79,80] Hair shafts are brittle because of a reduction of high-sulfur matrix proteins, and amino acid analysis of the hair demonstrates reduced levels of cysteine and cystine in hair shaft proteins. This is associated with a decrease in the ratio of strong to weak disulfide bonds within the hair shafts.[82]

Approximately 50 percent of TTD patients have clinical photosensitivity that ranges from subtle to severe. However, in contrast to the typical clinical features of XP, patients with TTD do not develop poikilodermatous changes (hyper- and hypo-pigmentation, telangiectasias, and atrophy) or skin cancers. Rarely, patients may have features of both TTD and XP, with typical hair features of TTD and the pigmentary and skin cancers characteristic of XP (see Fig. 140-1).[56]

The majority of TTD patients have a defect in *XPD (ERCC2)*. A few have mutations in *XPB (ERCC3)* or *TTDA (TFB5)*, genes which are components of the transcription factor TFIIH that regulates both DNA repair and transcription. Some TTD patients have mutations in *TTDN1*, a gene of unknown function.[85] It is believed that mutations that affect the repair function of the NER genes are associated with features of XP, whereas mutations affecting the transcription-related function results in features of TTD.[86]

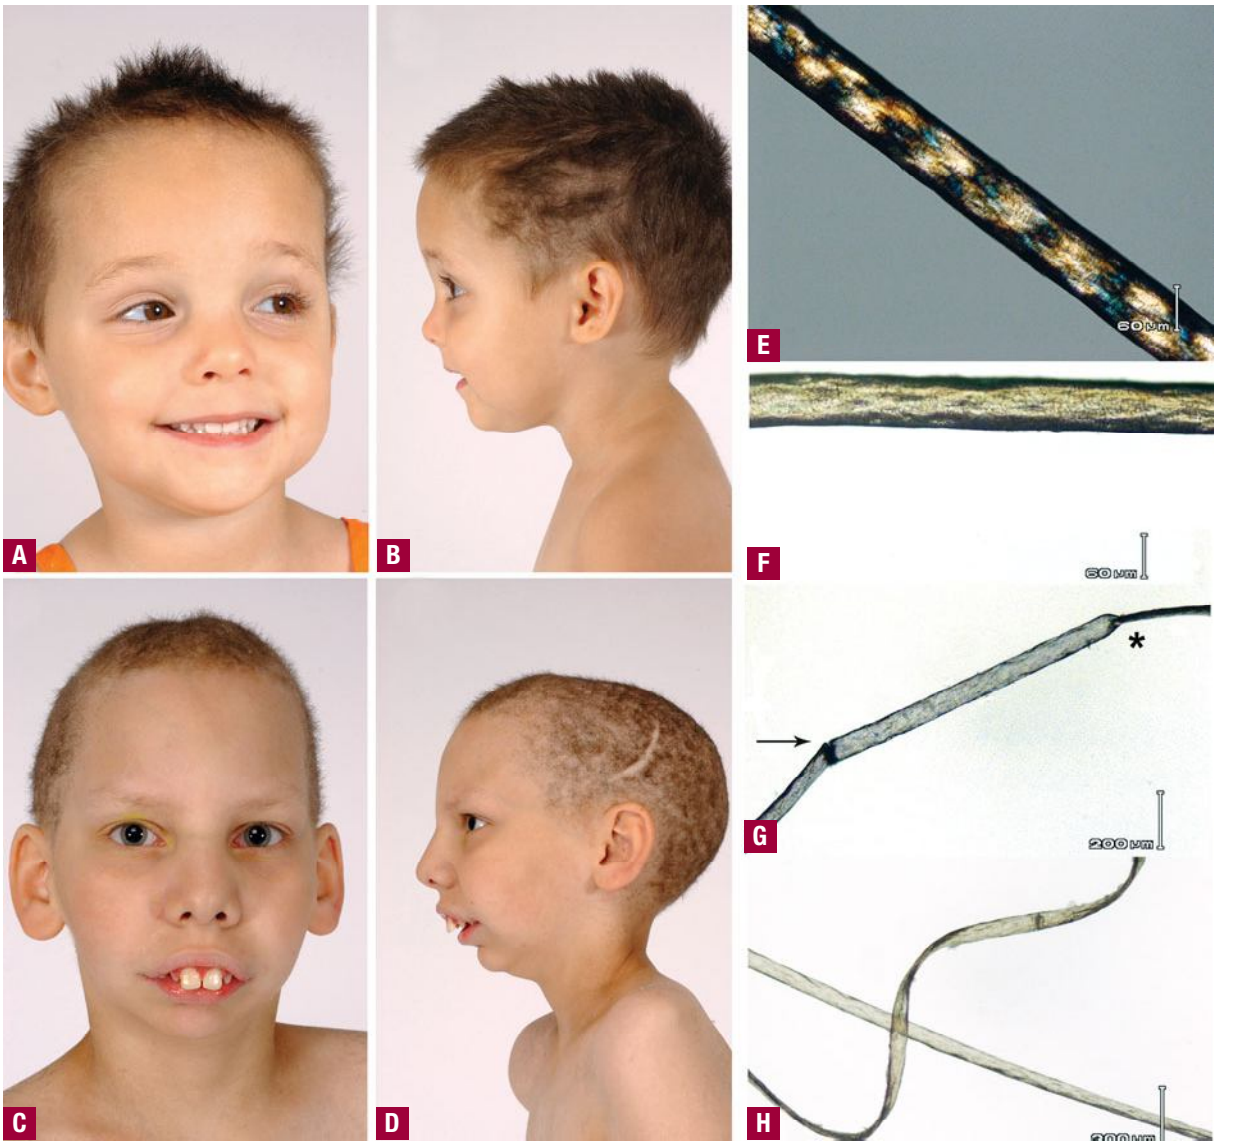
The diagnosis of TTD is based on examination of hair shafts (see Fig. 140-6E–H). TTD hair shafts display tiger tail banding under polarizing microscopy. In addition, they show a spectrum of typical hair shaft abnormalities, including trichoschisis, trichorrhexis nodosa–like fractures, surface irregularities, and ribboning.[79,80] Amino acid analysis of hair shafts can confirm reduced levels of cysteine and cystine (see Chap. 86).

Management includes sun protection and varies with the individual clinical features. Patients with developmental delay and intellectual impairment may have dysmyelination as seen on MRI of the brain and may benefit from neurologic and developmental assessment. Ophthalmologic involvement can include cataracts (which may be congenital), nystagmus, and errors of refraction. Some patients have recurrent infections that have been managed with prophylactic antibiotics or intravenous immunoglobulin G. Patients with skeletal abnormalities may benefit from rehabilitation medicine evaluation and support.

DISORDERS OF GENOME INSTABILITY

Bloom Syndrome

BS is a rare, autosomal recessive disorder characterized by growth deficiency, unusual facies, sun-sensitive telangiectatic erythema, immunodeficiency, and predisposition to a variety of different cancers.[8,87] It is most frequent among



▲ **FIGURE 140-6** Trichothiodystrophy (TTD): Clinical and microscopic hair findings. **A,B.** Mild clinical phenotype: Three-year-old girl with TTD having short, brittle hair that is sparse and broken off at different lengths. She rarely has haircuts except to trim uneven hairs. She has no other abnormal findings. **C,D.** Severe clinical phenotype: 14-year-old boy with short brittle hair and dysmorphic facies with protruding ears, micrognathia, deep set eyes, head elongation in frontooccipital plane. He also has ichthyosis, intellectual impairment, short stature, photosensitivity, osteosclerosis, neurologic abnormalities, and recurrent infections. Light microscopy findings: **E.** TTD hairs displaying alternating light and dark "tiger tail" bands using polarizing microscopy. **F.** Irregular, undulating hair shaft with light microscopy **G.** Trichoschisis (*arrow*): Clean, transverse cleavage fracture; marked narrowing of shaft diameter (*asterisk*). **H.** Ribboning. (Modified from Liang C et al: Characterization of tiger tail banding and hair shaft abnormalities in trichothiodystrophy. *J Am Acad Dermatol* **52**:224, 2005.)

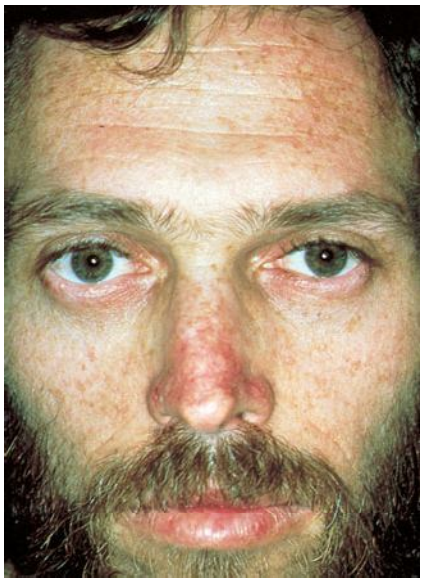
Ashkenazi Jews.[88] Approximately 250 patients have been recognized.

CLINICAL FEATURES Facial erythema and telangiectasia superficially resembling lupus erythematosus (Fig. 140-7) are often present within the first few weeks after birth in the malar area, on the nose, and around the ears.[87] Sun exposure accentuates these abnormalities and may induce bullae, bleeding, and crusting of the lips and eyelids. Café-au-lait spots are common, at times accompanied by adjacent depigmented areas. Patients are well proportioned but small. Adult height is usually under 150 cm. Patients have a long, narrow head with a characteristic facies consisting of a narrow, prominent nose, relatively hypoplastic malar areas, and a receding chin.

Patients with BS are predisposed to multiple infections, as there is immune dysfunction. Fertility is decreased and diabetes mellitus is common.

Approximately 20 percent of patients with BS develop malignancies, comprising a normal spectrum of cancer types, of which one-half occur before age 20 years.[87] Patients usually die before the age of 30 years from either cancer or infection.

GENE DEFECT, PATHOGENESIS, AND LABORATORY ABNORMALITIES BS is caused by mutations in *BLM*, which encodes a RecQ helicase.[8,10,89] BS cells are characterized by an increase in the frequency of spontaneous sister chromatid exchanges (see Chap. 109) and in exchanges between homologous chromosomes. The latter is often visualized by quadriradial chromosomes. These are four-armed chromosomes most likely formed by recombination between two chromosomes (and almost never found in unaffected individuals). These observations demonstrate that BS cells are characterized by hyper-recombination.



▲ **FIGURE 140-7** Bloom syndrome. Prominent telangiectasia in malar distribution.

Although the exact mechanisms of how mutations in the BLM helicase lead to hyper-recombination are still not completely understood, it has been suggested that they are related to defective DNA replication or defective resolution of stalled replication forks. Hyper-recombination may result in an increased frequency of loss of heterozygosity and through that mechanism, in conjunction with increased spontaneous mutation frequency, an increased frequency of malignant transformation. The immune deficiency, characterized by diminished immunoglobulin levels, reduced cellular proliferative response to mitogens, and decreased proliferation in the mixed leukocyte reaction, probably further contributes to the increased cancer risk.

TESTING The observation of quadriradial chromosomes (observed in 0.5 percent to 14 percent of lymphocytes of BS patients) and the approximately 10-fold increased frequency of spontaneous sister chromatid exchanges are used to diagnose BS.[90] A founder deletion/insertion mutation in the *BLM* gene was identified in Ashkenazi Jews at a frequency of approximately 1 percent (BLM^{Ash})[88,91] and can be used for DNA diagnosis of BS patients and carriers among Ashkenazi Jews.

Werner Syndrome (Adult Progeria)

WS is a rare, autosomal recessive disorder, characterized by several features of premature aging and an increased cancer risk. More than 800 patients have been reported.[92] Most of the WS patients are Japanese.

CLINICAL FEATURES Patients with WS are clinically normal until adolescence, when they do not show the usual growth spurt and start to prematurely develop features and disease of aging, including graying and thinning of hair, loss of subcutaneous fat, wrinkling of skin, type 2 diabetes, osteoporosis, and cardiovascular disease secondary to atherosclerosis.[93] Often, ophthalmologists are first to make the diagnosis of WS, as cataracts develop early.[94] Other features that are not part of the normal aging process are scleroderma-like changes with subcutaneous atrophy, leg ulcers, soft tissue calcifications, and a bird-like facies. Although an increased incidence and early onset of cancer is related to aging, the 10:1 ratio between epithelial to mesenchymal cancers seen in a normal aging population is shifted to 1:1 in WS patients, with, for example, sarcomas and melanomas being more frequent.[95] As in the Japanese general population, most of the melanomas are of the acral-lentiginous type or arise from mucous membranes and are therefore not considered to be related to UV-exposure. Thyroid cancer occurs at a younger age in WS patients than in the Japanese general population. Death usually occurs before the age of 50 years due to either myocardial infarction or cancer.

GENE DEFECT, PATHOGENESIS, AND LABORATORY ABNORMALITIES WS is caused by a mutation in *WRN*, which encodes a RecQ helicase.[8,96,97] Most mutations of *WRN* result in truncation of the protein, sometimes by only a small amount, with loss of the nuclear targeting sequence. WRN is involved in many metabolic processes of DNA metabolism and *WRN* mutations cause various defects in DNA replication, recombination, base excision repair of oxidative DNA damage, repair of DNA strand breaks, recombination, DNA damage signaling and transcription. Cells from WS patients have a reduced replicative lifespan in culture[98] and show altered telomere structure and length. Genome instability in WS cells is shown by an increased frequency of non-homologous chromosome exchanges and of large chromosomal deletions.

Rothmund-Thomson Syndrome

CLINICAL FEATURES The hallmark of RTS, a rare, autosomal recessive disorder, is poikiloderma with variegated cutaneous pigmentation, atrophy, and telangiectasias beginning in infancy.[99] RTS patients are photosensitive and develop prominent erythema and facial swelling on sun exposure early in life, which may be accompanied by blister formation. They often have sparse scalp hair, eyebrows, and eyelashes. Other clinical features include juvenile cataracts, stunted growth, skeletal abnormalities including radial bone defects, and a predisposition for cancer, in particular for osteosarcomas (32 percent of patients). Five percent of RTS patients also develop non-melanoma skin cancer.

GENE DEFECT, PATHOGENESIS, AND LABORATORY ABNORMALITIES Mutations in the helicase RecQL4 have been identified in a majority of patients with RTS.[100] Cells from RTS patients have been reported with an increased sensitivity to ionizing radiation with increased formation of chromosome gaps and breaks, suggesting a role of RECQL4 in maintaining chromosome stability.[102,103] This, however, was not confirmed in other patients, possibly reflecting heterogeneity in this disease.[104] The exact function of the RECQL4 helicase remains unclear.[105] Cells from one patient had reduced DNA repair after exposure to UVC.[106] One RTS patient had increased acute toxicity after high-dose radiotherapy after surgery and subsequent palliative chemotherapy. However, another RTS patient was reported to have a normal acute response to radiation therapy for a squamous cell carcinoma of his tongue.[107] He died 2 years later with extensive squamous cell carcinoma in the thorax, but no tumor in the oral cavity.

Fanconi Anemia

FA is an autosomal recessive disease characterized by progressive pancytopenia, growth retardation, various congenital abnormalities of the heart, kidney, and limbs, and a predisposition to cancer.[108,109] More than 1200 patients have been reported to the International Fanconi Anemia Registry.

CLINICAL FEATURES Cutaneous abnormalities are present in almost 80 percent of patients (Fig. 140-8A–D).[108,110] Hyperpigmentation is present from birth or early childhood and is diffuse and accentuated over the neck, joints, and trunk. Café-au-lait spots and achromic lesions are also present.

Hematopoietic manifestations usually have their onset before age 10 years and most commonly lead pediatricians to make the diagnosis of FA. These consist of a hypocellular bone marrow with pro-

▲ **FIGURE 140-8** Skin and oral mucous membrane findings in Fanconi anemia (**A–D**) and dyskeratosis congenita (**E–H**). **A–D.** Fanconi anemia. **A.** Congenital absence of thumb. The second finger has been surgically altered to function as a thumb. Keratotic papules are present on the palm. (**B**) Oral leukoplakia on right buccal mucosa (*arrow*). **C,D.** Dyspigmentation of Fanconi anemia. **C.** Hyperpigmentation of left axilla with discrete hyperpigmented and hypopigmented macules. **D.** Several irregular café-au lait macules, smaller fine tan hyperpigmented macules, and dozens of guttate hypopigmented macules in the lower back. **E–H.** Dyskeratosis congenita. **E.** Oral leukoplakia involving the tongue. **F.** Severe atrophy of all fingernails and thickening of the palm. **G.** Longitudinal ridging and dystrophy of several fingernails with dyspigmentation and thickening of the palm. **H.** Poikiloderma showing reticular hypo- and hyperpigmentation of the skin of the neck and chest. (A–D modified from Braun M et al: Thrombocytopenia, multiple mucosal squamous cell carcinomas, and dyspigmentation. *J Am Acad Dermatol* **54**:1056, 2006; E–H used with permission from Dr. Blanche Alter, NCI, Bethesda, MD.)

gressive decrease in the number of circulating platelets, granulocytes, and erythrocytes. Skeletal malformations are common and often include aplasia or hypoplasia of the thumb, metacarpals, or radius.[111,112] Short stature, renal deformities, strabismus, microphthalmia, hypogonadism, and central nervous system abnormalities, including hyperreflexia and mild mental retardation, are also observed. The frequency of acute myelogenous leukemia has been reported to be elevated 15,000-fold.[113–116] If patients survive aplastic anemia and/or leukemia (e.g., as a result of bone marrow transplantation) they often develop solid tumors by the fifth decade of life, mostly squamous cell carcinomas of the head and neck and the anogenital area.

GENE DEFECT, PATHOGENESIS, AND LABORATORY ABNORMALITIES FA is genetically heterogeneous with at least twelve complementation groups (FANCA to FANCM), all of which, except FANCI, have been cloned. Most of the FA proteins have been shown to act in a common DNA damage response signaling pathway, which also involves BRCA1 and BRCA2 (these genes are mutated in hereditary breast cancer; see Chap. 109).[117–120] Activation of this FA/BRCA pathway is thought to mediate DNA recombination to repair DNA strand breaks and DNA cross-links, generated, e.g., by ionizing radiation or DNA cross-linking agents.

TESTING Central to the FA/BRCA pathway is the mono-ubiquitination of the FANCD2 protein. The inability of FA cells to ubiquitinate the FANCD2 protein, as shown in Western blots after, for example, exposure to DNA cross-linking agents, is currently used as a screening tool to confirm the diagnosis of FA.

RESOURCES

Patients, physicians, and researchers may obtain information from the Fanconi Anemia Research Fund, Inc. (http://www.fanconi.org) or from Fanconi Canada (http://www.fanconicanada.org).

Dyskeratosis Congenita

Dyskeratosis congenita, the Zinsser-Cole-Engman syndrome, is an X-linked multisystem disease with cutaneous, mucosal, ocular, gastrointestinal, and hematologic abnormalities and an increased incidence of cancer (see Table 140-1). A Registry at Hammersmith Hospital in London recruited 228 families having 354 affected patients from 40 countries.[129] Affected females may have either the autosomal dominant or autosomal recessive form.

CLINICAL FEATURES The most common features are a triad of reticulated hyperpigmentation, dystrophic nails, and mucosal leukoplakia (see Fig. 140-8E–H).[130–132] During the first decade of life, patients develop reticulated poikiloderma of sun-exposed areas, with hyperpigmentation and, occasionally, bullae. Nail dystrophy is present in virtually all patients beginning at approximately age 2 to 5 years. The nails initially split easily, then develop longitudinal ridging with irregular free edges. Eventually, the nails become smaller, resulting in rudiments remaining. The fingernails are usually involved before the toenails. Other skin abnormalities include atrophic, wrinkled skin over the dorsum of hands and feet and hyperhidrosis and hyperkerato-

sis of palms and soles with disappearance of dermal ridges (absence of fingerprints).

Leukoplakia may be present in any mucosal site. The oral mucosa is the most frequent, but leukoplakia is also found in the urethra, glans penis, vagina, and rectum. Lingual hyperkeratosis may be present. Mucosal surfaces such as the esophagus, urethra, and lacrimal duct may become constricted and stenotic, resulting in dysphagia, dysuria, and epiphora. Multiple dental caries and early loss of teeth are common. Progressive pulmonary disease, including infections and fibrosis (and cirrhosis in some patients) was reported in 19 percent of affected males.[131] Approximately 20 percent of the patients had learning difficulties or mental retardation.[131] There have been several reports of intracranial calcifications, especially of the basal ganglia.[133,134] These are also seen in CS.

There is an increased incidence of neoplasia, particularly squamous cell carcinoma of the mouth, rectum, cervix, vagina, esophagus, and skin. A large British kindred had Hodgkin disease and adenocarcinoma of the pancreas.[135] Similar to FA, although hypoplasia is the main abnormality seen in bone marrow, there is a predisposition to both myelodysplasia and acute myeloid leukemia.[131]

The majority (93 percent) of patients developed bone marrow failure which was the main cause (71 percent) of early death.[131] Approximately one-half of the patients (21 of 41) developed pancytopenia under the age of 10 years with a hematologic picture similar to FA. Patients have been treated with bone marrow transplantation.[136]

LABORATORY STUDIES Chromosomes are usually normal in untreated cells; however, chromosomal abnormalities have been found in fibroblasts and bone marrow cells from a few patients.[137,138] The leukoplakia cells may show chromosomal changes presaging malignancy. Cultured skin fibroblasts have been reported to show increased frequency of chromatid breaks and gaps after x-radiation during the G_2 phase of the cell cycle. Increased chromosome breakage after x-radiation[139] or exposure to bleomycin[140] and other DNA-damaging agents[141] has been described.

A gene for dyskeratosis congenita (*DKC1*) has been cloned,[129,141,143] which is located on the q28 region of the X chromosome. The protein, dyskerin, has a nucleolar function, and a role in telomere maintenance and aging.[144–148] Mutations in the *DKC1* gene have been detected in affected patients.[129,142,149,150] There is also evidence for an autosomal form with affected females[129,131,151,152] having mutations in the *TERC* gene, which is also involved in telomere function.

CHAPTER 141

Tuberous Sclerosis Complex

Thomas N. Darling

EPIDEMIOLOGY

The incidence of tuberous sclerosis complex (TSC) is as high as 1 in 6000 live births.[1,2] It occurs with equal frequency in males and females and in different races and ethnicities. Hereditary transmission is evident in approximately one-third of patients. Sporadic disease occurs in about two-thirds of patients, and this is attributed to de novo mutations.[3]

ETIOLOGY AND PATHOGENESIS

TSC is caused by mutations in a tumor suppressor gene, either *TSC1* or *TSC2*.[3] Mutations in *TSC2* are observed in about three-fourths of patients, and even more commonly in de novo cases.[4,5] Patients with mutations in *TSC2* tend to exhibit a more severe phenotype.[4–7]

TSC1 maps to chromosome band 9q34. The 8.6-kb full-length transcript encodes a protein called *hamartin* or TSC1.[8] *TSC2* maps to chromosome band 16p13.3. The 5.5-kb transcript encodes a protein called *tuberin* or TSC2.[9] Immediately adjacent to *TSC2* on chromosome 16 is *PKD1*, the gene mutated in polycystic kidney disease. Some patients with TSC have severe, early-onset renal cystic disease, and most of these patients have a contiguous deletion of *TSC2* and *PKD1*.[10]

Typical of mutations in tumor suppressor genes, the mutations observed in patients with TSC are inactivating mutations located anywhere along the sequence of *TSC1* or *TSC2*. Consistent with Knudson's two-hit hypothesis, most TSC tumors show a second somatic mutation that inactivates the wild-type allele.[11,12] TSC1 and TSC2 form a complex that inhibits signaling through the mammalian target of rapamycin (mTOR) pathway (Fig. 141-1). Loss of TSC1/TSC2 function leads to increased mTOR signaling and increased cell growth. Rapamycin is a drug that inhibits its mTOR and may be useful for the treatment of internal tumors in TSC.[13]

CLINICAL FINDINGS

Clinical Criteria

The diagnosis of TSC is based on clinical criteria categorized as major or minor features (Table 141-1).[14,15] Cutaneous and oral lesions comprise 4 of 11 major

TUBEROUS SCLEROSIS COMPLEX AT A GLANCE

- Autosomal dominant syndrome with variable expressivity.
- Manifested by hamartomatous tumors in multiple organs, including brain (causing seizures), eyes, heart, kidneys, lungs, and skin.
- Skin lesions occur in nearly all individuals and are important for diagnosis.
- Skin lesions include hypomelanotic macules, "confetti" lesions, facial angiofibromas, fibrous facial plaque, shagreen patch, and ungual fibromas.
- Hypomelanotic macules appear at birth or shortly thereafter and are most useful in early diagnosis.
- Although the skin lesions are benign, they may require treatment due to symptoms or disfigurement.

features and 3 of 9 minor features. Major features are thought to have a high degree of specificity for TSC, whereas minor features are less specific or substantiated. No single feature is present in all patients, and no feature is specific for TSC. Genetic testing can be offered and may be important in particular situations (see Molecular Diagnosis).[15]

History

The medical and family history taking should include questions about seizures, mental retardation, behavioral disorders, visual problems, and tumors of the brain, heart, kidneys, lungs, and skin. Determining the ages of onset of skin lesions and their subsequent changes may assist in discriminating TSC skin lesions from similar-appearing non-TSC skin lesions. Many TSC skin lesions are not present at birth, but appear later at ages typical for the lesion.[16] For example, infants show multiple hypomelanotic macules but not angiofibromas or ungual fibromas. Adults may have multiple angiofibromas and ungual fibromas, but hypomelanotic macules may have faded or disappeared.

Cutaneous and Oral Lesions

HYPOMELANOTIC MACULES Hypomelanotic macules (Fig. 141-2) are observed in over 90 percent of children with TSC.[4,17–21] They are often present at birth or appear within the first few years of life and may fade or disappear in adulthood. The ultraviolet light of a Wood's lamp is used to improve detection, especially in lightly pigmented individuals[22] (Fig. 141-3).

Hypomelanotic macules typically measure 0.5 to 3.0 cm in diameter. They are off-white and not completely depigmented as in vitiligo.[23] Some are oval at one end and taper to a point at the other. Such lesions are called *ash-leaf spots* because of their resemblance to the leaf of the European mountain ash.[24] They number from 1 to over 20. They can be located anywhere on the body but tend to occur on the trunk and buttocks. When located on the scalp, they cause poliosis.[17]

Three or more hypopigmented macules constitutes a major feature for the diagnosis of tuberous sclerosis. One or two, and in rare individuals up to three, hypomelanotic macules occur in 4.7 percent of the general population.[25] A less common type of hypopigmentation is the "confetti" skin lesion (Fig. 141-4), which is considered a minor feature for diagnosis. It typically occurs on the legs below the knees or on the forearms, and consists of multiple hypopigmented macules 2 to 3 mm in diameter.[17,24]

FACIAL ANGIOFIBROMAS Angiofibromas appear at 2 to 5 years of age and eventually affect 75 percent to 90 percent of patients.[4,17,20,21] These 1 to 3 mm in diameter pink to red papules have a smooth surface (Fig. 141-5). They may be hyperpigmented, especially in individuals with darker pigmentation. They occur on the central face and are often concentrated in the nasolabial folds (see eFig. 141-5.1 in on-line edition), extending symmetrically onto the cheeks and to the nose, nasal opening, and chin, with relative sparing of the upper lip and lateral face. Sometimes lesions occur on the forehead, scalp, or eyelids. They may number from 1 to over 100. Lesions may coalesce to form large nodules, especially in the nasolabial folds.[17,20,22] Angiofibromas are unilateral in rare cases and may indicate a segmental or mosaic defect.[26–29]

The development of papules may be preceded by mild erythema that is intensified by emotion or heat. During puberty, angiofibromas may grow in size and number. During adulthood they tend to be stable in size, but redness may gradually diminish.[22]

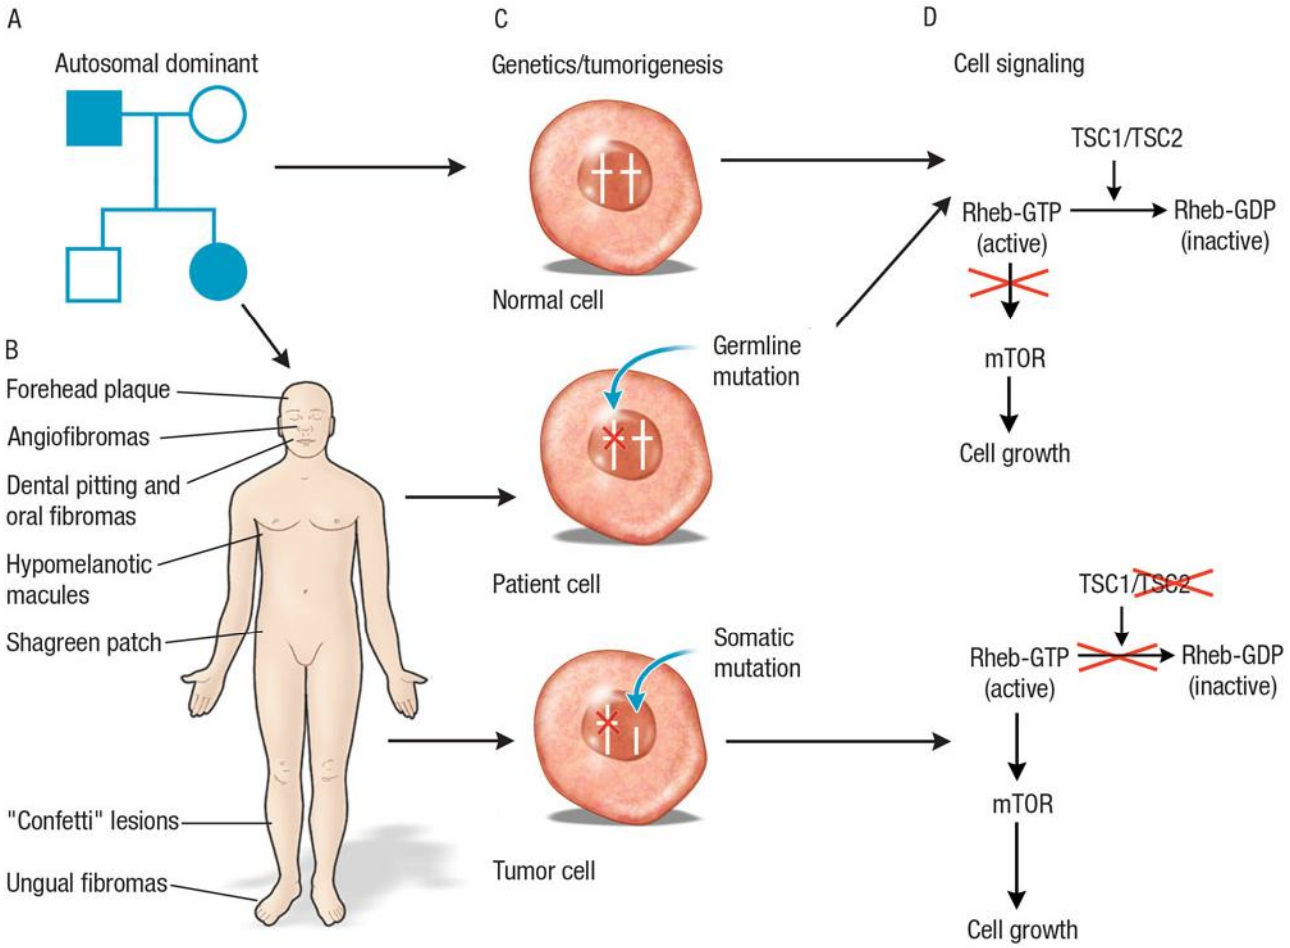
Angiofibromas must be multiple to be counted as a major feature. A solitary angiofibroma is clinically and histologically indistinguishable from the fibrous papule that occurs sporadically as a single lesion in the general population.[30] Multiple angiofibromas are also observed in multiple endocrine neoplasia type 1,[31–33] and as an unusual finding in Birt-Hogg-Dubé syndrome.[34]

FIBROUS FACIAL PLAQUE The forehead plaque may be congenital or show gradual development over years.[17,35] It is present in 20 percent to 40 percent of patients.[4,17,20] It is an irregular, soft to firm, connective tissue nevus with the color of the normal surrounding skin, red, or hyperpigmented in darkly pigmented individuals (Fig. 141-6). The plaque can also be found on the scalp, cheeks, and elsewhere on the face and is therefore sometimes referred to as a fibrous facial plaque. The forehead plaque is grouped together with angiofibromas as a major feature for diagnosis.[14]

SHAGREEN PATCH The shagreen patch is observed in approximately 50 percent of patients.[4,17,20,21] It may be present in infancy but usually becomes apparent later. It is a firm or rubbery irregular plaque ranging in size from 1 to 10 cm (Fig. 141-7). The surface may appear bumpy with coalescing papules and nodules, or the patch may have the surface appearance of an orange peel. The color may be that of the surrounding skin, or it may be slightly pink or brown. There may be scattered smaller oval papules with or without a larger plaque (see eFig. 141-7.1 in on-line edition). The most common locations are on the lower back and buttocks; the patch is found less commonly on the thighs.[22]

UNGUAL FIBROMAS Ungual fibromas, also known as *Koenen's tumors*, usually appear after the first decade and eventually affect up to 88 percent of adults with TSC.[20] They are more common on the toes than on the fingers.

Ungual fibromas measure 1 mm to 1 cm in diameter. They arise from under the proximal nail fold (periungual fibromas) and under the nail plate (subungual fibromas). Periungual fibromas are red papules and nodules that are firm, pointed, and hyperkeratotic, or soft and rounded (Fig. 141-8). They press on the nail matrix and cause



▲ FIGURE 141-1 Molecular pathogenesis of tuberous sclerosis complex (TSC). **A.** An example is shown in which a mutation in *TSC2* is passed from the father (*blue square*) to the daughter (*blue circle*), whereas the mother (*white circle*) and son (*white square*) are unaffected. **B.** Skin lesions are observed in the daughter at the indicated locations. **C.** A cell from the mother shows two normal alleles for *TSC2* on chromosome band 16p13.3. A cell from the daughter shows the *TSC2* mutation inherited from her father. A tumor from the daughter has this germline mutation and a "second-hit" mutation that inactivates the other allele, which leads to loss of heterozygosity. **D.** TSC2, in a complex with TSC1, is a guanosine triphosphatase–activating protein, converting active Ras-homolog enriched in brain (Rheb) guanosine triphosphate (GTP) to inactive Rheb guanosine diphosphate (GDP). Rheb GTP activates mammalian target of rapamycin (mTOR), a kinase that increases protein translation and cell growth, so TSC2 normally acts to inhibit cell growth. Loss of TSC2 function in tumors results in increased levels of Rheb GTP, activation of mTOR, and increased cell growth.

a longitudinal groove, and sometimes a groove forms without an evident papule[20] (see eFig. 141-8.1 in on-line edition). Subungual fibromas can be seen through the nail plate as red or white oval lesions or as red papules emerging from the distal nail plate, causing distal subungual onycholysis (see eFig. 141-8.2 in on-line edition).

Presence of a non-traumatic ungual fibroma is a major feature for diagnosis of TSC.[14] Solitary lesions (also termed *acral* or *acquired digital fibrokeratomas*) are also observed in the general population, especially after nail trauma.[36,37] Multiple acral fibromas with a myxoid stroma were reported in one patient with familial retinoblastoma.[38]

OTHER SKIN LESIONS Molluscum fibrosum pendulum (skin tags) is the name given to multiple fibroepithelial polyps in TSC. These range from soft pedunculated papules to larger firm pedunculated nodules located on the neck, axillae, trunk, and flexures (see eFig. 141-8.3 in on-line edition). They can be skin colored or hyperpigmented.[17] Skin tags are common in the general population, so these are not useful for diagnosis. Miliary fibromas are patches of multiple minute papules, usually on the neck or trunk, that appear like "gooseflesh."[22] Pachydermodactyly is a benign thickening of the proximal fingers that has been observed in a few patients with TSC.[39,40] Other lesions reported in TSC include café-au-lait macules (not six or more as in neurofibromatosis, but only one to three as in the general population), appendageal tumors (trichoepitheliomas, syringocystadenomas), lipomas, fibromyolipomas, and neurofibromas.[22]

DENTAL PITTING Multiple pits of the dental enamel are observed in up to 100 percent of TSC patients.[41–44] These pits can be tiny pinpoint lesions or larger crater-like lesions (see eFig. 141-8.4 in on-line edition). They occur on both deciduous and permanent teeth. The identification of these lesions is enhanced by using a dental plaque stain. Dental pits can also be seen in the general population, albeit with lower prevalence and at lower numbers than in TSC.[41] The presence of multiple dental pits is a minor feature for diagnosis.[14]

ORAL FIBROMAS Approximately 50 percent of TSC patients have oral fibromas[20,45] (see eFig. 141-8.5 in on-line edition). These sometimes occur in the first decade but are more common in adulthood. They are most common on the gingiva, but also occur on the buccal and labial mucosa, hard palate, and tongue.[45] Some patients have diffuse

TABLE 141-1
Diagnostic Criteria for Tuberous Sclerosis Complex (TSC)

Major features
- **Facial angiofibromas or forehead plaque**
- **Non-traumatic ungual or periungual fibroma**
- **Hypomelanotic macules (three or more)**
- **Shagreen patch (connective tissue nevus)**
- Multiple retinal nodular hamartomas
- Cortical tuber[a]
- Subependymal nodule
- Subependymal giant cell astrocytoma
- Cardiac rhabdomyoma, single or multiple
- Lymphangiomyomatosis[b]
- Renal angiomyolipomas[b]

Minor features
- **Multiple randomly distributed pits in dental enamel**
- Hamartomatous rectal polyps[c]
- Bone cysts
- Cerebral white matter migration lines[a,d,e]
- **Gingival fibromas**
- Non-renal hamartoma[c]
- Retinal achromic patch
- **Confetti skin lesions**
- Multiple renal cysts[c]

[a]When cerebral cortical dysplasia and cerebral white matter migration tracts occur together, they should be counted as one rather than two features of TSC.
[b]When both lymphangiomyomatosis and renal angiomyolipomas are present, other features of TSC should be present before a definitive diagnosis is assigned.
[c]Histologic confirmation is suggested.
[d]Radiographic confirmation is sufficient.
[e]One panel member recommended that three or more radial migration lines constitute a major feature.
Note: Cutaneous and oral lesions are in bold.
Definite TSC: Presence of either two major features or one major feature and two minor features.
Probable TSC: Presence of one major feature and one minor feature.
Possible TSC: Presence of either one major feature or two or more minor features.
Adapted from Roach ES, Gomez MR, Northrup H: Tuberous sclerosis complex consensus conference: Revised clinical diagnostic criteria. *J Child Neurol* **13**:624, 1998.

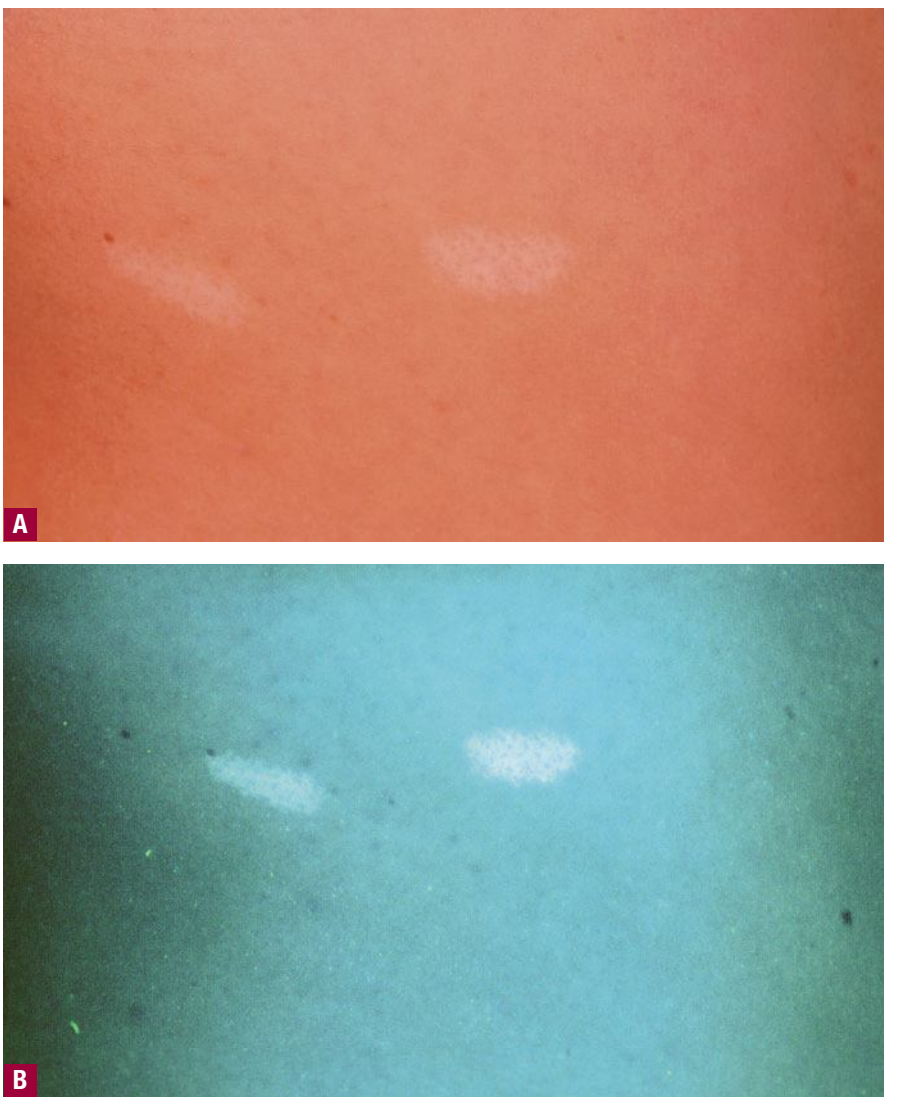
gingival overgrowth. Gingival overgrowth is a common side effect of anticonvulsants, especially phenytoin and cyclosporin, but gingival overgrowth can be observed in TSC even in patients not treated with anticonvulsants or immunosuppressive agents.[45,46] Gingival fibromas are a minor feature for diagnosis.[14] Oral fibromas in the general population are typically single and form at sites of trauma, usually on the tongue or buccal mucosa.[47]

▲ **FIGURE 141-2** Hypomelanotic ash-leaf macules on the lower leg of a child with tuberous sclerosis complex.

Related Physical Findings

Tuberous sclerosis can affect almost any organ. Only one-third of patients have the classic triad of seizures, mental retardation, and angiofibromas.

BRAIN Cerebral lesions include cortical tubers, subependymal nodules, and subependymal giant cell astrocytomas. Cerebral lesions may manifest as seizures, mental retardation, and behavioral disorders. Seizures occur in approximately 80 percent of patients, with onset common in the first 2 months and usual by the first 2 years of life. Seizures are most likely infantile spasms but can be all types except pure absence (classic petit mal).[48] Seizures are controlled with anti-epileptic drugs, and a ketogenic diet can decrease seizures.[49,50] Epilepsy surgery may be required for seizures intractable to anticonvulsant therapy.[51,52]



▲ **FIGURE 141-3** **A.** Hypomelanotic macules on the lateral chest of an adult with tuberous sclerosis complex. The macules may be easily overlooked. **B.** Wood's lamp accentuates the macules.

▲ **FIGURE 141-4** Confetti-like hypopigmented macules on the lower leg of an adult with tuberous sclerosis complex.

Mental retardation tends to occur in patients with seizures, but many children with seizures have no obvious neurologic impairment.

HEART Cardiac rhabdomyomas are observed in about half of infants with TSC.[56] Most of these neoplasms are asymptomatic and spontaneously regress, but in rare cases they cause fetal demise or heart failure shortly after birth.[57] Cardiac rhabdomyomas may cause dysrhythmias, commonly Wolff-Parkinson-White syndrome, noticed in utero or in the first year of life in TSC patients.[57–59]

▲ **FIGURE 141-5** Multiple facial angiofibromas on the nose, cheeks, and chin, with relative sparing of the upper lip as commonly observed in tuberous sclerosis complex.

▲ **FIGURE 141-6** The forehead fibrous plaque in tuberous sclerosis complex is often pink-red and has a bumpy surface and irregular outline.

KIDNEYS Angiomyolipomas (AMLs) are observed in approximately 75 percent TSC patients over 10 years of age.[60] Additional renal lesions include renal cysts and rarely renal cell carcinoma.[61] Polycystic kidney disease is present in 3 percent to 5 percent of patients.[56] Renal lesions can cause renal insufficiency, hypertension, and potentially fatal retroperitoneal hemorrhage. Patients may require selective embolization or partial nephrectomy.[62–65]

LUNGS Lung involvement in TSC includes lymphangioleiomyomatosis (LAM), multifocal micronodular pneumocyte hyperplasia, and clear cell tumors of the lung.

EYES Retinal astrocytic hamartomas are observed in 44 percent to 87 percent of patients.[68] The most common type is a flat, smooth, translucent, gray, non-calcified circular or oval lesion with indistinct boundaries. Also common are elevated and opaque multinodular "mulberry" lesions that have calcified, glistening nodules. Retinal astrocytic hamartomas can be indistinguishable from retinal lesions in neurofibromatosis type 1 and may appear similar to retinoblastomas. Some patients have vision loss, but blindness is rare.[69]

GASTROINTESTINAL TRACT Rectal polyps, usually asymptomatic, have been observed in 14 of 18 adults (78 percent) with TSC.[71] Histologically they are hamartomas and rarely adenomas.

OTHER ORGANS

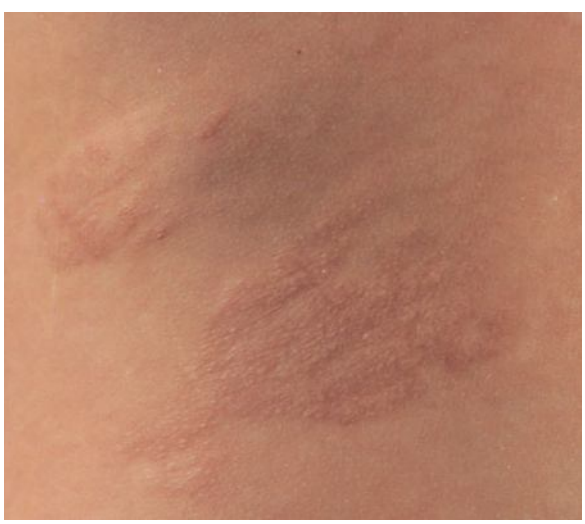
LABORATORY TESTS

Skin Histopathologic Findings

Hypomelanotic macules have normal numbers of melanocytes, in contrast to the lesions of vitiligo, in which melanocytes are absent. The melanocytes in hypomelanotic macules have poorly developed dendritic processes, and melanosomes are decreased in numbers, size, and melanization.[23] Angiofibromas contain plump, spindle-shaped or stellate fibroblastic cells in the dermis among increased numbers of dilated vessels (see eFig. 141-8.6 in on-line edition). Collagen fibers are oriented in an onionskin pattern around follicles and vessels. The epidermis shows melanocytic hyperplasia and flattening of rete ridges. Periungual fibromas are similar, but with more extensive hyperkeratosis and a variable increase in vascularity (see eFig. 141-8.7 in on-line edition). The shagreen patch has sclerotic bundles of collagen in the reticular dermis (see eFig. 141-8.8 in on-line edition). Elastic fibers are typically reduced in amount.

Special Tests (Including Imaging Studies)

Besides dermatologic and ophthalmologic examination, the initial evaluation



◀ **FIGURE 141-7** The shagreen patch in tuberous sclerosis complex is a firm, bumpy plaque that is usually located on the lower back.

▲ **FIGURE 141-8** Multiple periungual and subungual fibromas on the toes in a patient with tuberous sclerosis complex.

of a patient suspected to have TSC includes the following: (1) cranial computed tomography (CT) or cranial magnetic resonance imaging (MRI), (2) renal ultrasonography (or MRI or CT), and (3) electrocardiography.[60] In addition, the following tests are recommended for subsets of patients. Electroencephalography is valuable if seizures are suspected and subsequently for seizure management. In children, standardized cognitive and behavioral assessments are indicated at the time of diagnosis, in response to changes in behavior or worsening performance, and at regular intervals tailored to the individual.[53] In adult women, high-resolution chest CT is used to detect LAM. Echocardiography is indicated if the patient exhibits cardiac symptoms.[60]

After diagnosis, the patient should have periodic surveillance for the development of new lesions or changes in existing lesions. Cranial CT or MRI is recommended every 1 to 3 years in children. This may reveal the presence of a subependymal giant cell astrocytoma, which allows removal before it becomes locally invasive or causes symptoms. Similarly, renal ultrasonography is recommended every 1 to 3 years, depending on clinical suspicion and results of previous examinations. If large or numerous renal tumors are present, renal CT or MRI should be performed. Echocardiography and chest CT are indicated for cardiac and pulmonary symptoms, respectively.[60]

Box 141-1

Differential Diagnosis of Hypomelanotic Macules

- Polygonal or ash leaf
  - Nevus depigmentosus
  - Piebaldism
  - Vitiligo
  - MEN1 hypomelanotic macules
  - Nevus anemicus
- Confetti
  - Idiopathic guttate hypomelanosis (adults)
  - MEN1 confetti lesions
  - Pityriasis alba
  - Pityriasis lichenoides chronica
- Poliosis
  - Waardenburg syndrome
  - Piebaldism
  - Vitiligo
  - Vogt-Koyanagi-Harada syndrome
  - MEN1 hypomelanotic macules
  - Nevus anemicus
  - Segmental pigment mosaicism

MEN1 = multiple endocrine neoplasia type 1.

Molecular Diagnosis

Genetic testing may be useful to confirm diagnosis in individuals not meeting criteria for definite TSC.[60] It can provide additional information for genetic counseling, and it can be used in prenatal diagnosis.[15] Genetic testing may yield false-negative or inconclusive results. Extensive analysis of *TSC1* and *TSC2* fails to identify a mutation in approximately 15 percent of TSC patients.[4,5] *TSC1* and *TSC2* are large genes, and mutations may occur anywhere along the sequence. Also, sequence analysis does not identify large deletions and must be supplemented by other methods of analysis.[4,5,79] Mutation detection may also be hampered by somatic mosaicism.

Box 141-2

Differential Diagnosis of Angiofibromas

- Fibrous papules
- Multiple endocrine neoplasia type 1 angiofibromas
- Birt-Hogg-Dubé angiofibromas
- Trichoepitheliomas
- Fibrofolliculomas/trichodiscomas
- Tricholemmomas
- Syringomas
- Dermal melanocytic nevi
- Acne vulgaris
- Rosacea

Box 141-3

Differential Diagnosis of Ungual Fibroma

Most Likely

- Periungual
  - Acral fibrokeratoma
  - Superficial acral fibromyxoma
  - Epidermoid cyst
  - Pseudomyxoid cyst
  - Wart
  - Pyogenic granuloma
  - Juvenile xanthogranuloma
- Subungual
  - Acral fibrokeratoma
  - Superficial acral fibromyxoma
  - Wart
  - Subungual exostosis
  - Subungual horn
  - Familial retinoblastoma
  - Pyogenic granuloma
  - Onychomycosis
  - Psoriasis

Always Rule Out

- Subungual
  - Squamous cell carcinoma
  - Bowen disease
  - Amelanotic melanoma

DIFFERENTIAL DIAGNOSIS

Differential diagnosis for several major features of TSC are summarized in Boxes 141-1, 141-2, 141-3, and 141-4.

COMPLICATIONS

None of the skin lesions in TSC is prone to malignant degeneration, but the lesions can be a major cosmetic concern for the patient, causing social isolation and difficulties with self-esteem.[80] Angiofibromas, facial plaques, and ungual fibromas can be painful or bleed sponta-

Box 141-4

Differential Diagnosis of Shagreen Patch

Most Likely

- Familial cutaneous collagenoma
- Eruptive collagenomas
- Dermatofibrosis lenticularis disseminata (in Buschke-Ollendorf syndrome)

Consider

- Multiple endocrine neoplasia type 1 collagenomas
- Sclerotic fibroma (Cowden syndrome)
- Isolated connective tissue nevus
- Juvenile elastoma
- Nevus elasticus
- Nevus mucinosis (Hunter syndrome)

neously or in response to minor trauma. Ungual fibromas can cause nail dystrophy and eventual loss of the nail. Large facial lesions may obstruct vision or occlude the nasal passages.[81]

PROGNOSIS AND CLINICAL COURSE

Individuals with tuberous sclerosis exhibit decreased overall survival compared with the general population. The causes of premature death include renal failure, intractable seizures, obstructive hydrocephalus, cardiac outflow obstruction, arrhythmia, respiratory failure, pneumothorax, and hemorrhage from an aneurysm or a tumor, especially AMLs.[82,83] Fatal events may occur at any age. Brain and heart tumors may cause death in infancy, whereas lung and kidney tumors are more likely to cause premature death in adulthood. The prognosis for the individual patient depends on disease expressivity. Some individuals have a normal life span with few medical complications.

TREATMENT

When an infant is newly diagnosed with TSC, a major aspect of care is answering questions and addressing the concerns of the family. Unfortunately, many parents report negative experiences because of physician insensitivity and the provision of inaccurate information and inadequate support.[84] Patients should be promptly referred to other specialists and social services as needed, and genetic counseling should be offered. Families should be informed about organizations dedicated to TSC, such as the Tuberous Sclerosis Alliance (http://www.tsalliance.org).

Current treatments for TSC skin tumors are mostly surgical.

Clinical trials are in progress to test potential medical therapies for TSC tumors. Oral rapamycin caused regression of subependymal giant cell astrocytomas,[90] and its use for treatment of AMLs and LAM is being investigated. Its utility for treatment of angiofibromas is currently unknown, but the potential for serious side effects is likely to limit systemic use for these benign skin lesions, especially in children.

GENETIC COUNSELING ISSUES

It is not unusual for a child with TSC to be born to parents who do not carry the diagnosis of TSC. This may represent a de novo mutation, or it may indicate that one parent has a very mild form of TSC that has escaped detection. Both parents should be carefully screened as described earlier. If one parent has TSC, there is a 50 percent chance that subsequent children will inherit the mutation.

Prenatal testing can be performed on cells obtained by chorionic villus sampling or amniocentesis.[15,93,94] It is also possible to use high-resolution ultrasonography and ultrafast MRI to examine for TSC tumors in the fetus, but the sensitivity of these tests is unknown.[15,95–98] It should be emphasized that TSC is highly variable, even within a family, and that genetic testing does not predict disease severity in offspring. Also, this brief summary does not detail many issues surrounding genetic testing that require utmost thought and sensitivity and consultation with genetics professionals.

CHAPTER 142

The Neurofibromatoses

Robert Listernick
Joel Charrow

EPIDEMIOLOGY

The "modern age" of neurofibromatosis began in 1981, with Riccardi's detailed clinical descriptions of the features and natural history of von Recklinghausen disease and the subsequent description of "central neurofibromatosis with bilateral acoustic neuroma."[1] With the availability of gene-based diagnosis, several distinct clinical syndromes have been identified: (1) neurofibromatosis type 1 (NF-1), also known as *von Recklinghausen disease*; (2) neurofibromatosis type 2 (NF-2), whose cardinal feature is the development of bilateral vestibular schwannomas; (3) segmental or mosaic NF-1; (4) familial café-au-lait spots; and (5) schwannomatosis. Both NF-1 and NF-2 occur equally in all ethnic groups. NF-1 occurs at an incidence of 1 in 3000 live births, whereas NF-2 is much less common, with an estimated incidence of 1 in 40,000 live births.

ETIOLOGY AND PATHOGENESIS

Genetics

NF-1 is inherited in an autosomal dominant fashion. Although the expressivity of NF-1 varies considerably, even among individuals in the same family who are genotypically identical, the disorder is considered to be 100 percent penetrant. Thus, apparent skipping of NF-1 between generations may be the result of misdiagnosis, nonpaternity, or the occurrence of a new mutation in the grandchild. Although a large number of *NF1* mutations have been described, there have been no genotype-phenotype correlations noted except for individuals who have deletions of the entire *NF1* gene. These individuals appear to have an increased risk of facial dysmorphism, mental retardation, early appearance of neurofibromas, and the presence of plexiform neurofibromas.[2] There is evidence that NF-1 is more severe when inherited from the mother rather than from the father.

The gene *NF1* is located on the long arm of chromosome 17 and encodes a protein called *neurofibromin*. Homozygosity for mutant *NF1* alleles has not been reported, probably because it is a lethal condition. *NF1* has an unusually high mutation rate, estimated at 2.4 to 10 ×

THE NEUROFIBROMATOSES AT A GLANCE

- Neurofibromatosis type 1 (NF-1), an autosomal dominant condition, occurs at an incidence of 1 in 3000 live births. Neurofibromatosis type 2 (NF-2), a separate autosomal dominant disorder, occurs at an incidence of 1 in 40,000 live births.
- NF-1 can be diagnosed clinically if two of the following features are present: six or more café-au-lait spots (larger than 0.5 cm in children, larger than 1.5 cm in adults), intertriginous freckling, two or more cutaneous neurofibromas or one plexiform neurofibroma, optic nerve glioma, characteristic bony lesion, iris Lisch nodules, or a first-degree relative with NF-1.
- Cutaneous neurofibromas are softer than the surrounding connective tissue and protrude just above the skin surface or lie just under the skin. Subcutaneous neurofibromas that arise from peripheral nerves, both under the skin and deep in the viscera, are generally much harder.
- Plexiform neurofibromas, generally present at birth or apparent during the first several years of life, may lead to disfigurement, blindness (secondary to amblyopia, glaucoma, or proptosis), loss of limb function, or organ dysfunction by compression of vital structures.
- The hallmark of NF-2 is the presence of bilateral vestibular schwannomas. Individuals with NF-2 are also at risk for the development of multiple meningiomas, schwannomas, gliomas, and neurofibromas throughout the neural axis.
- Segmental NF-1 has manifestations of NF-1, usually café-au-lait macules and neurofibromas, limited to one area of the body. This occurs as a result of a postconceptional mutation in the NF-1 gene, which leads to somatic mosaicism.

10^{-5} gametes per generation, one of the highest rates of known inherited disorders.[3] This may reflect the large size of the gene, which spans 350 kb of genomic DNA and contains 59 exons that encode a peptide containing over 2800 amino acids. An alternative hypothesis is that there is some structural property of the gene that renders it particularly susceptible to mutation. New mutations account for approximately 50 percent of cases and are usually on the paternally inherited allele. Unlike with many other dominant disorders, the frequency of new mutations does not appear to increase with advancing paternal age.

Molecular Biology

Most *NF1* mutations result in reduced intracellular levels of the *NF1* gene product, neurofibromin. This appears to be sufficient to cause most of the clinical manifestations of the disease. Tumorigenesis, including the development of benign dermal neurofibromas, appears to be dependent on inactivation of the normal *NF1* allele in somatic cells, a process referred to as *loss of heterozygosity*.[4] Loss of heterozygosity is a critical step in tumorigenesis in many inherited cancer predisposition syndromes (e.g., retinoblastoma, Li-Fraumeni syndrome), and the genes involved are called *tumor suppressor genes*. Tumorigenesis is initiated when both copies of the gene cease functioning normally, the first as a result of an inherited mutation and the second as the result of a second somatic "hit" that interferes with the function of the previously normal allele.

Neurofibromin is found in a variety of cell types, including neurons, oligodendrocytes, and nonmyelinating Schwann cells. Considerable evidence has been developed for the role of neurofibromin as a negative regulator of RAS.[5,6] The RAS gene family encodes membrane-associated, guanine nucleotide–binding proteins that are involved in the regulation of cellular proliferation, differentiation, and learning. RAS exists in an active (RAS–guanosine triphosphate) and inactive (RAS–guanosine diphosphate) state. By favoring conversion of RAS from its active state to its inactive state, neurofibromin downregulates the downstream effects of RAS, which include promoting learning, memory, synaptic plasticity, and cell growth and proliferation.[5,7] Four different forms of neurofibromin exist, resulting from alternate splicing. The type II variant includes a 21–amino acid sequence encoded by exon 23a, whereas type I does not. This sequence appears to be critical for RAS regulation and learning. In the brain, there are three major isoforms of RAS. K-RAS has been shown to be the primary target of neurofibromin activity.[6] Activation of RAS by neurofibromin stimulates G protein activity, which results in activation of adenylyl cyclase. Cyclic adenosine monophosphate and other downstream intermediates appear to play a role in cell growth, learning, and memory. Neurofibromin also associates with microtubules and plays a role in regulating γ-aminobutyric acid–ergic inhibitory neuronal activity in the hippocampus.[8]

RAS is a membrane-bound protein and requires farnesylation (addition of a C15 isoprenoid to a cysteine residue near the C-terminus) for activity, a process that is catalyzed by farnesyl transferase. Agents that inhibit farnesyl transferase cause general inhibition of the RAS pathway, much as neurofibromin does. Farnesyl transferase inhibitors reverse the proliferative phenotype in *Nf1*-deficient mouse cells and can reverse spatial learning impairments in a mouse model of *NF1* by decreasing RAS levels.[7] These observations have prompted investigations into the use of farnesyl transferase inhibitors for the treatment of NF-1–related complications, such as rapidly growing plexiform neurofibromas.

Loss of heterozygosity of the *NF1* gene in Schwann cells has been shown to be the necessary event for the development of discrete neurofibromas.[9] Furthermore, neurofibromin-deficient Schwann cells secrete a substance that stimulates mast cell migration, which, in turn, stimulates production of extracellular matrix and angiogenesis.[10] Astrocytes lacking *NF1* expression cannot form optic nerve gliomas on their own; a brain environment heterozygous for *NF1* is necessary for the development of these tumors.[11]

CLINICAL FINDINGS

A consensus development conference was held by the National Institutes of Health in 1987 to establish diagnostic criteria to promote better clinical research and better care of patients with NF-1.[12] The seven diagnostic features recognized at this conference (Table 142-1), and the recommendation that two or more of these seven features be present before a diagnosis of NF-1 is established, have proven extremely useful and continue to be applied without modification 20 years later.

Café-au-Lait Spots

Café-au-lait spots, which are flat, pigmented macules, are often the first man-

TABLE 142-1
Diagnostic Criteria for Neurofibromatosis Type 1 (NF-1)[a]

- Six or more café-au-lait macules larger than 5 mm in greatest diameter in prepubertal individuals and over 15 mm in postpubertal individuals
- Two or more neurofibromas of any type *or* one plexiform neurofibroma
- Freckling in the axillary or inguinal regions
- Optic glioma
- Two or more iris Lisch nodules
- A distinctive osseous lesion such as sphenoid dysplasia or thinning of long bone cortex with or without pseudarthrosis
- A first-degree relative (parent, sibling, or offspring) with NF-1 by the above criteria

[a]Two or more required for diagnosis.

Box 142-1
Differential Diagnosis of Syndromes Associated with Multiple Café-au-Lait Spots[a]

- Neurofibromatosis type 1
- Familial café-au-lait spots
- LEOPARD (multiple *l*entigines, *e*lectrocardiographic abnormalities, *o*cular hypertelorism, *p*ulmonary stenosis, *a*bnormalities of the genitalia, growth *r*etardation, *d*eafness) syndrome (multiple lentigines syndrome)
- Neurofibromatosis type 2
- McCune-Albright syndrome (polyostotic fibrous dysplasia)
- Tuberous sclerosis
- Fanconi anemia
- Multiple endocrine neoplasia type 2B
- Bannayan-Riley-Ruvalcaba syndrome
- Bloom syndrome
- Ataxia-telangiectasia

[a]Order based on typical numbers of macules.

ifestation of NF-1 to appear (Fig. 142-1). Frequently present at birth, they become more numerous as the infant grows. New ones may continue to appear throughout the first decade of life. Once noticed, they tend to grow in size in proportion to the overall growth of the child. Although infrequently found on the face, they may be noted anywhere on the body. The size, shape, and contour of café-au-lait spots are of no diagnostic significance, although the majority of café-au-lait spots in NF-1 are oval and have a smooth border. The oft-quoted adage that smooth-edged café-au-lait spots indicate NF-1 and irregular café-au-lait spots are more typical of McCune-Albright syndrome can be misleading (Box 142-1). When café-au-lait spots overlap each other, the area of overlap may be darker than either individual spot. When found within mongolian spots, they are typically surrounded by a more lightly pigmented halo. Individuals with large numbers of café-au-lait spots do not have "more severe" NF-1, and the location of the macules in no way predicts the location of subsequent neurofibromas.[13]

Café-au-lait spots represent collections of heavily pigmented melanocytes of neural crest origin in the epidermis. Although the cells may contain increased numbers of "giant" melanosomes, or melanin macroglobules, these are not unique to NF-1, and their presence or absence in biopsy specimens is not helpful diagnostically.

▲ **FIGURE 142-1** Café-au-lait spots. Note halo (*arrow*) around café-au-lait spot within light mongolian spot.

The diagnostic criterion for NF-1 is six or more café-au-lait spots larger than 5 mm in diameter in prepubertal individuals or 1.5 cm in adults. Of all children ultimately diagnosed with NF-1, 53 percent will have six or more café-au-lait spots by age 3 years and 97 percent by age 6 years.[14] Light brown macules that resemble café-au-lait spots are also seen with increased frequency in red-headed children, often of Irish descent. Usually such children have fewer than six macules and no other stigmata of NF-1. Individuals with multiple lentiginosis syndrome and LEOPARD (multiple *l*entigines, *e*lectrocardiographic abnormalities, *o*cular hypertelorism, *p*ulmonary stenosis, *a*bnormalities of the genitalia, growth *r*etardation, *d*eafness) syndrome (see Chap. 73) may present with café-au-lait macules during infancy or at birth and may not begin to develop lentigines until early childhood.

Intertriginous Freckling

Café-au-lait spots smaller than 5 mm are referred to as *freckles* and are commonly present in the axilla, inguinal region, and under the breasts (Fig. 142-2). Unlike ordinary freckles in these locations, these lesions are not related to sun exposure and are considered virtually pathognomonic of NF-1 (Crowe sign). Of all children ultimately diagnosed with NF-1, 81 percent will have intertriginous freckling by age 6 years.[14]

Discrete Neurofibromas (See also Chap. 127)

Neurofibromas, which consist of Schwann cells,mast cells, fibroblasts, and perineural cells, are benign nerve sheath tumors that appear as discrete masses arising from peripheral nerves.[15] Cutaneous neurofibromas protrude just above the skin surface

▲ **FIGURE 142-2** Axillary freckling and multiple small and larger (less than 1 cm) café-au-lait spots in a brown-skinned woman.

▲ **FIGURE 142-3** Cutaneous neurofibromas with overlying hyperpigmentation.

▲ **FIGURE 142-4** Multiple cutaneous neurofibromas on the back of a woman.

or lie just under the skin with an overlying violaceous hue (Fig. 142-3). They are softer than the surrounding connective tissue, often creating a "buttonholing" sensation when a finger is rubbed gently over the surface (Fig. 142-4). Subcutaneous neurofibromas that arise from peripheral nerves, both under the skin and deep in the viscera, are generally much harder (see eFig. 142-4.1 in on-line edition). If they arise from the dorsal root ganglia, they may grow through neural foramina, compressing the spinal cord and creating a "dumbbell" appearance. Subcutaneous neurofibromas in the neck may feel like a "beaded necklace" and are often confused with lymph nodes. Fewer than 20 percent of children younger than 10 years of age have cutaneous neurofibromas.[14] These lesions generally start appearing after puberty and increase in number as the patient grows older. Women who have NF-1 often comment on the appearance of cutaneous neurofibromas during pregnancy. Although it has not yet been investigated, the majority of adult patients with NF-1 likely have numerous asymptomatic deep neurofibromas involving the dorsal roots and other larger nerves. On occasion, neurofibroma-associated pruritus may be severe enough to require treatment with antihistamines.

Plexiform Neurofibromas (See also Chap. 127)

Plexiform neurofibromas, histologically similar to discrete neurofibromas, are benign peripheral nerve sheath tumors that involve single or multiple nerve fascicles, often arising from branches of major nerves.[16] They may elicit a "wormy" sensation on palpation, as one feels multiple thickened nerve fascicles. Often there is overlying hyperpigmentation ("giant café-au-lait spot") or hypertrichosis (Fig. 142-5). Most plexiform neurofibromas are present at birth or become apparent during the first several years of life. Externally visible plexiform neurofibromas are easily identified and may lead to disfigurement, blindness (secondary to amblyopia, glaucoma, or proptosis), or loss of limb function (see eFigs. 142-5.1, 142-5.2, and 142-5.3 in on-line edition). In contrast, thoracic or abdominal plexiform neurofibromas may have no external manifestations but may have equally devastating consequences due to invasion or compression of vital structures (e.g., ureters, bowel, spinal cord).

The growth rate of plexiform neurofibromas is highly variable. Periods of rapid growth alternating with long periods of quiescence are common. Malignant peripheral nerve sheath tumors, which generally arise from plexiform neurofibromas, may develop silently in deep plexiform neurofibromas and not give rise to symptoms until distant metastases have occurred. Although loss of heterozygosity at the NF-1 locus may lead to the formation of benign neurofibromas, the malignant transformation of a benign plexiform neurofibroma may be initiated by cell cycle regulators beyond the *ras* oncogene. For example, mice that have null mutations in both the NF-1 and *p53* genes uniformly develop malignant tumors.[17,18] Physicians caring for individuals with NF-1 should be alert to the development of a malignancy. Biopsy of plexiform neurofibromas should be performed if the lesions exhibit rapid growth or cause significant pain or focal neurologic dysfunction.

Optic Pathway Tumors

Approximately 15 percent of children with NF-1 will develop optic pathway tumors (OPTs); however, only one-half of these patients will ever develop symptoms, with an overall incidence of symptomatic OPT of 7 percent.[19,20] Study series of NF-1-associated OPT have identified an approximately 2:1 female predominance in patients, as well as a lower incidence in African American children. These observations suggest the possibility that either hormonal factors or modifying genes may influence the development of OPT.

The period of greatest risk for the development of symptomatic OPTs in NF-1 is during the first 6 years of life. The development of a symptomatic tumor after age 6 years is extremely unusual.[19,20] Thus, physicians caring for children with NF-1 should be sensitive to the signs and symptoms of OPT in this young age group. Approximately 30 percent of children with symptomatic OPTs will show the rapid onset of proptosis, with moderate to severe vision loss in the affected eye (see eFig. 142-5.4 in on-line edition). Another 30 percent of children will have abnormal ophthalmologic examinations, without any visual symptoms, which leads to discovery of the tumors. Because young children rarely complain of vision

▲ **FIGURE 142-5** Plexiform neurofibroma with overlying hyperpigmentation and hypertrichosis.

loss, even when it is severe, thorough annual eye examinations are imperative in all young children with NF-1. Ophthalmologic signs may include an afferent papillary defect, optic nerve atrophy, papilledema, strabismus, or defects in color vision. Finally, as many as 40 percent of children who have chiasmal tumors develop precocious puberty. Accelerated linear growth will be the first sign of precocious puberty, which underscores the need for all children with NF-1 to have annual assessments of growth using standard growth charts. Children with chiasmal tumors often have no ophthalmologic symptoms or signs. Early detection of precocious puberty is important, because both the accelerated linear growth and the development of secondary sexual characteristics can be aborted with the use of a long-acting luteinizing hormone–releasing hormone agonist.[21]

Lisch Nodules

Lisch nodules are slightly raised, well-circumscribed melanocytic hamartomas of the iris thought to be virtually pathognomonic of NF-1 (Fig. 142-6). They are best seen using a slit lamp, which is necessary to distinguish them from the more commonly encountered flat iris nevi, which are not associated with NF-1. They do not cause any functional impairment of vision. The frequency with which they are found increases with age: Although Lisch nodules are found in more than 90 percent of adults with NF-1, only 30 percent of children with NF-1 younger than 6 years of age have them.[14]

Distinctive Osseous Lesions

There are two bony lesions distinctive enough to be included in the diagnostic criteria for NF-1. The first, dysplasia of the wing of the sphenoid bone, results in poor formation of the wall and/or floor of the orbit (see eFig. 142-6.1 in on-line edition). This congenital mesodermal dysplasia may be, but is not always, clinically apparent, leading to proptosis (from herniation of meninges or brain into the orbit) or enophthalmos.

▲ **FIGURE 142-6** Lisch nodules.

Dysplasia of a long bone, characterized by congenital thinning and bowing, affects approximately 2 percent of children with NF-1. Although the tibia is most commonly affected, the femur, humerus, and other long bones may also be involved. Even when the bone is intact, thinning and bowing produce a visible deformity, and the weakened mechanical properties of the bone predispose to fracture, particularly of the weight-bearing bones. Failure of primary union after a fracture results in a "false joint," or pseudarthrosis.[22]

LABORATORY TESTS

Despite the identification of the NF-1 gene and its complete sequencing, the diagnosis of NF-1 remains primarily a clinical one. Although laboratory confirmation of the diagnosis is extremely useful in specific circumstances, in most cases it is unnecessary. Because no common mutations have been identified, molecular diagnosis can be based only on strategies that screen the entire gene for mutations. Several laboratories now offer sequencing of some or all exons and/or mutation scanning with a resulting sensitivity of as high as 95 percent. This testing is available for presymptomatic individuals and can also be applied to prenatal diagnosis of NF-1 when a mutation has been identified in an affected parent.

Inexperienced clinicians often perform biopsy on cutaneous masses in an effort to confirm the diagnosis of NF-1 in an individual with multiple café-au-lait spots or other stigmata of NF-1. Such procedures are invariably unnecessary, because the clinical diagnosis of NF-1 is quite straightforward. Biopsy of a plexiform neurofibroma should be reserved for those situations in which the physician wishes to exclude the possibility of a malignancy.

RADIOGRAPHIC EVALUATION

There has been considerable debate regarding the role of screening neuroimaging in the care of asymptomatic children with NF-1. Routine screening would be important if it led to early detection of OPT and early initiation of therapy that prevented visual deterioration. A longitudinal study of children with NF-1 failed to identify any tumors in which early detection altered the clinical course.[19] Moreover, targeted screening of very young children with NF-1, the high-risk group for the development of OPTs, failed because three children developed symptomatic tumors shortly after magnetic resonance imaging (MRI) yielded normal findings. Brainstem tumors in both children and adults with NF-1 are generally more indolent than their counterparts in individuals without NF-1, which suggests that routine screening would not be beneficial.[23] Thus, the National Neurofibromatosis Foundation Optic Pathway Task Force has recommended against routine screening neuroimaging of all children with NF-1.[24] Although there are no comparable longitudinal data for adults regarding the performance of routine MRI scans of the head and spinal cord, it seems reasonable to perform such testing only in individuals who have symptoms or signs suggestive of central nervous system pathology.

Similarly, there is debate as to whether patients with NF-1 should be screened for the presence of hidden, internal plexiform neurofibromas. Most studies have demonstrated an approximately 30 percent incidence.[25,26] Because such a strategy incurs great cost without offering any proven benefit in preventing growth of plexiform neurofibromas and subsequent long-term complications, it is not recommended.[27] However, if current chemotherapeutic trials demonstrate success in the treatment of rapidly growing tumors, their identification at an early age may become more important.

COMPLICATIONS OF NEUROFIBROMATOSIS TYPE 1

Skeletal Complications

All children with NF-1 should be regularly screened for scoliosis, beginning in early childhood. Scoliosis is the most common skeletal manifestation of NF-1, affecting 10 percent to 30 percent of patients. Scoliosis is divided into dystrophic and non-dystrophic types. Dystrophic scoliosis is the result of primary bone dysplasia and may present very early in childhood, typically resulting in a sharply angulated curve spanning relatively few vertebral bodies. It is often accompanied by extreme rotation, scalloping of the posterior margins of the vertebral bodies, vertebral wedging, defective pedicles, and enlargement of the

neural foramina and spinal canal.[22] The curvature may progress rapidly, necessitating surgery, which may be particularly complicated because of the complex, multiplanar curves, poor quality of bone, potential for nerve root and spinal cord injury, and presence of intraspinal and extraspinal neurofibromas. The non-dystrophic type of scoliosis is more common and is similar to idiopathic scoliosis in adolescents. In many children it can be managed expectantly or with bracing.

Localized regions of bony overgrowth may also occur in children with NF-1 and are often in areas free of neurofibromas. The overgrowth may affect only a single digit or a larger region such as a hand or an extremity, but true hemihypertrophy is unusual. Bony overgrowth may also occur in a region affected by a plexiform neurofibroma.

Cancer

There is little doubt that NF-1 predisposes one to an increased risk for certain cancers. In a Swedish cohort of 212 probands and their affected relatives followed for more than 40 years, malignant neoplasms or central nervous system tumors occurred in 45 percent of the probands, for a relative risk of 4 compared with that in the general population. However, when the affected relatives of the probands were examined, only the female relatives with NF-1 were found to have an increased risk of neoplasms.[28] This illustrates the tremendous bias inherent in data obtained through hospital records and disease-specific clinics. When the records of Japan's Children's Cancer Registry were reviewed, the incidence of NF-1 was 6.45 times the expected estimated rate.[29]

Malignant peripheral nerve sheath tumors arise almost exclusively from preexisting plexiform neurofibromas. Estimates of the lifetime risk for the development of this tumor vary but the rate may be as high as 13 percent.[30,31] Because the outcome of therapy is poor, physicians should be diligently aware of the early symptoms referable to these tumors, including a rapidly growing mass or unexplained pain or dysfunction. Although conventional imaging cannot identify malignant tissue within a benign plexiform neurofibroma, newer modalities such as 18-fluorodeoxyglucose positron emission tomography may be useful.[32]

Pheochromocytoma clearly is associated with NF-1, with an incidence potentially as high as 1.4 percent. In one review, the mean age at presentation was 42 years; 84 percent of patients had solitary adrenal tumors, 9.6 percent had bilateral adrenal tumors, and 6 percent had ectopic tumors in the abdominal sympathetic chain, organ of Zuckerkandl, and the bladder.[33]

Catecholamine-associated symptoms and hypertension were both present in 61 percent of patients; 22 percent of patients had neither of these findings. Malignant pheochromocytomas were found in 11.5 percent of patients, often with distant metastases at presentation. Loss of heterozygosity of the NF-1 gene has been demonstrated both in NF-1–associated and sporadic pheochromocytomas.[34,35]

There is an increased risk of chronic myelomonocytic leukemia and acute lymphoblastic leukemia in children with NF-1. In contrast to the fourfold predominance of lymphocytic leukemia generally seen in childhood, there is a clear excess of cases of myelogenous leukemia in children with NF-1.[36] Homozygous inactivation of the NF-1 gene in the bone marrow cells of children with NF-1 and malignant myeloid disorders have been identified, which suggests that the NF-1 gene plays a role in downregulating the growth of immature myeloid cells.[37]

An unusual association between juvenile xanthogranulomas, NF-1, and the development of myeloid leukemias has been reported.[38,39] Although the pathogenesis is obscure, this association also has been observed independent of NF-1. Juvenile xanthogranulomas (see Chap. 149) are yellowish papules less than 1 cm in diameter usually found on the head or trunk (see eFig. 142-6.2 in online edition). Some authors have recommended screening blood counts for individuals who have juvenile xanthogranulomas and NF-1. Although the exact magnitude of the risk is unknown, it is exceedingly low. Screening blood counts are not recommended as they provide no useful information and, in our experience, serve only to increase parental anxiety.

Rhabdomyosarcoma also occurs more frequently in individuals with NF-1[40,41] (see Chap. 127). Although a relationship between both neuroblastoma and Wilms tumor and NF-1 has been suggested, there are no strong epidemiologic data linking these tumors with NF-1. Other tumors that appear to occur with excess frequency in adults with NF-1 are somatostatinomas of the duodenum and the ampulla of Vater, and gastrointestinal stromal tumors. Compared with the tumors seen in individuals without NF-1, somatostatinomas in NF-1 patients rarely arise in the pancreas, are smaller, and generally are not associated with hormonal symptoms (i.e., diabetes, steatorrhea, and gallbladder disease).[42]

Vasculopathy

Patients with NF-1 may have a vasculopathy affecting essentially any arterial vessel. Clinical manifestations may include renal artery stenosis with hypertension, cerebral infarcts, bleeding aneurysms, and intermittent claudication of an extremity. This vasculopathy is a developmental problem not related to compression of an arteriole by a neurofibroma and appears to be acquired after birth, because the appearance of new lesions and the progression of preexisting ones have been described. Characteristic pathologic changes have been described in all layers of the vascular wall, which ultimately leads to narrowing of the arterial lumen.[43,44]

The most commonly identified vascular lesion in patients with NF-1 is in the renal artery, leading to renovascular hypertension.[45] Renal artery vasculopathy should be considered in any adult NF-1 patient with hypertension that is not easily controlled with a single antihypertensive medication. All children with NF-1 should be evaluated for this complication. Aortography with selective angiography of the renal arteries should be used to confirm the diagnosis. If the blood pressure is uncontrollable using oral antihypertensives, percutaneous transluminal angioplasty can be performed and repeated if initially unsuccessful.

Unidentified Bright Objects

Brain MRI of children with NF-1 frequently demonstrates regions of increased signal intensity on T2-weighted images, referred to as *unidentified bright objects* or UBOs. UBOs may be found in the internal capsule, basal ganglia, cortex, cerebellar hemispheres, optic tract, or brainstem. They do not enhance and are not associated with compression of surrounding tissue, features that distinguish them from neoplasms. UBOs are present in approximately 60 percent of children with NF-1 but disappear with age and are uncommon in adults. They are not associated with focal neurologic signs and are of uncertain significance. Histopathologic studies have shown that the UBOs correspond to areas of myelin vacuolization with increased water content.[46] Some studies have

found that children with NF-1 who have UBOs have significantly lower IQ and language scores, show significantly impaired visual-motor integration and motor coordination, and are at much greater risk for impaired academic achievement compared with NF-1 patients without UBOs.[47]

Intelligence and Learning Disabilities

Contrary to gross misstatements in the older literature, the mean IQ of patients with NF-1 is only 5 to 10 points lower than that of the general population and unaffected siblings.[48] However, learning disabilities, defined as discrepancies between ability (intellect) and performance, are quite common, with an estimated prevalence of 30 percent to 60 percent.[49,50] Although earlier reports suggested there might be a specific "cognitive phenotype" in NF-1 characterized by an excess of visual-perceptual disabilities, more recent studies have demonstrated that verbal deficits (e.g., reading) are at least as common as nonverbal disabilities in individuals with NF-1. These learning disabilities are lifelong and can affect adult functioning. Many children with NF-1 also have poor attention and impulse control and may be diagnosed with attention-deficit/hyperactivity disorder, which significantly interferes with school performance and learning. The use of stimulant medications may have a profound beneficial effect on the ability of these individuals to succeed academically and professionally.

TREATMENT OF NEUROFIBROMATOSIS TYPE 1

Individuals with NF-1 are best cared for within a multi-disciplinary clinic that has access to a wide range of subspecialists. The exact physician composition of the clinic is less important than the ability to obtain expeditious subspecialty consultation. All first-degree relatives should be examined for the cutaneous manifestations of NF-1 and should undergo slit-lamp examination at the first visit to ascertain the presence of Lisch nodules. Yearly visits allow the physician to identify NF-1 complications early while providing counseling and dissemination of information regarding NF-1.[13] Individuals and families can obtain further information from the websites of the two national support groups, the Children's Tumor Foundation (http://www.ctf.org) and Neurofibromatosis, Inc. (http://www.nfinc.org).

All children with NF-1 who are 10 years of age or younger should have yearly complete ophthalmologic examinations to look for signs of an OPT. These examinations should include assessment of visual acuity, color vision, and visual fields, as well as funduscopy and slit-lamp examination. Because almost all OPTs arise in children in this age group, the frequency of ophthalmologic examinations can be reduced in children older than 10 years of age. Yearly measurements of weight and height should be plotted on standardized growth charts, because the earliest indication of precocious puberty may be accelerated linear growth. Blood pressure measurements should be obtained at each visit to look for signs of renovascular hypertension. In addition, the spine should be examined each year for early signs of scoliosis.[13]

Café-au-Lait Spots

Café-au-lait spots on the face are unusual in individuals with NF-1. On occasion, they do occur, and affected individuals may seek to improve cosmesis. Attempts to remove café-au-lait spots with laser therapy have provided very mixed results. Although total disappearance of the lesion may be achieved, some studies cite a recurrence rate as high as 67 percent. Although results with use of the Q-switched ruby laser (694 nm) have been mixed, favorable reports in a limited number of cases using either the continuous-mode copper vapor laser (511 nm) or the erbium:yttrium-aluminum-garnet laser (2940 nm) have been published.[51,52] Multiple treatments of a single lesion may be more effective.

Cutaneous Neurofibromas

Discrete cutaneous neurofibromas may be removed surgically to improve cosmesis or to prevent local irritation (e.g., from brushing for lesions in the hairline or from rubbing against the shoe for those on the foot). Deeper neurofibromas may require surgical removal when they push on vital structures, such as a dorsal root neurofibroma that infiltrates the neural foramen and compresses the spinal cord. Complications of surgery include regrowth of the original tumor and nerve damage. In individuals who have severe pruritus from a large burden of cutaneous neurofibromas, antihistamines may provide symptomatic relief. Uncontrolled anecdotal case reports have suggested that ketotifen, an antihistamine and mast cell stabilizer (not currently available in the United States), has provided relief from pruritus and pain and prevented the rapid growth of new neurofibromas.[53] Use of the CO_2 laser under general anesthesia to remove hundreds of cutaneous neurofibromas has resulted in markedly increased patient quality of life and decreased pain and pruritus.[54] The residua of a flat, smooth, depigmented scar was not felt to be an impediment to such surgery by most patients.

Plexiform Neurofibromas

Until recently, the treatment of plexiform neurofibromas was limited to surgical debulking either to improve cosmesis or to prevent loss of function (e.g., upper airway obstruction, blindness). Such surgery was highly limited in its efficacy. Complete resection was impossible given the highly infiltrative nature of these tumors, and tumor regrowth was common. Thus, there has been considerable interest in the development of nontraditional chemotherapy for use against these tumors. Not surprisingly, the design of studies to test the efficacy of such agents is fraught with complications. Plexiform neurofibromas are quite different biologically from more conventional solid neoplasms. Lack of growth after treatment may be part of the natural history of the tumor rather than a true therapeutic response. In addition, tumor burden may be difficult to quantify radiographically. Plexiform neurofibromas may spread along nerve roots, sending out multiple finger-like projections, which is quite different from a single, solid tumor mass.

The aforementioned difficulties not withstanding, several phase I and II chemotherapeutic trials are in progress. The agents currently being studied include (1) pirfenidone, an antifibrotic agent that decreases proliferation of fibroblasts and collagen matrix synthesis; (2) a farnesyl transferase inhibitor that downregulates the *ras* oncogene; (3) peginterferon alfa-2b; and (4) conventional chemotherapy with a combination of methotrexate and vinblastine. If any of these studies demonstrates potential efficacy, the role of screening imaging to detect hidden plexiform neurofibromas would need to be readdressed.

Optic Pathway Tumors

Once identified, OPTs should be followed by serial MRI and ophthalmologic examinations. Treatment should be initiated only after demonstration of clear radiographic progression or deteri-

oration of vision. The goal of treatment should be to preserve vision while minimizing the side effects of therapy. Radiation therapy, although a mainstay of treatment of progressive central nervous system neoplasms not associated with NF-1, is rarely necessary in NF-1 OPT and is associated with neurocognitive and endocrinologic side effects in very young children. Rather, chemotherapy with carboplatin and vincristine has proven effective in the management of these tumors.[55]

RELATED CONDITIONS

Neurofibromatosis Type 2

NF-2 is a condition with an autosomal dominant inheritance pattern characterized by bilateral vestibular schwannomas, other schwannomas (dorsal roots of the spinal cord, peripheral nerves, and cranial nerves), meningiomas (intracranial, intraspinal, and optic nerve sheath), ependymomas and gliomas of the central nervous system, and juvenile posterior subcapsular cataracts.[56] The estimated birth incidence is 1 in 40,000 live births. Although NF-2 is much less common than NF-1, its morbidity is much greater, with patients frequently becoming paralyzed and deaf. Use of the Manchester clinical diagnostic criteria[56] has led to increased sensitivity in establishing the diagnosis, particularly in those cases without a positive family history (Table 142-2). Approximately 60 percent of patients present in adulthood with hearing loss, tinnitus, or loss of balance. The younger the age at presentation, the greater the ultimate severity of the disease. Children are more apt to present with a non–eighth nerve tumor such as an optic nerve sheath meningioma. Ophthalmologic findings include juvenile posterior subcapsular cataracts (60 percent to 80 percent of patients), retinal hamartomas, epiretinal membranes, and optic nerve sheath meningiomas.[56]

Individuals with NF-2 may have several café-au-lait spots but rarely have more than six; intertriginous freckling is not seen. The characteristic cutaneous lesion of NF-2 is the cutaneous schwannoma (see eFig. 142-6.3 in on-line edition). It is a plaque-like, slightly raised lesion with a faint violaceous hue, occasionally with hair. Less commonly, cutaneous neurofibromas, indistinguishable from those seen in NF-1, may be found.

NF-2 is caused by mutations in a gene on chromosome 22, which encodes the membrane-related protein merlin, also known as *schwannomin*. As in NF-1, the NF-2 gene is a tumor suppressor gene that downregulates cellular growth. The exact cellular pathways by which this control is exerted have yet to be delineated.

TABLE 142-2
Manchester Clinical Diagnostic Criteria for Neurofibromatosis Type 2 (NF-2)

A patient has the clinical diagnosis of NF-2 if one of the following criteria is present:

A. Bilateral vestibular schwannomas
B. First-degree family relative with NF-2 and unilateral vestibular schwannoma or any two[a] of the following: meningioma, schwannoma, glioma, neurofibroma, or posterior subcapsular lenticular opacities
C. Unilateral vestibular schwannoma and any two[a] of the following: meningioma, schwannoma, glioma, neurofibroma, or posterior subcapsular lenticular opacities
D. Multiple meningiomas (two or more) and unilateral vestibular schwannoma and any two[a] of the following: schwannoma, glioma, neurofibroma, cataract

[a]"Any two" refers to two individual tumors or cataracts.

From Evans DGR et al: Management of the patient and family with neurofibromatosis 2: A consensus conference statement. *Br J Neurosurg* **19**:5, 2005.

Segmental Neurofibromatosis Type 1

The term *segmental neurofibromatosis* refers to NF-1 with manifestations, usually café-au-lait macules and neurofibromas, that are limited to one area of the body.[57] Ruggieri and Huson have proposed the term *mosaic localized NF-1* for these cases, as an acknowledgment that the pathogenesis of this condition is a post-conceptional mutation in the NF-1 gene leading to somatic mosaicism.[58] This has been confirmed in a patient in whom the mutant NF-1 allele was present in a mosaic pattern in cultured fibroblasts from a café-au-lait macule and absent in fibroblasts from normal skin.[59]

The vast majority of patients with segmental NF-1 have café-au-lait macules or intertriginous freckling limited to one area of the body. These individuals are at risk for developing complications of NF-1 in the affected area, most commonly neurofibromas. Localized manifestations of NF-1 other than café-au-lait macules, freckling, or cutaneous neurofibromas may also represent examples of somatic mosaicism. There have been numerous reports of isolated plexiform neurofibromas, including one case in which loss of heterozygosity of the NF-1 gene in Schwann cells from the tumor was demonstrated. Because only 50 percent of cases of tibial pseudarthrosis occur in the context of NF-1, the others may actually represent cases of segmental NF-1. Patients with other examples of segmental NF-1 include a child who had a unilateral optic pathway glioma that acted biologically like an NF-1–associated tumor and individuals with isolated sphenoid bone dysplasia.

Genetic counseling of patients with segmental NF-1 is problematic. Many of these patients are misdiagnosed as having NF-1, which leads to unnecessary anxiety and inappropriate genetic counseling. In addition, gonadal mosaicism for NF-1 has been demonstrated. Patients with segmental NF-1 have had offspring with complete NF-1.

Neurofibromatosis Type 1–Noonan Syndrome

It has been recognized that there are individuals who meet the diagnostic criteria for NF-1, yet have many features of Noonan syndrome, which is characterized by hypertelorism, ptosis, downsloping palpebral fissures, low-set and posteriorly rotated ears, webbed neck, pectus deformities, and short stature. Over 50 percent of children with Noonan syndrome have cardiovascular disease, most commonly pulmonary valve stenosis. Noonan syndrome is caused by a mutation in the gene *PTPN11*. Genetic testing has shown that most individuals with LEOPARD syndrome (see Chap. 73) also have mutations in *PTPN11*. One study documented mutations in the *NF-1* gene in 16 of 17 unrelated subjects who clinically had the NF-1–Noonan phenotype; no mutations in *PTPN11* were found.[60] Thus, it appears that the vast majority of cases of NF-1–Noonan syndrome are due to mutations in *NF-1*.

Familial Café-au-Lait Spots

The occurrence of multiple café-au-lait spots without other signs of NF-1 may be inherited as an autosomal dominant trait. This condition can be diagnosed reliably only when the patient is an older child or adult who clearly lacks other stigmata of NF-1 or when there is a first-degree relative with multiple café-au-lait spots and no other features of NF-1. Intertriginous freckling is absent in most families, although exceptions have been reported. Linkage to the NF-1 gene was reported in one family and excluded in two other families.[61–63]

Schwannomatosis

It had been noted for some time that there were patients who developed multiple schwannomas (see Chap. 127) but who failed to develop other manifestations of NF-2, particularly vestibular schwannomas.[64,65] Patients with this condition, now called *schwannomatosis*, develop multiple painful schwannomas within peripheral nerves and paraspinal nerve roots. The tumors most often start appearing during the second and third decades of life. Surgical treatment of individual lesions is often necessary to manage intractable pain. In contrast to individuals with NF-2, those with schwannomatosis have a normal life span. Before a diagnosis of schwannomatosis is made, it is extremely important to exclude the possibility of NF-2 by both genetic testing and MRI scanning to look for vestibular schwannomas. Although most cases of schwannomatosis are sporadic, autosomal dominant transmission of the syndrome has been documented.

CHAPTER 143

Ectodermal Dysplasias

Virginia P. Sybert

The ectodermal dysplasias (EDs) are a group of inherited disorders that share in common developmental defects involving at least two of the major structures classically held to derive from the embryonic ectoderm—hair, teeth, nails, sweat glands. Freire-Maia and Pinheiro[1] published an exhaustive review and classification system for these disorders using a numeric system of 1 (hair), 2 (teeth), 3 (nail), and 4 (sweat glands) for characterization. This system has little use in practice, although it did allow for a rational approach to a previously chaotic field. Freire-Maia and Pinheiro laid claim to more than 150 ectodermal disorders in their most recent compilation.[2] Several other classification schemes have been suggested. Each has limited clinical application but can help in ordering thinking about these disorders.[3,4] This chapter covers only the more common of these conditions and those in which ectodermal defects are likely to bring them to a dermatologist for diagnosis and medical attention.

Fig. 143-1 is an algorithm showing the approach to the diagnosis of EDs. The first step in the algorithm for making a specific diagnosis of an ED is to determine the presence of sweating (hidrotic) or absence of sweating (hypohidrotic/anhidrotic). The involvement of other ectodermal structures and of non-ectodermally derived tissues provide further branching points in a diagnostic hierarchy. Mode of inheritance may differ within a seemingly uniform diagnostic group, and care must be taken in evaluating family members before providing recurrence risks.

Within the last few years, causal genes have been identified in many of the EDs. Given continuing discoveries, the reader is directed to the following resources: http://www3.ncbi.nlm.nih.gov/Omim (Online Catalog of Mendelian Inheritance in Humans) and http://www.genetests.org (an up-to-date listing of laboratories offering molecular testing). The OMIM (Online Mendelian Inheritance in Man) numbers with each section heading refer to the numbering system at http://www3.ncbi.nlm.nih.gov/Omim. The National Foundation for Ectodermal Dysplasias (http://www.nfed.org) is a lay support group that has numerous informative pamphlets for families and physicians, as well as a strong advocacy program for dental care, insurance coverage, and research.

HYPOHIDROTIC ECTODERMAL DYSPLASIA [ANHIDROTIC ECTODERMAL DYSPLASIA, CHRIST-SIEMENS-TOURAINE SYNDROME; OMIM #305100]

Historical Aspects

Epidemiology

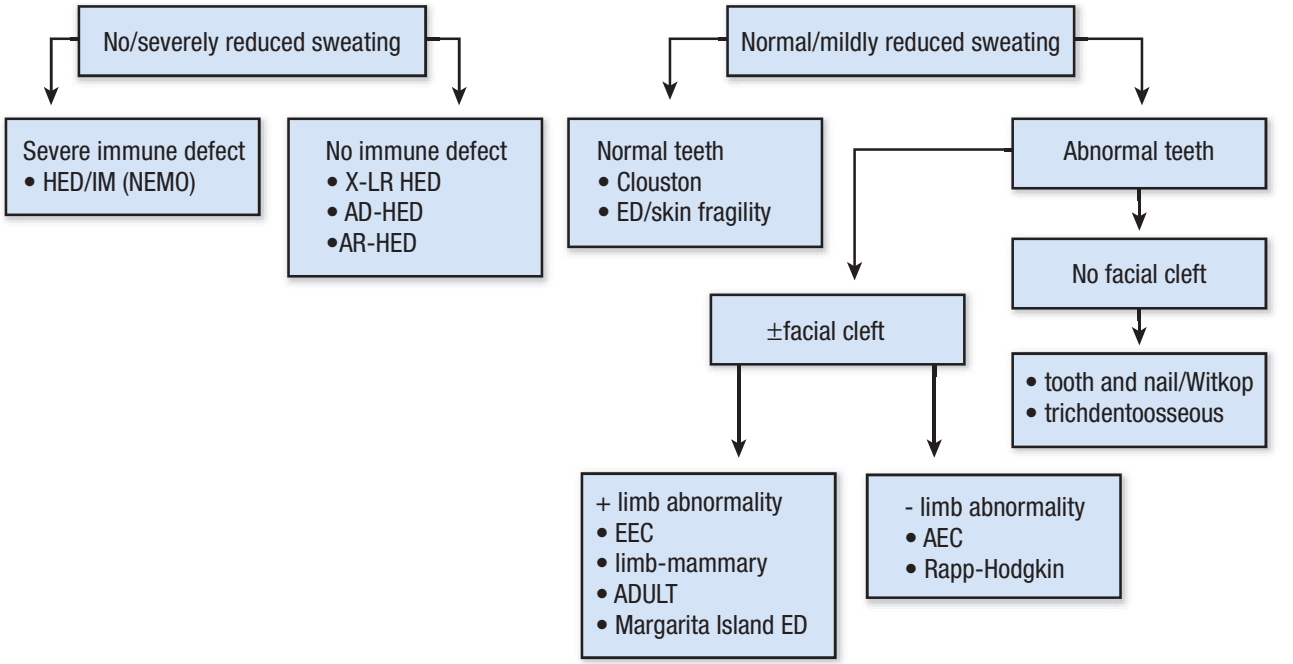
X-linked hypohidrotic ED (X-LHED) occurs in all racial groups and is thought to have an incidence at birth of approximately 1 in 100,000 males.[5]

Etiology, Pathogenesis, and Genetics

X-LHED results from alterations in the gene *ectodysplasin* (*EDA, EDA1*) located at Xq12-13.[6] It codes for a transmembrane protein, ectodysplasin, which is composed of 391 amino acids and has

ECTODERMAL DYSPLASIAS AT A GLANCE

- A group of inherited disorders characterized by developmental abnormalities in two or more ectodermal structures.
- These include hair, teeth, nails, and sebaceous and sweat glands.
- There may be abnormalities in non-ectodermal structures and functions.
- Distinction is based on clinical features, mode of inheritance, and molecular findings.
- Clinically distinct disorders may be due to different mutations in the same gene (allelic heterogeneity), and clinically similar conditions may be due to mutations in different genes (locus heterogeneity).



▲ **FIGURE 143-1** Approach to the diagnosis of ectodermal dysplasias. AD = autosomal dominant; ADULT = *a*cro-*d*ermato-*u*ngual-/acrimal-*t*ooth syndrome; AEC = *a*nkyloblepharon filiforme adnatum–*e*ctodermal dysplasia–*c*left palate syndrome; AR = autosomal recessive; ED = ectodermal dysplasia; EEC = ectrodactyly–ED–cleft lip/palate syndrome; HED = hypohidrotic ectodermal dysplasia; IM = immune defects; X-LR = X-linked recessive.

alternative splicing forms, the significance of which is not known. A multitude of mutations in this gene causing X-LHED has been identified. There does not appear to be a correlation between the nature of the mutation and the clinical features[7] (i.e., to date, there have been no phenotype-genotype correlations). Interfamilial and intrafamilial variation occurs to a mild degree. Ectodysplasin belongs to the tumor necrosis factor family and plays a role in regulation of the formation of ectodermal structures. It forms trimers and is expressed in keratinocytes, the outer root sheath of hair follicles, and sweat glands. It localizes to the lateral and apical surfaces of cells.

As is typical of X-linked recessive disorders, expression is full blown in affected males, and carrier females may express none, some, or all of the features of the disorder, often in a patchy distribution. The disorder can be inherited from a carrier mother or newly occur in an affected individual as the result of a de novo mutation. Approximately 70 percent of affected males inherited the mutation from a carrier mother. Between 60 percent and 80 percent of carrier females express some clinical signs of the disorder; the most frequent are patchy hypotrichosis and hypodontia.

Mutations in an autosomal gene, *EDAR,* mapped to 2q11-q13, have been implicated in an autosomal dominant form of hypohidrotic ectodermal dysplasia (HED; OMIM #129490) and in an autosomal recessive form (OMIM #224900)[8] that are clinically similar to X-LHED. Both these entities are much rarer. EDAR acts as a receptor for ectodysplasin. Mutations in yet another gene, *EDARADD,* have been identified recently in autosomal recessive HED.[9] EDARADD is an intracellular adaptor protein that assists in transmitting the signal from the activated EDA receptor to the nucleus of the cell. Individuals with autosomal dominant HED appear to have a milder defect in the ability to sweat.

Certain mutations in the X-linked *NEMO* gene, which causes incontinentia pigmenti (IP) in females, have been shown to result in males with HED and immune defects (see Chap. 144).[10,11]

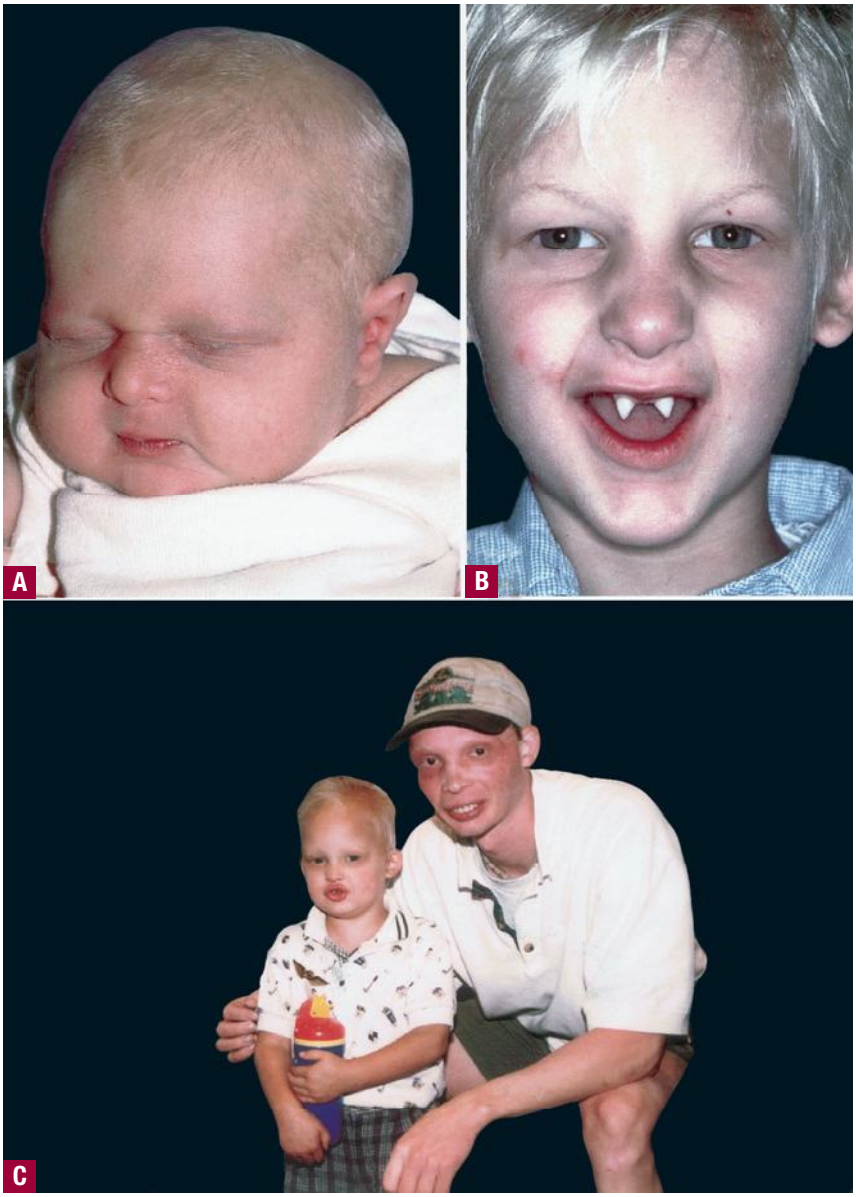
Clinical Manifestations

DERMATOLOGIC Affected males may present at birth with a collodion membrane or with marked scaling of the skin,[13] similar to congenital ichthyosis. Scalp hair is usually sparse, fine, and blonde. It may thicken and darken at puberty, and secondary sexual hair may be normal. Other body hair is usually sparse or absent.

The ability to sweat is significantly compromised, and most affected males have marked heat intolerance. Sweat pores are usually undetectable on physical examination, and fingerprint ridges are effaced. The inability to sweat adequately in response to environmental heat results in an elevation of core temperature and bouts of unexplained high fevers, usually leading to an extensive workup for infectious disease, malignancy, or autoimmune disease before the correct diagnosis is recognized. In an older series of patients, mental retardation was reported as a feature of X-LHED. Currently, this is believed to have been due to damage from prolonged high fevers and convulsions and not to be an intrinsic feature of the disorder.

The nails are usually normal; reports of thin, fragile nails are not convincing, and nail dystrophy plays little role in the burden of the disorder.[14] Periorbital wrinkling and hyperpigmentation are typical and often present, albeit unappreciated, at birth (Fig. 143-2A–C). Eczema plagues more than two-thirds of affected males and is often difficult to manage. Hyperplasia of sebaceous glands, particularly on the face, can develop over time and appear as small, pearly, flesh-colored to white papules that may resemble milia.

SYSTEMIC ASSOCIATIONS Hypodontia, oligodontia, or anodontia are invariable features of X-LHED in affected males. Appreciation of hypoplastic gum ridges in an affected infant can be an early clue to the diagnosis of the disorder. Teeth that do erupt are usually peg-shaped and small (see Fig. 143-2B). The facies of the disorder are characterized by frontal bossing and a depressed midface with a



▲ **FIGURE 143-2** Hypohidrotic ectodermal dysplasia. **A.** Newborn with periorbital wrinkling, beaked nose. Diagnosis would not be suspected unless there were a positive family history. **B.** Peg-shaped teeth; fine periorbital wrinkling can be appreciated. (From Sybert VP: *Genetic Skin Disorders.* New York, Oxford University Press, 1997.) **C.** Two unrelated males with X-linked hypohidrotic ectodermal dysplasia; adult is wearing dentures; periorbital wrinkling and hyperpigmentation are evident. (Used with permission from the National Foundation for Ectodermal Dysplasias.)

saddle nose and full, everted lips. Otolaryngologic manifestations include thick nasal secretions and impaction, ozena, sinusitis, recurrent upper respiratory tract infections and pneumonias, decreased saliva production, hoarse voice, and an increased frequency of asthma. Gastroesophageal reflux and feeding difficulties may be a problem in infancy. Preliminary studies suggest that there may be failure to thrive in infancy and early childhood in as many as 20 percent to 40 percent of affected boys, with catch-up growth seen later.[15] Although several reviews have suggested that infant mortality may be increased, unbiased confirmatory data are lacking.

Female carriers for X-LHED may be affected as severely as males or show few, if any, signs of the disorder (Fig. 143-3). Heat intolerance, if present, is usually mild; adult carrier women comment that they do not sweat much or that they do not like very warm weather, but it is unusual for a female to experience fever due to inability to sweat. Typically, a few teeth may be peg-shaped or missing and scalp hair may be patchy or thin. Careful examination of the skin of carrier females often reveals a diminution in or patchy distribution of sweat pores. This sometimes can be appreciated readily just by magnification of fingertip pads or may require more sophisticated sweat testing.

VARIANTS As noted in Etiology, Pathogenesis, and Genetics, the autosomal dominant and autosomal recessive forms of HED are similar, although the autosomal dominant form may be milder. The X-linked form is by far the most common and always should be the diagnosis of default in a sporadic case.

Histopathology

The epidermis is thinned and flattened. There is a reduction in the number of sebaceous glands and hair follicles. Eccrine glands are absent or incompletely developed. Histologic evaluation of the skin is usually not necessary.

Diagnosis and Differential Diagnosis (Box 143-1)

The scaling skin at birth may result in a misdiagnosis of congenital ichthyosis. Repeated bouts of fever may be thought to have an infectious source. The diagnosis of HED is recognized readily when expected, such as when an at-risk male is born into a family in which the disorder is known to segregate. Examination for sweat pores and a Panorex view of the jaw leads quickly to the correct diagnosis. In an isolated, fully expressing female, the autosomal dominant and recessive forms of HED need to be considered. Family history, examination of parents, and molecular testing may be helpful. Mothers always should be examined fully to detect mild manifestations of the X-linked form. Molecular testing is not indicated for clinical diagnosis in most instances.

Treatment

Maintenance of cool ambient temperatures is vital to prevent hyperpyrexia. Most children do well with simple measures, such as wet T-shirts, air conditioning in home and school, wet headbands, etc. Occasionally, cooling vests allow a broader range of participation in sports and vigorous physical activity in warm climates.

Dental restoration is of primary importance, and early implementation of dentures and ultimate use of dental implants are mainstays of treatment.

Management of otolaryngologic complications, asthma, and recurrent infec-

▲ **FIGURE 143-3** Hypohidrotic ectodermal dysplasia. **A.** Female carrier of X-linked hypohidrotic ectodermal dysplasia with two affected sons. (Used with permission from the National Foundation for Ectodermal Dysplasias.) **B.** Two sisters with X-linked hypohidrotic ectodermal dysplasia manifesting to different degrees. Note periorbital hyperpigmentation, full everted lips, and sculpted noses. (From Sybert VP: *Genetic Skin Disorders*. New York, Oxford University Press, 1997.)

tions needs to be individualized. The eczema may be quite refractory to care.

The National Foundation for Ectodermal Dysplasias (http://www.nfed.org) has several pamphlets for individuals and professionals dealing with diagnosis and treatment.

Although infancy and childhood are complicated by many problems, most individuals with HED lead adult lives that allow them to function successfully in society. Heat intolerance seems to decrease due to the development of some ability to sweat in adolescence or to the development of common sense and adaptation of lifestyle, or both.

HIDROTIC ECTODERMAL DYSPLASIA (CLOUSTON SYNDROME; OMIM #129500)

Epidemiology

Hidrotic ED was first described in a French-Canadian kindred.[16] It has been reported in other ethnic groups, but the majority of affected individuals can trace their ancestry back to an original French-Canadian settler.

Box 143-1

Differential Diagnosis of Some Diagnostic Features of Ectodermal Dysplasias

- Collodion membrane
  - Lamellar exfoliation of the newborn
  - Neutral lipid storage disease
  - Non-bullous congenital ichthyosiform erythroderma
  - Lamellar ichthyosis
  - Trichothiodystrophy
  - Storage diseases (e.g., Gaucher)
  - Chondrodysplasia punctata
- Ankyloblepharon filiforme adnatum (AFA)
  - Lethal popliteal pterygium syndrome
  - Popliteal pterygium syndrome
  - Isolated AFA
  - AFA and cleft palate
- Hypodontia
  - Isolated hypodontia
  - Incontinentia pigmenti
- Skin fragility/erosions
  - Epidermolysis bullosa disorders
  - Incontinentia pigmenti
  - Acrodermatitis enteropathica
  - Plakophilin/ectodermal dysplasia
  - Congenital erythropoietic porphyria
  - LOGIC (*l*aryngeal and *o*cular *g*ranulation tissue *i*n *c*hildren from the Indian subcontinent)
- Atrophic streaks
  - Incontinentia pigmenti—stage 4
  - MIDAS (*mi*crophthalmia, *d*ermal *a*plasia, and *s*clerocornea)
  - Focal dermal hypoplasia

Etiology, Pathogenesis, and Genetics

The disorder is caused by mutations in a connexin gene, *GJB6* or *connexin-30*.[17] Different mutations in the same gene are responsible for a form of nonsyndromic autosomal dominant deafness and at least one patient with *k*eratitis-*i*chthyosis-*d*eafness (KID syndrome) (see Chap. 47). Other connexin genes show similar variability in mutation: disease correlations [e.g., mutations in *connexin-31 (GJB3)*] can cause either erythrokeratodermia variabilis (see Chap. 47) or late-onset autosomal deafness. The pathway by which allelic mutations result in such different diseases is not yet known.

Hidrotic ED is autosomal dominant with variable expression (the degree of severity can vary within and between families). Males and females are affected in equal numbers and to equal degree.

▲ **FIGURE 143-4** Hidrotic ectodermal dysplasia (Clouston syndrome) **A.** Patchy alopecia in adult. Coarseness of hair can be appreciated. **B.** Palmar hyperkeratosis. **C.** Nail dystrophy.

The gene maps to the centromeric region of the long arm of chromosome 13.

Clinical Manifestations

The scalp hair is wiry, brittle, and pale, and there is often patchy alopecia (Fig. 143-4A). This progresses in adult life and may lead to total alopecia. Body and facial hair are affected. The nails may be milky white in infancy and early childhood, gradually thickening and becoming dystrophic. The nail plates in adults are thick, short, slow-growing, separate distally from the nail bed (see Fig. 143-4C), and may cause pain. Anonychia has been reported. Not all the nails are necessarily affected to the same degree. Progressive palmar/plantar hyperkeratosis is common (see Fig. 143-4B). In contrast to HED, sweating is normal, as are the teeth. Oral leukoplakia has been reported. Conjunctivitis and blepharitis, possibly due to poor function of sparse eyelashes, are common.

Histopathology

The thickened palms and soles show orthohyperkeratosis with a normal granular layer. On electron microscopy, an increase in the number of desmosomes in the cells of the stratum corneum is found. The hair shows nonspecific changes.

Diagnosis and Differential Diagnosis (see Box 143-1)

The diagnosis is straightforward. The involvement of nails and hair and palmar/plantar thickening, in the absence of other signs of ED, are reasonably specific. Other palmar/plantar hyperkeratoses do not have similar hair changes. Orofacial clefting differentiates other forms of autosomal dominant hidrotic ED, such as ankyloblepharon filiforme adnatum (AFA)–ED–cleft palate (AEC) syndrome or Rapp-Hodgkin syndrome. Although the nail changes are similar to those of pachyonychia congenita, the hair changes are distinctive.

Treatment

Occasionally, ablation of the nail matrix is necessary for relief of pain. Wigs may provide cosmetic benefit. Treatment of the thickened palms and soles is not specific and minimally successful.

ANKYLOBLEPHARON FILIFORME ADNATUM-ECTODERMAL DYSPLASIA-CLEFT PALATE SYNDROME (HAY-WELLS SYNDROME; OMIM #106260)

Epidemiology

Described first in 1976,[18] Hay-Wells syndrome has been found in ethnically and geographically disparate families.

Etiology, Pathogenesis, and Genetics

The disorder is caused by mutations in the tumor-suppressor gene *p63*, a gene that has been implicated in the pathogenesis of ectrodactyly–ED–cleft lip/palate (EEC) syndrome, limb-mammary syndrome, *a*cro-*d*ermato-*u*ngual-*l*acrimal-*t*ooth (ADULT) syndrome, and other autosomal dominant forms of ED. Mutations that cause EEC and AEC cluster in different regions of the gene.[19,20]

AEC syndrome is an autosomal dominant disorder with complete penetrance and variable expression.

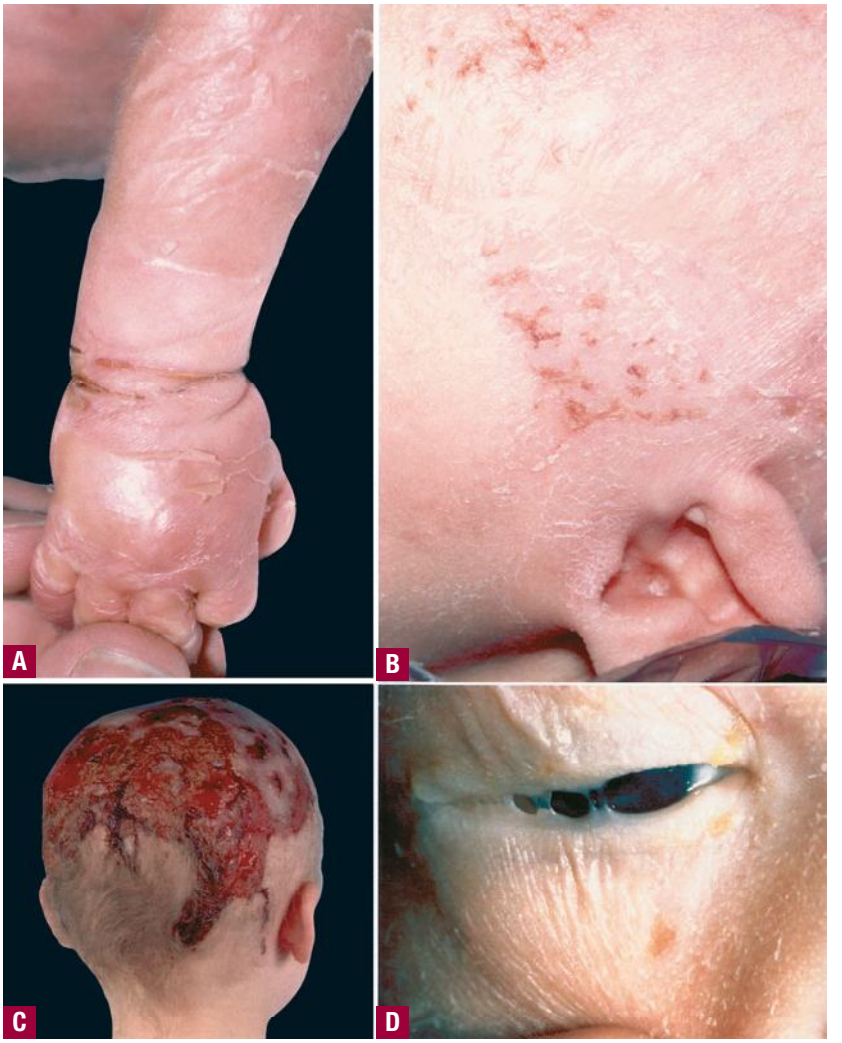
Clinical Features

DERMATOLOGIC Ninety percent of affected infants present at birth with shiny red, cracking, peeling skin and superficial erosions, similar to the appearance of a collodion membrane (Fig. 143-5A).[14] This sheds within a few weeks, and the skin underneath is dry and thin. The scalp is almost invariably involved, and many affected individuals are plagued by a chronic erosive dermatitis with abnormal granulation tissue on the scalp (see Fig. 143-5B,C).[21] Recurrent bacterial infection of the scalp is common. Patchy alopecia is the rule, and the scalp hair that is present is often wiry, coarse, and light in color. Sparseness to absence of body hair is typical. AFA—strands of skin between the eyelids—is seen in approximately 70 percent of affected infants (see Fig. 143-5D). These may tear spontaneously or require surgical lysis. Lacrimal duct atresia or obstruction is common. The nails may be normal, hyperconvex and thickened, absent, or partially dystrophic, and all changes can be found in a single individual. Sweating is usually normal, although some affected individuals describe subjective heat intolerance. Supernumerary nipples and ectopic breast tissue are seen occasionally, as is mild cutaneous syndactyly of toes two and three.

SYSTEMIC ASSOCIATIONS Cleft palate, with or without cleft lip, occurs in 80 percent of reported cases. There may be hypodontia with missing or misshapen teeth. Malformed auricles have been described in some. Recurrent otitis media and secondary conductive hearing loss are common and may be consequences of the cleft palate rather than primary. Hypospadias has been described in several affected males.

Histopathology

Some patients show a decrease in the number of sweat glands. Electron microscopy of hairs shows a defective cuticular structure. There is a decrease in the keratins of the basal and suprabasal layers of the epidermis and disorganized keratin filaments in the stratum corneum.



▲ **FIGURE 143-5** Ankyloblepharon filiforme adnatum–ectodermal dysplasia–cleft palate (Hay-Wells) syndrome. **A.** Newborn with peeling collodion membrane. **B.** Superficial erosion and thin skin of scalp in same patient, age 5 days **C.** Abnormal granulation tissue on scalp in older affected female. **D.** Fine strands of tissue (ankyloblepharon filiforme adnatum) between eyelids.

Diagnosis and Differential Diagnosis (See Box 143-1)

Among the autosomal dominant EDs associated with clefting, Rapp-Hodgkin syndrome lacks the ankyloblepharon and has a much lower occurrence of scalp involvement. Rapp-Hodgkin is also due to mutations in *p63*. Although the disorders have clinical distinctions, there is significant overlap and the utility of splitting rather than lumping is unclear.[22] The EEC syndrome is characterized by bony hand and foot abnormalities not seen in AEC and also lacks the ankyloblepharon. The peeling, eroded skin of the newborn can lead to misdiagnosis of epidermolysis bullosa or congenital ichthyosis. AFA can occur in the absence of syndromic associations, and strands of tissue between the eyelids have been seen in several forms of arthrogryposis, in association with chromosomal aneuploidy, and in CHANDS (*c*urly *h*air, *a*nkyloblepharon, and *n*ail *d*ysplasia *s*yndrome), an autosomal recessive form of ED.

Treatment and Prognosis

Light emollients should be used until the collodion membrane sheds. Ankyloblepharon may require surgical lysis. Ongoing ocular hygiene is important. Vigorous and meticulous but gentle scalp care with prompt treatment of infection is extremely important. Grafting of skin to the scalp is not often successful. Clefting requires a team approach for repair and follow-up for secondary issues, such as feeding difficulties, speech defects, orthodontia, and ear infections.

ECTRODACTYLY ECTODERMAL DYSPLASIA–CLEFT LIP/PALATE SYNDROME; SPLIT HAND–SPLIT FOOT–ECTODERMAL DYSPLASIA–CLEFT LIP/PALATE SYNDROME (OMIM #604292)

Historical Aspects and Epidemiology

EEC syndrome is an ED classified as a multiple congenital anomaly syndrome because it has major involvement of structures other than those derived ectodermally. EEC syndrome has occurred in all racial groups worldwide.

Etiology, Pathogenesis, and Genetics

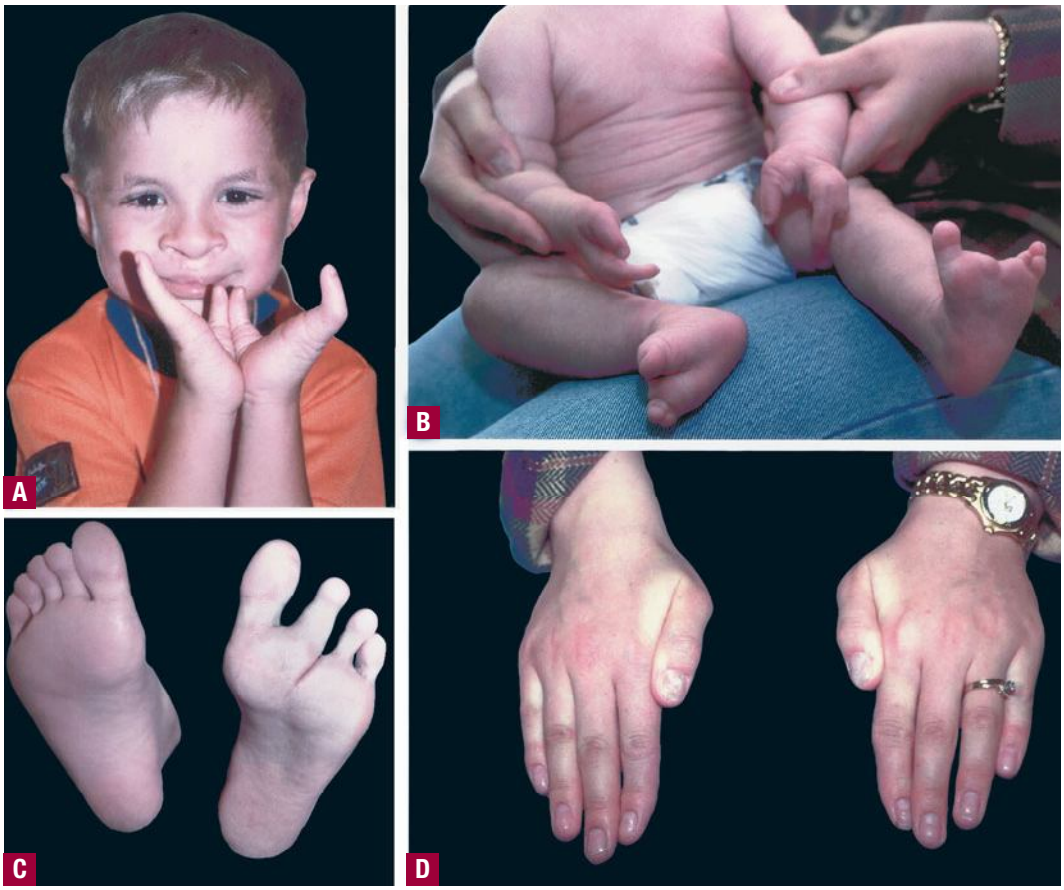
Mutations in *p63*, a tumor-suppressor gene mapped to 3q27, have been found in most, but not all, individuals with EEC syndrome.[23] The gene is expressed widely, including in the basal cells of proliferating epithelial tissues. Mutations in the same gene cause some cases of isolated split hand–split foot disease, limb-mammary syndrome, the ADULT (OMIM #103285) syndrome, Hay-Wells syndrome and Rapp-Hodgkin syndrome. There appear to be genotype-phenotype correlations.[24] All alterations identified thus far in Hay-Wells syndrome have been missense mutations in the sterile α motif domain; in EEC syndrome, the majority of mutations result in single-amino-acid substitutions in the DNA-binding domain.[15] Frameshift mutations in *p63* cause limb-mammary syndrome, in which ectodermal structures other than the mammary gland often, but not always, appear normal. Among three unrelated families with ADULT syndrome, all shared the same point mutation in *p63*.[25]

EEC syndrome is an autosomal dominant disorder with variable expression and reduced penetrance. Intrafamilial and interfamilial differences in severity are common.

Clinical Manifestations

DERMATOLOGIC The ED may be quite mild. The hair is usually blond, coarse, and dry. It may be sparse and slow growing. Axillary and pubic hair also may be affected. The nails are dystrophic in approximately four-fifths of individuals with transverse ridging, pitting, and slow growth. Dry skin and thickening of the palms and soles can occur. Sweating is usually normal.

SYSTEMIC ASSOCIATIONS Hypodontia and premature loss of secondary teeth and



◀ **FIGURE 143-6** Ectrodactyly–ectodermal dysplasia–clefting syndrome. **A.** Mild thinness of hair. (Used with permission from the National Foundation for Ectodermal Dysplasias.) **B.** Hands and feet of affected infant. **C,D.** Feet and hands of parent of infant in (**B**) demonstrating variability of expression both among limbs and between family members. Note the nail dystrophy, especially evident on the thumbs.

the dental abnormalities associated with clefting are found in most affected individuals. Lacrimal gland abnormalities are common.

The major distinguishing feature of EEC syndrome is ectrodactyly—abnormal development of the median rays of the hands and feet (Fig. 143-6A–C). The feet are involved more frequently than the hands, and there may be asymmetry of involvement (see Fig. 143-6A–C). Cleft palate, with or without cleft lip, occurs in 70 percent to 100 percent depending on the series.[26,27] Secondary conductive hearing loss is frequent. Genitourinary abnormalities that include hydronephrosis, and structural renal or genital malformations affect one-third or more of persons with EEC syndrome. Although mental retardation has been reported, it is not believed to be an inherent feature of the disorder.

Diagnosis and Differential Diagnosis

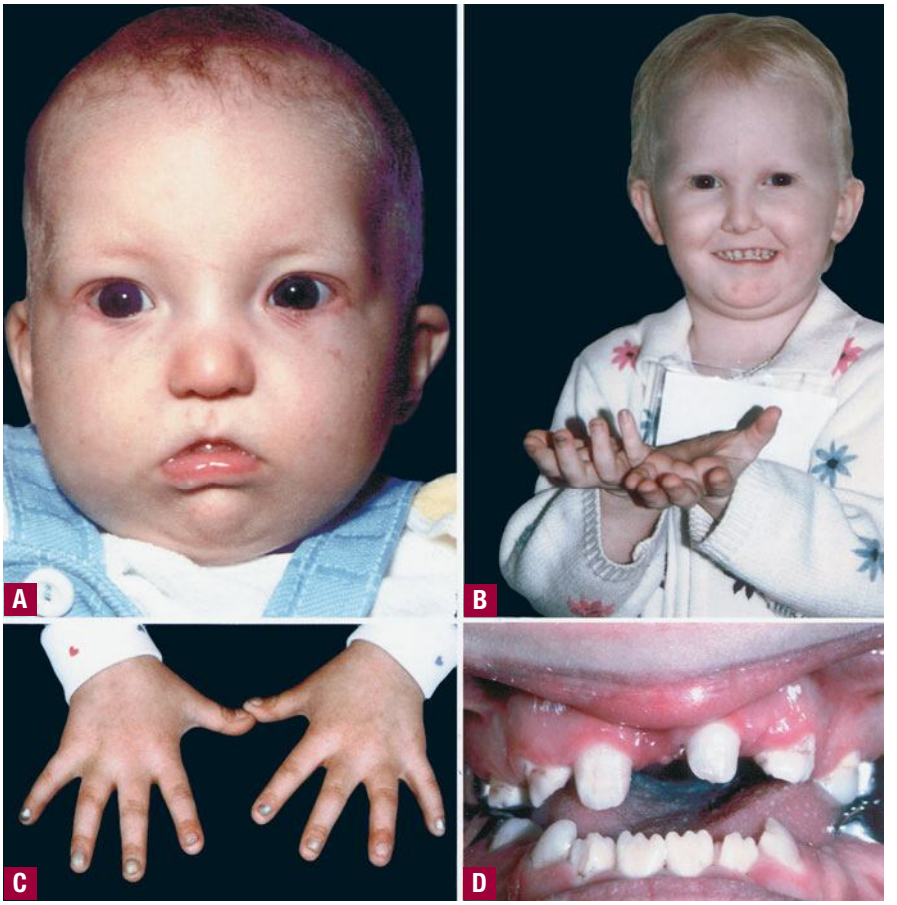
Among disorders with limb defects that need to be considered in the differential diagnosis of EEC syndrome are the odontotrichomelic syndrome (OMIM #273400), in which there are severe absence deformities of the limbs, and aplasia cutis congenita with limb defects (Adams-Oliver syndrome, OMIM #100300), which does not have clefting or ectodermal defects other than absence of skin. Cutis marmorata telangiectatica congenital (see Chap. 106) has been described in some individuals with Adams-Oliver syndrome. Other EDs with clefting include Hay-Wells syndrome, Rapp-Hodgkin syndrome, and limb-mammary syndrome, all of which, in at least some families, appear to be allelic to EEC syndrome. Ectrodactyly with cleft palate without ED (OMIM #129830) also may be a distinct entity. There appear to be some families with EEC in whom linkage studies have suggested other causal genes located at different chromosomal loci. These genes have not yet been identified. Prenatal diagnosis by ultrasound for detection of limb abnormalities is unreliable; molecular testing may prove useful in some families.

Treatment

As for other EDs with orofacial clefting and ophthalmologic involvement, management requires a team approach. Similarly, treatment for the limb defects must be individualized. Renal ultrasound and a high index of suspicion for urinary tract problems may be appropriate.

RAPP-HODGKIN SYNDROME (OMIM #129400)

Described in 1968, Rapp-Hodgkin syndrome is an autosomal dominant disorder that shares in common with Hay-Wells syndrome cleft palate with or without cleft lip, hypohidrosis usually without episodes of frank hyperpyrexia, abnormal hair with pili torti or pili trianguli et canaliculi and progressive balding, and nail dystrophy.[28,29] The face in Rapp-Hodgkin syndrome is striking, with a short nasal columella and maxillary hypoplasia, thin upper lip, and full lower lip (Fig. 143-7A,B). The nails are thick and short, worsening with age (see Fig. 143-7C). The teeth may be conical and prone to caries (see Fig. 143-7D). The lacrimal puncta are aplastic in almost one-third of affected individuals. Hypospadias has been reported in two-fifths of affected males; labial hypoplasia and absence of the opening of the vagina have been reported in a single female. These features are also reminiscent of the EEC syndrome. Rapp-Hodgkin syndrome has proven to be due to mutations in *p63*. Scalp involvement with breakdown and granulation tissue formation appears to be far less common in patients with Rapp-Hodgkin than in AEC syndrome, and AFA is rare. Treatment is the same for these similar disorders.



▲ **FIGURE 143-7** Rapp-Hodgkin syndrome. **A.** Affected infant at 5 months. **B.** Fine, blond, sparse hair; beginnings of nail changes on middle finger of right hand. (Used with permission from the National Foundation for Ectodermal Dysplasias.) **C.** Abnormal nails in same patient as (**A**), at age 4 and one-half years with thickened and friable nail plates. (From Sybert VP: *Genetic Skin Disorders*. New York, Oxford University Press, 1997.) **D.** Abnormal dentition, missing teeth, and peg teeth.

TOOTH AND NAIL SYNDROME (WITKOP SYNDROME; HYPODONTIA WITH NAIL DYSGENESIS; OMIM #189500)

Historical Aspects and Epidemiology

Etiology, Pathogenesis, and Genetics

A nonsense mutation in *MSX1*, a gene expressed in the developing teeth and nail beds in mice, has been found in one family with Witkop syndrome.[31] Other mutations in *MSX1* have been associated with isolated tooth agenesis or tooth agenesis with cleft palate. Tooth and nail syndrome is autosomal dominant, with variable expression and intrafamilial variability.

Clinical Manifestations

DERMATOLOGIC The nails are thin, small, and friable and may show koilonychia at birth. Toenails are usually more severely involved than fingernails (Fig. 143-8B). Nail changes improve with age and may be unappreciated in affected adults. A few individuals have reported thin, fine hair.

SYSTEMIC ASSOCIATIONS The primary teeth usually are unaffected, although they may be small. The secondary teeth may fail to erupt, and there can be partial or total absence (see Fig. 143-8A). The mandibular incisors, second molars, and maxillary canines are missing most often. No other ectodermal structures are affected.

Diagnosis and Differential Diagnosis

This is an easy condition to miss. The nail changes may be subtle. The tooth abnormalities may be mild enough to escape detection by a physician. The lack of associated features, either dermatologic or systemic, readily distinguish Witkop syndrome from other EDs. There is a presumed autosomal recessive disorder characterized by taurodontia (teeth with an elongated body and pulp chamber and short roots), absent teeth, sparse hair, and hypoplastic nails that appears similar.

Treatment and Prognosis

The nails usually require no treatment. Restorative dentistry is important.

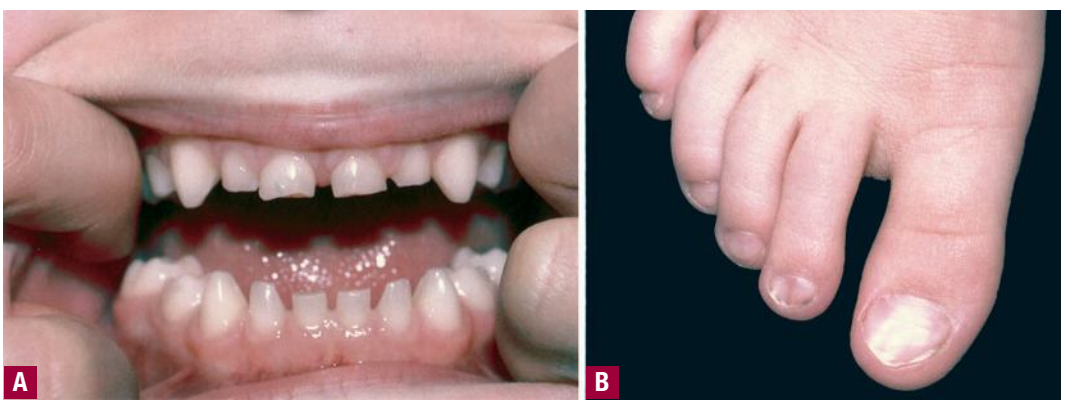
FOCAL DERMAL HYPOPLASIA OF GOLTZ (OMIM #305600)

Epidemiology

Focal dermal hypoplasia of Goltz (FDH), first described in 1934, received its name from a report by Goltz and co-authors[32] of three patients. Subsequently, there have been over 200 case reports published.

Etiology, Pathogenesis, and Genetics

Focal dermal hypoplasia is an X-linked dominant disorder, usually lethal in



◀ **FIGURE 143-8** Tooth-nail syndrome. **A.** Primary teeth still in place; failure of adult teeth to erupt. **B.** Dystrophic toenails with flattening of nail plates.

males. Case reports of males with the condition are believed to be due to mosaicism for postzygotic mutations (as is true for incontinentia pigmenti); the presence of some normal cells allows survival in the male. The mutated gene is *PORCN*, the human homologue of the porcupine gene in drosophila. PORCN is thought to be important for palmitoylation and secretion of Wnt protein, a key regulator of the development of skin and bone.[33, 34]

Clinical Manifestations

DERMATOLOGIC The skin changes of FDH are the primary diagnostic features. There is linear, punctate, streaky cribriform atrophy (Fig. 143-9) with telangiectasia. The cribriform atrophy is marked by tiny ice pick–like depressions in the skin. These are distributed along the lines of Blaschko. Areas of thinned to absent dermis are irregularly distributed and the resultant herniations of fat appear as yellow-pink excrescences on the skin surface (see Fig. 143-9C). These are easily depressed. Papillomas that may be fleshy or vascular develop throughout life and favor the perigenital, perioral, intertriginous, and mucosal surfaces.

Other dermatologic features include patchy alopecia, brittle or sparse hair, and palmar and plantar hyperkeratoses. Some individuals have had hyperhidrosis and some have had aplasia cutis congenita.

SYSTEMIC ASSOCIATIONS The other organ systems most frequently involved in FDH are the skeletal, central nervous system, teeth, and eyes. Microphthalmia and coloboma are common and the diagnosis of FDH should prompt a full ophthalmologic evaluation. Oligodontia, tooth dysplasia, and enamel defects are common. The skeletal abnormalities are too numerous to list; the more common are vertical banding of the bones (osteopathia striata), syndactyly (both cutaneous and bony), asymmetry, and short stature. Mental retardation has been reported in approximately 15 percent of cases.

Defects in other organ systems have been described in a minority of cases, including cardiac defects, abdominal wall defects, and renal malformations. It is not certain that these are inherent features of FDH.

Diagnosis and Differential Diagnosis (See Box 143-1)

The diagnosis of FDH is relatively straightforward. Cribriform atrophy has been described in X-linked dominant Conradi-Hünermann syndrome (chondrodysplasia punctata), but ichthyosis is not a feature of FDH, and fat herniation is not part of Conradi-Hünermann. The streaky distribution of the atrophic lesions of IP is similar, as are the other system malformations, but the blistering, hyperkeratosis, and hyperpigmentation of IP are not found in FDH. In microphthalmia and linear skin defects/microphthalmia, dermal aplasia, sclerocornea, the skin defects are limited to the head and neck; there is atrophy and scarring of the skin more similar to aplasia cutis congenita and not dermal atrophy alone. The disorders do share similar ocular abnormalities.

▲ **FIGURE 143-9** Focal dermal hypoplasia of Goltz. **A.** Streaky and patchy involvement in the newborn. Note similarity to the distribution of lesions in incontinentia pigmenti. **B,C.** Same girl at age 2 showing atrophy and fat herniation. **D.** Now a young adult, erythema and atrophy, with dryness and scale, predominate. (From Sybert VP: *Genetic Skin Disorders*. New York, Oxford University Press, 1997.)

Treatment and Prognosis

There is no specific treatment for the dermatologic and systemic features of FDH. Papillomas can be excised if they interfere with function. Use of vascular lasers to decrease the erythema of telangiectatic areas may have cosmetic benefit. As with most X-linked dominant disorders, clinical involvement varies considerably, and the range in severity is marked. This makes prognostic counseling difficult early in infancy, and usually it is wiser to counsel patience and reassurance until the extent to which there is systemic involvement becomes clear. It is important to inquire about the family history of lost pregnancies (a distorted male-female ratio in offspring and increased pregnancy loss are clues to the mother being a carrier). Both mothers and fathers should be examined carefully; fathers may have subtle features, and, presumably, represent individuals with postzygotic mutations for the FDH gene.

CHAPTER 144

Genetic Immunodeficiency Diseases

Amy S. Paller
Melissa Abrams

Immunodeficiency disorders may be associated with a variety of cutaneous abnormalities, and recognition of these clinical features may allow an early diagnosis of primary immunodeficiency. Cutaneous abnormalities may include cutaneous infections, atopic- or seborrheic-like dermatitis, macular erythemas, alopecia, poor wound healing, purpura, petechiae, telangiectasias, pigmentary dilution, cutaneous granulomas, extensive warts, angioedema, and lupus-like changes (Table 144-1). Other clinical features often include failure to thrive, visceral infection, autoimmune disorders, connective tissue/rheumatologic diseases, allergic reactions, and neoplasias.

CLINICAL FINDINGS

In general, immunodeficiency should be suspected when patients have recurrent infections of increased duration and severity, particularly with unusual organisms. Incomplete clearing of infections, unexpected or severe complications of infection, or poor response to antibiotics may be associated.[1] Affected infants often grow poorly (failure to thrive). The most common non-cutaneous abnormalities are infections, diarrhea, vomiting, hepatosplenomegaly, arthritis, adenopathy or paucity of lymph nodes/tonsils, and hematologic abnormalities.

The classification of genetic immunodeficiency disorders includes (1) antibody deficiencies, (2) cellular deficiencies, (3) combined antibody and cellular deficiencies, (4) disorders of phagocytosis and cell killing, and (5) complement defects. The characteristic clinical signs of each group suggest that proper classification and laboratory tests may be used to confirm the diagnosis. The laboratory testing and clinical patterns of illness associated with each group of immunodeficiency disorders that allow their differential diagnosis are outlined in Table 144-2 and Fig. 144-1. Most important in the differential diagnosis of all genetic immunodeficiency disorders is human immunodeficiency virus (HIV) infection. In addition to the lack of HIV antigen as detected by polymerase chain reaction in patients with genetic immunodeficiency, other features help to differentiate the disorders. Patients with HIV infection tend to show an inverted CD4/CD8 ratio and hypergammaglobulinemia, in contrast to the hypogammaglobulinemia of many patients with genetic immunodeficiency.

ANTIBODY DEFICIENCY DISORDERS

X-Linked Agammaglobulinemia

EPIDEMIOLOGY X-linked agammaglobulininemia (XLA) is inherited in an X-linked fashion, and approximately 50 percent of affected boys have a family history of the disorder.[2]

ETIOLOGY AND PATHOGENESIS The underlying defect in XLA is failure of maturation of the pre-B cell to a differentiating B cell; B-cell precursors are found in the bone marrow in normal numbers. The causative gene, BTK (Bruton or B-cell tyrosine kinase) encodes a kinase (Btk)

X-LINKED AGAMMAGLOBULINEMIA AT A GLANCE

- Synonym: Bruton disease
- Early onset, recurrent bacterial infections
- Absent or barely detectable tonsillar and cervical lymph node tissue
- Profound hypogammaglobulinemia and decreased or absent peripheral B cells

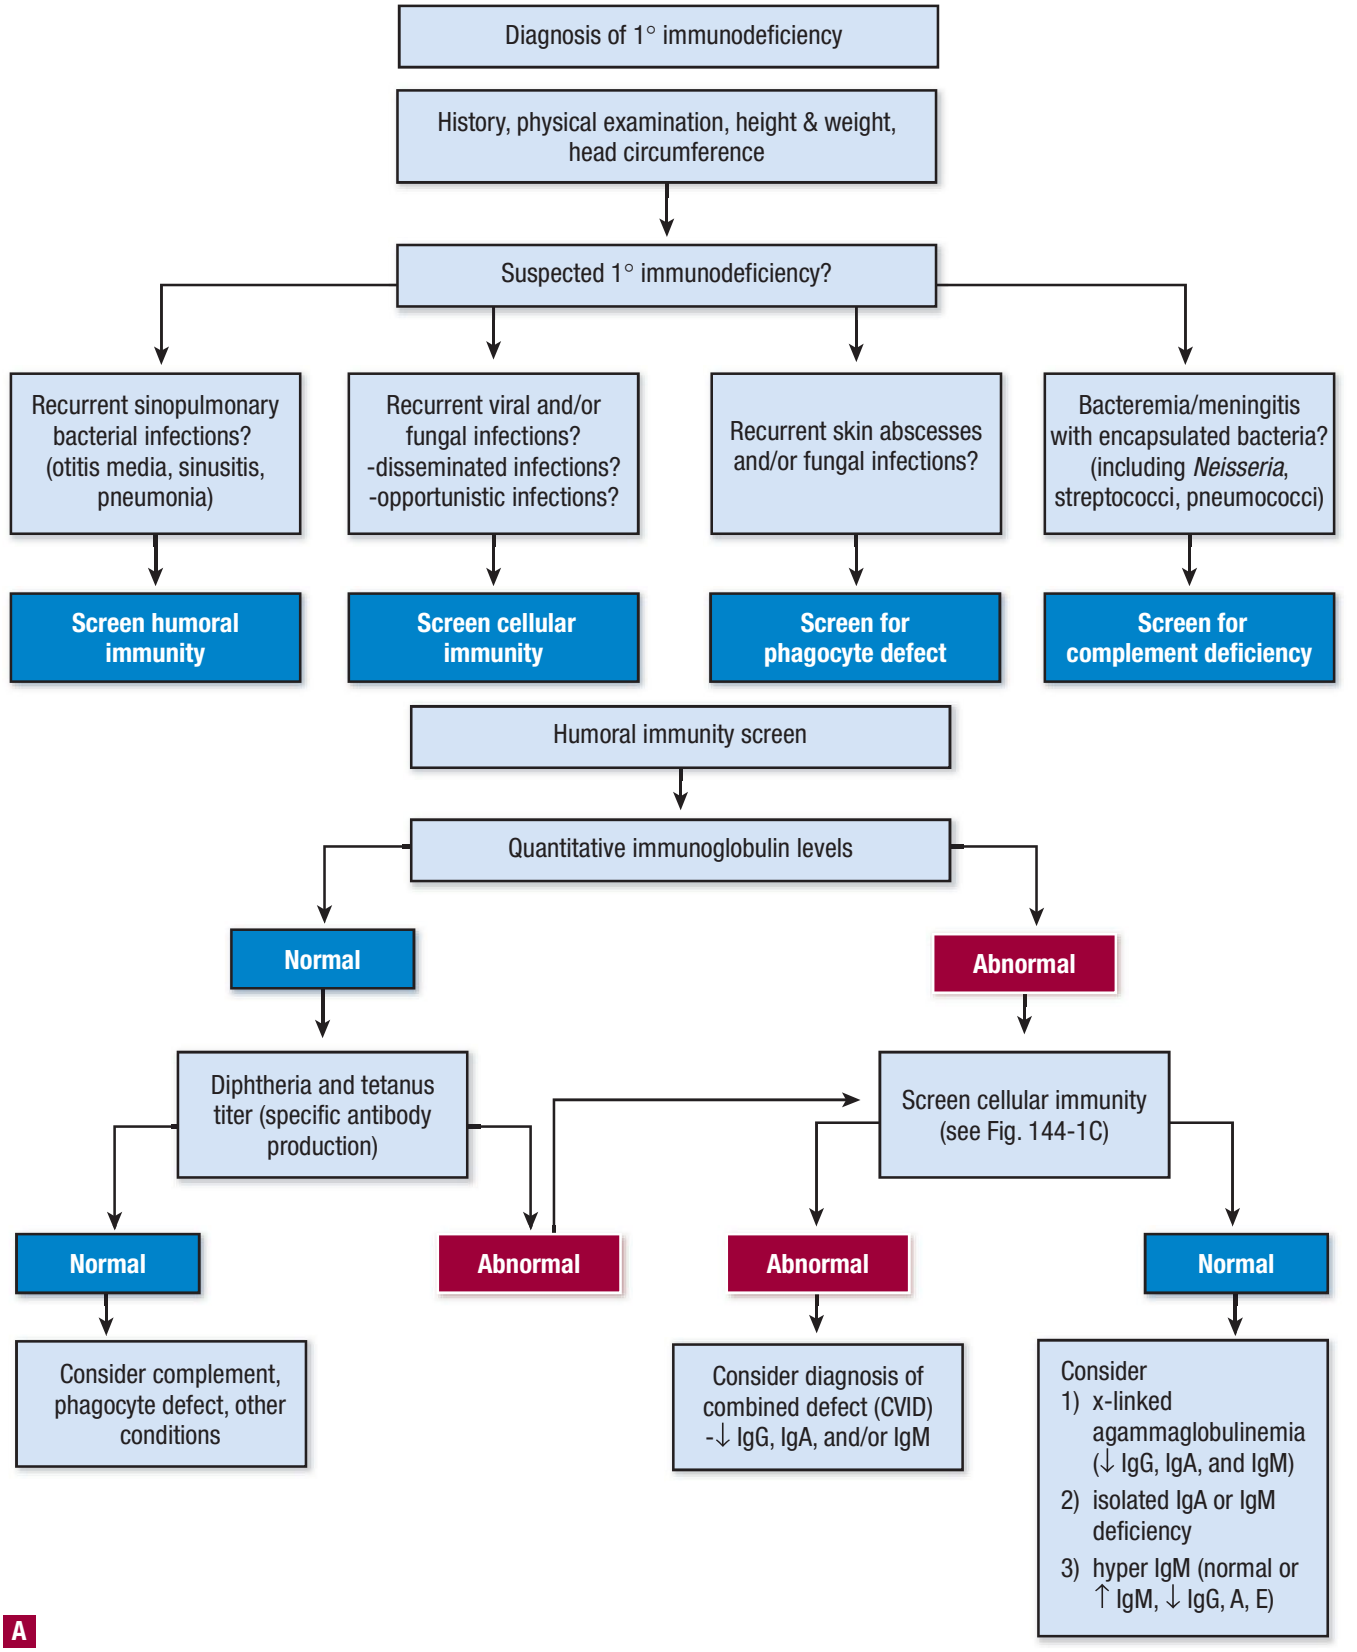
TABLE 144-1
Manifestations of Genetic Immunodeficiencies

Cutaneous Manifestations	Associated Immunodeficiencies
Angioedema	• Hereditary angioedema
Atopic-like dermatitis	• IgA deficiency/IgM deficiency
	• Chronic granulomatous disease
	• Common variable immunodeficiency
	• Elevated IgM with hypogammaglobulinemia
	• Ectodermal dysplasia with immunodeficiency
	• Hyperimmunoglobulinemia E syndrome
	• Severe combined immunodeficiency
	• Wiskott-Aldrich syndrome
	• X-linked agammaglobulinemia
Cutaneous abscesses	• Chronic granulomatous disease
	• Hyperimmunoglobulinemia E syndrome
	• Leukocyte adhesion deficiency
Cutaneous granulomas	• Ataxia-telangiectasia
	• Chronic granulomatous disease
	• Chronic mucocutaneous candidiasis
	• Common variable immunodeficiency
	• Severe combined immunodeficiency, especially TAP2 deficiency
	• X-linked hypogammaglobulinemia
Cutaneous candidal infection	• Chronic mucocutaneous candidiasis
	• DiGeorge syndrome
	• Hyperimmunoglobulinemia E syndrome
	• Severe combined immunodeficiency
Eosinophilic folliculitis, infantile	• Hyperimmunoglobulinemia E syndrome
Graft-versus-host disease	• DiGeorge syndrome
	• Severe combined immunodeficiency
Lupus-like cutaneous change	• IgA deficiency
	• Chronic granulomatous disease, autosomal recessive
	• Chronic granulomatous disease, X-linked carrier
	• Common variable immunodeficiency
	• Complement deficiency, early components
	• Elevated IgM with hypogammaglobulinemia
Mucocutaneous telangiectases	• Ataxia-telangiectasia
Petechiae and/or purpura	• Chédiak-Higashi syndrome
	• Griscelli syndrome
	• Wiskott-Aldrich syndrome
Pigmentary dilution/ silvery hair	• Chédiak-Higashi syndrome
	• Griscelli syndrome
Pyoderma gangrenosum-like ulcerations	• IgA deficiency
	• Chédiak-Higashi syndrome
	• Chronic granulomatous disease
	• Hyperimmunoglobulinemia E syndrome
	• Leukocyte adhesion deficiency
	• X-linked hypogammaglobulinemia
Seborrheic-like or exfoliative dermatitis	• Ataxia-telangiectasia
	• "Leiner" phenotype: complement deficiency or dysfunction
	• Severe combined immunodeficiency
	• X-linked agammaglobulinemia
Warts, extensive	• Common variable immunodeficiency
	• Elevated IgM with hypogammaglobulinemia
	• Epidermodysplasia verruciformis (see Chap. 196)
	• IgM deficiency
	• Severe combined immunodeficiency after transplantation (mutations in *IL2RG* or *JAK3*)
	• WHIM syndrome

Ig = immunoglobulin; TAP = Transporter associated with Antigen Processing or Transporter, ATP-binding cassette; WHIM = warts, hypogammaglobulinemia, infections, myelokathexis.

TABLE 144-2
Patterns Associated with Primary Immune Deficiency

Disorder	Infection	Other
Antibody	Sinopulmonary (pyogenic bacteria)	Autoimmune disease (autoantibodies, inflammatory bowel disease)
	Gastrointestinal (enterovirus, *Giardia*)	Minimal growth retardation
	Normal handling of fungal and viral infections (exception is enterovirus)	Paucity of lymphoid tissue
Cellular	Low-grade or opportunistic infections	Growth retardation
	Pneumonia (pyogenic bacteria, *Pneumocystis*, viruses)	Graft-versus-host disease
	Gastrointestinal (viruses)	Fatal infections from live vaccines
	Skin, mucous membranes (fungi)	Malignancy
Phagocytosis and cell killing	Skin, reticuloendothelial system (*Staphylococcus*, enteric bacteria, *Aspergillus*, mycobacteria)	Ulcerative stomatitis
Complement	Alternative, late components	Early components
	Sepsis/blood-borne (streptococci, pneumococci, *Neisseria*)	Autoimmune disease (systemic lupus erythematosus, glomerulonephritis)
		C1 esterase inhibitor deficiency
		Angioedema



▲ **FIGURE 144-1 A–C.** Algorithm for immunodeficiency disorders in neonates and infants. *If the clinical presentation is concerning for severe combined immunodeficiency (SCID), this is a medical emergency and patient needs immediate referral to an immunologist. AT = ataxia-telangiectasia; CBC = complete blood cell count; CVID = common variable immunodeficiency; HIV = human immunodeficiency virus; Ig = immunoglobulin; NK cell = natural killer cell; NL = normal; ↓ = decreased; ↑ = increased. *(continued)*

that participates in B-cell receptor intracellular signaling and is essential for B-cell maturation. Cell-mediated immunity is normal. More than 500 different mutations in Btk have been reported, and no single mutation is detected in more than 3 percent of the patients.[3] Carrier detection is possible by analyzing the patterns of X-chromosome inactivation, with selective inactivation of the abnormal X chromosome in B lymphocytes from female carriers.

CLINICAL FINDINGS XLA is characterized by recurrent pyogenic infections that often begin approximately 9 months after birth, concurrent with the disappearance of maternal immunoglobulins. These patients have absent or barely detectable tonsils and cervical lymph nodes.[4] Skin infections, especially furunculosis and impetigo, occur in 28 percent of patients and often surround body orifices. An atopic-like eczematous eruption that fails to improve with immunoglobulin therapy has been described in many affected children. Pyoderma gangrenosum and non-infectious cutaneous granulomas have been reported. Childhood exanthematous disorders are handled appropriately, but the infections may recur, owing to a failure to develop specific antibodies.

The diagnosis of XLA is made by serum concentrations of immunoglobulin G (IgG), IgA, and IgM that are far below the 95 percent confidence limits for appropriate controls (usually less than 100 mg/dL total immunoglobulin). The number of B cells in the peripheral circulation is also low (< 1 percent of normal).

TREATMENT, PROGNOSIS, AND CLINICAL COURSE Early intravenous immunoglobulin (IVIG) replacement and antibiotic use markedly reduces the risk of infections, although it may not be helpful in diminishing the risk and morbidity of chronic lung disease, chronic enterovirus infection, or of lymphoreticular malignancy (as high as 6 percent).

Common Variable Immunodeficiency

EPIDEMIOLOGY The disease prevalence of common variable immunodeficiency (CVI) is estimated at 1 in 25,000.[6] Age at first diagnosis shows a bimodal distribu-

COMMON VARIABLE IMMUNODEFICIENCY AT A GLANCE

- Heterogeneous group of disorders in which both antibody deficiency and abnormalities of T cells may be found
- Most common underlying gene defect in transmembrane activator, calcium modulator, and cyclophilin ligand interactor, which also can lead to immunoglobulin A deficiency
- May manifest during childhood, but average of onset is almost 30 years old
- Variable severity of autoimmune and infectious complications

tion with one peak between 6 and 10 years and another peak at 26 to 30 years of age, with males and females affected equally. Most cases are sporadic, but at least 10 percent are familial with a predominance of autosomal dominant over autosomal recessive inheritance.

ETIOLOGY AND PATHOGENESIS Identified genetic defects underlying CVI include defects in transmembrane activator, calcium modulator, and cyclophilin ligand interactor (TACI), inducible co-stimulator (ICOS), B-cell activation factor of the tumor necrosis factor family receptor (BAFF-R), and CD19. Each of these is critical for B-lymphocyte activation and differentiation. Altogether, mutations in these genes account for approximately 10 percent to 20 percent of patients, with defects in TACI being the most common.[6] The majority of defects have yet to be discovered.

CLINICAL FINDINGS CVI commonly presents in young adults, but 45 percent of cases are diagnosed before the age of 21 years old.[7] Patients have infections similar to those in patients with XLA, particularly sinopulmonary infections, but are less susceptible to enteroviral infections and more susceptible to *Giardia* infections. Many patients with CVI have liver disease and gastrointestinal (GI) disease, causing malabsorption syndromes. Noncaseating granulomas of skin (Fig. 144-2), lungs, liver, and spleen have been reported. Caseating granulomas of the skin and viscera, although rare, have also been described.[8,9] Extensive warts can be a major problem in individuals with CVI (Fig. 144-3). Lymphoid tissues often are enlarged, and

▲ **FIGURE 144-2** Noncaseating granulomas on the legs of a child with common variable immunodeficiency. Cultures and special stains showed no organisms.

▲ **FIGURE 144-3** The dorsal aspect of the hands were covered with recalcitrant verrucae vulgares in this girl with common variable immunodeficiency.

splenomegaly with hypersplenism is found in 25 percent of patients. Autoimmune disorders are especially frequent (11 percent to 22 percent),[7,10] particularly autoimmune thrombocytopenia, autoimmune hemolytic anemia, rheumatoid arthritis, sicca syndrome, and pernicious anemia. Alopecia areata and lupus also have been described. In 10 percent to 20 percent of patients, at least one family member is also immunodeficient, particularly with CVI or IgA deficiency.[11] The incidence of lymphoreticular malignancy and gastric carcinoma are markedly increased, particularly in the fifth and sixth decades of life.[12]

LABORATORY FINDINGS Failure in B-cell differentiation leading to impaired secretion of immunoglobulins leads to reduced serum IgG and IgA and/or IgM, two standard deviations or more below the mean.[7] The numbers of circulating B lymphocytes are usually normal. Cellular immunity is also impaired.[13] Approximately one-half of patients have T-cell dysfunction,[14] with the incidence increasing with advancing age. Patients have a lower number of circulating absolute $CD4^+$ T cells and a normal number of $CD8^+$ T cells.[15]

PROGNOSIS, CLINICAL COURSE, AND TREATMENT Periodic IVIG administration is standard treatment for CVI. Prophylactic antibiotics should be initiated in patients who continue to have infections despite immunoglobulin therapy.[16] Patients with granulomatous inflammation have a worse prognosis.[17] The mean age of death for females is 45.5 years old and for males, 40 years old. The majority die from either lymphoma or chronic sinopulmonary infections.[7]

SELECTIVE IMMUNOGLOBULIN DISORDERS

Immunoglobulin A Deficiency

Immunoglobulin M Deficiency

Hyper-Immunoglobulin M Syndrome

EPIDEMIOLOGY The disorder usually occurs in males, with X-linked inheritance in approximately 70 percent of affected individuals. Incidence is approximately 1 in 1 million live births.[20] An X-linked recessive form and two autosomal recessive forms have also been described.

PATHOGENESIS Hyper-IgM syndrome is caused by a defect of B-cell differentiation.[20] Normally, the humoral immune response begins with production of IgM and IgD antibodies. Subsequently, IgG, then IgA, and, finally, IgE antibodies are produced. The sequential production of different classes of immunoglobulins is called *class switching*. This mechanism enables the immune system to produce antibodies with different effector functions while retaining variable region specificity. In hyper-IgM syndrome, B cells are unable to switch from IgM/IgD secretion to the production of other immunoglobulin isotypes (see Chap. 36).

In contrast to the case in X-linked agammaglobulinemia, female carriers of the hyper-IgM syndrome due to mutations in CD40 ligand have random inacti-

SELECTIVE IMMUNOGLOBULIN DISORDERS AT A GLANCE

- Immunoglobulin A deficiency is usually asymptomatic; only 10 percent to 15 percent of affected individuals demonstrate clinical manifestations, especially bacterial sinopulmonary infections and autoimmune disorders.
- Most cases of hyper-immunoglobulin M syndrome have the X-linked recessive form with deficiency of CD40 ligand; common clinical features are recurrent sinopulmonary and gastrointestinal infections, oral ulcerations, and verrucae.

vation of the X chromosome in T lymphocytes because the CD40 ligand is not required for the normal development of T lymphocytes. Female carriers, in general, do not tend to show clinical manifestations. However, a female carrier who was noted to have 95 percent of her T cells expressing the mutant X chromosome had recurrent infections of the upper and lower respiratory tract[28] and another carrier had gastric lymphoma.[29]

CLINICAL FINDINGS More than one-half of patients develop symptoms of immunodeficiency and are diagnosed before age 1 year. Nearly all patients have symptoms by 4 years of age.[20] Most notable are respiratory tract infections, seen in 81 percent of patients,[20] dermatitis, an increased incidence and severity of warts, and oral ulcerations, sometimes in association with neutropenia.[30,31] Cellulitis and subcutaneous abscesses are seen in 13 percent of patients.[20] Recurrent diarrhea, central nervous system (CNS) infections and sepsis are also common. In addition to pyogenic and opportunistic infections, including *Pneumocystis carinii*, patients tend to develop autoimmune disorders of the hematopoietic system. Uncontrolled proliferation of IgM-producing plasma cells often occurs during the second decade of life, at times resulting in potentially fatal, massive infiltration of the GI tract, liver, and gallbladder. Patients with hyper-IgM syndrome also have an increased risk of cancer involving the GI tract. The sera of patients with hyper-IgM syndrome have very low amounts of IgG, IgA, and IgE, but normal or high concentrations of IgM and IgD. Despite the name, high levels of IgM are found in fewer than one-third of patients.[20]

PROGNOSIS, CLINICAL COURSE, AND TREATMENT The leading causes of death are pneumonia, encephalitis, and malignancy. The condition is treated prophylactically with intravenous γ-globulin; the autoimmune neutropenia also may respond to granulocyte-macrophage colony-stimulating factor. More than one-half of the patients benefit from prophylactic antibiotics for *P. carinii*. Allogeneic bone marrow transplantation may correct the disorder.

X-Linked Lymphoproliferative Disease (Duncan Disease)

EPIDEMIOLOGY The incidence of X-linked lymphoproliferative disease (XLP) is 1 in 3 million males.[32,33]

PATHOGENESIS XLP disease results from mutations in *SH2D1A*,[34,35] which encodes an adapter protein, signaling lymphocytic activation molecule (SLAM)-associated protein (SAP), critical to intracellular signaling pathways.[36] SAP is expressed in T cells, natural killer (NK) cells, and NKT cells.

CLINICAL FINDINGS XLP is characterized by fulminant infectious mononucleosis, dysgammaglobulinemia, and lymphoproliferative disorders.[36] Patients are also at risk for the development of autoimmune disorders. These clinical manifestations usually develop following Epstein-Barr virus (EBV) infection in boys who have previously had normal immunologic responses. With EBV infection; however, patients respond abnormally to the antigen and fail to develop EBV-specific serologic responses.

Malignant lymphomas and nonmalignant lymphoproliferative disorders, including lymphomatoid granulomatosis, Wegener granulomatosis, and necrotizing vasculitis, affect 20 percent to 30 percent of patients.[37] The majority of malignant tumors are of B-cell origin.

PROGNOSIS, CLINICAL COURSE, AND TREATMENT XLP is a fatal disease and 70 percent of patients die by the age of 10 years.[36] The median survival after development of primary EBV infection and fulminant mononucleosis is 1 to 2 months.[33] Most patients die from severe hepatitis, liver necrosis, and hepatic failure. Patients with isolated hypogammaglobulinemia treated with intravenous immunoglobulin have a better prognosis than those who develop infectious mononucleosis or lymphoma.[36]

CELLULAR DEFICIENCIES

Chronic Mucocutaneous Candidiasis

EPIDEMIOLOGY Several clinical sub-types have been defined (Table 144-3). They have varied clinical manifestations, variable immunodeficiency, and different forms of genetic inheritance. Patients with chronic mucocutaneous candidiasis (CMC) may have childhood or mature onset, familial, or sporadic occurrence, and CMC may be present with or without endocrinopathy. Patients with *a*utoimmune *p*oly*e*ndocrinopathy-*c*andidiasis-*e*ctodermal *d*ystrophy (APECED or autoimmune polyendocrine syndrome or APS, type 1) often have affected siblings. APECED and other familial forms of CMC are autosomal recessive. Autosomal dominant inheritance is seen in patients with associated keratitis.

CHRONIC MUCOCUTANEOUS CANDIDIASIS AT A GLANCE

- A heterogeneous group of disorders with altered immune responses selective to candida
- Recurrent, progressive candidal infections of the skin, nails, and mucous membranes
- May be associated with the later development of endocrinopathy [(APECED) *a*utoimmune *p*oly*e*ndocrinopathy-*c*andidiasis-*e*ctodermal *d*ystrophy]

ETIOLOGY AND PATHOGENESIS The clinical features of CMC may be seen in a variety of immunologic disorders, all characterized by ineffective defense mechanisms against *Candida*. In general, the patients with greater severity and an earlier onset of cutaneous candidal infections have more severe immunologic alterations. CMC patients have shown general dysregulation of interleukin 12 (IL-12), IL-6, and interferon-γ (IFN-γ) production,[39] resulting in an inability to mount a cell-mediated response to clear candidal organisms. Chronic infections result in production of high levels of inflammatory cytokines (IL-6) followed by anti-inflammatory cytokines (IL-10) that further reduce the production of T helper 1 (Th1)-inducing cytokines via a positive feedback loop.[39]

Humoral immunity appears normal in most patients and 25 percent to 35 percent of patients with CMC have no demonstrable immunologic defects. Many patients with CMC have associated APECED syndrome,[40] owing to mutations in the autoimmune regulator (*AIRE*) gene which maps to 21q22.3 and encodes a DNA transcription factor.[41] Mice that are deficient in AIRE do not delete organ-specific T cells in the thymus, thus promoting the development of autoimmune disease.[42] The reason for susceptibility to mucocuta-

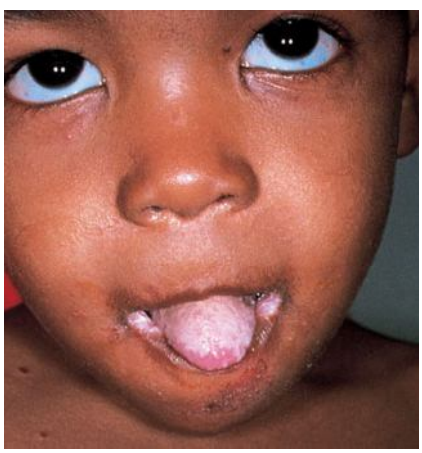
TABLE 144-3
Classification of Patients with Chronic Mucocutaneous Candidiasis[a]

CMC Type	Inheritance/Gene Defect	Onset	Clinical Features	Associated Disorders	Non-Candidal Infections
Chronic oral candidiasis	No known genetic defect.	Middle-aged or elderly women.	Candidiasis of tongue and buccal mucosa. No esophageal, skin, or nail involvement.	Fe^{2+} deficiency	No
Familial chronic mucocutaneous candidiasis	Autosomal recessive and autosomal dominant. Males and females are equally affected.	Early childhood, often before age 2 yr.	Oral candidiasis. Limited skin and nail involvement.	No endocrinopathies	Yes
Autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy syndrome	Autosomal recessive. Mutations in the *AIRE* (autoimmune regulator) gene on 21q22.3. More common in the Finnish population, Iranian Jews, and Sardinians. Rarely, dominant form with AIRE mutations or mapped to chromosome 2p.	Candidal infections before age 5 yr. Endocrine abnormalities between 10 and 15 yr of age.	Oral and diaper area candidiasis more often than skin and nail involvement. Endocrinopathies and autoimmune disorders.	Most common endocrinopathies: Hypoparathyroidism Hypoadrenalism Other associated disorders: Thyroid disease Primary hypogonadism Hepatitis Malabsorption Pernicious anemia Alopecia areata Vitiligo Ectodermal manifestations: Dental enamel hypoplasia Pitted nail dystrophy Keratoconjunctivitis	Yes
CMC with thymoma	No known genetic basis.	Adult onset.	Mucous membrane and cutaneous candidiasis.	Malignant/benign thymomas Aplastic anemia Myasthenia gravis Hypogammaglobulinemia	No
Chronic localized candidiasis (candida granuloma)	No known genetic basis. Males and females are equally affected.	Early childhood, often before age 5 yr.	Thick, adherent candidal crusts on the scalp and face. Oral candidiasis.	None	Yes
CMC with keratitis	Autosomal dominant.	Early childhood.	Candidiasis of the oral cavity, diaper area.	Keratoconjunctivitis Alopecia Endocrine abnormalities	Yes

CMC = chronic mucocutaneous candidiasis.
[a]Chronic candidal infections have been described in patients with DiGeorge, hyperimmunoglobulinemia E, severe combined immunodeficiency, ectrodactyly-ectodermal dysplasia-clefting, and keratitis-ichthyosis-deafness syndromes; multiple carboxylase deficiency; and acrodermatitis enteropathica.

neous candidal infections is unclear. APECED must be distinguished from *i*mmune dysregulation, *p*olyendocrinopathy, *e*nteropathy, *X*-linked (IPEX) syndrome, an X-linked recessive disorder in which the abnormal development of regulatory T cells results from mutations in the *FOXP3* gene. Patients with IPEX syndrome show psoriasiform dermatitis, nail dystrophy, autoimmune endocrinopathies (overlapping with those seen in APECED syndrome), and autoimmune skin conditions such as alopecia universalis.[43]

CLINICAL FINDINGS Patients with CMC have recurrent, progressive infections of the skin, nails, and mucous membranes most commonly due to *C. albicans*.[41,44] Depending on the sub-type, the clinical presentation ranges from recurrent, recalcitrant thrush (Fig. 144-4) to mild erythematous scaling plaques (see eFig. 144-4.1 in on-line edition) with a few dystrophic nails to severe generalized, crusted granulomatous plaques (Fig. 144-5). The cutaneous plaques occur most commonly in intertriginous areas, periorificial sites, and the scalp, but they may be generalized. The nails are thickened, brittle, and discolored, and the paronychial areas are often erythematous, swollen, and tender. Scalp infections may lead to scarring and alopecia. Although the oral mucosa is the most frequent site of mucosal alteration, esophageal, genital, and laryngeal mucosae may be affected. Strictures may be formed by candidal infection at these mucosal sites. Scrapings and cultures



▲ **FIGURE 144-4** Recurrent thrush and candidal cheilitis in a boy with mucocutaneous candidiasis.

▲ **FIGURE 144-5** This 3-year-old child with hypothyroidism had oral thrush, intertriginous candidiasis, warty hyperkeratoses, and crusts on the scalp and face; and also, candidal onychomycosis. The warty growths shown in the photograph consisted of dried pus and serum, and grew pure cultures of *Candida*.

from cutaneous or mucosal lesions demonstrate candidal organisms.

Patients with CMC rarely develop systemic candidiasis, but 50 percent may develop recurrent or severe infections due to other organisms. In one study, 81 percent of patients with early-onset CMC also had infections with bacteria, fungi, and parasites, including bacterial septicemia.[41] Concomitant dermatophyte infections may occur.

In patients with APECED, the candidal infections tend to begin by 5 years of age, although the endocrinologic dysfunction may not be apparent until 12 to 13 years of age (see Fig. 144-5). The most commonly associated endocrinopathies are hypoparathyroidism (88 percent) and hypoadrenocorticism (60 percent). One-third of patients have candidiasis, hypoparathyroidism, and defective adrenal function. Other associated endocrinopathies or autoimmune disorders include gonadal insufficiency (45 percent), alopecia areata (20 percent), pernicious anemia (16 percent), thyroid abnormalities (12 percent), chronic active hepatitis or juvenile cirrhosis (9 percent), vitiligo, diabetes mellitus, and hypopituitarism. Chronic diarrhea and malabsorption have been reported in 25 percent of patients and usually are associated with hypoparathyroidism. Some affected patients also have pulmonary fibrosis, dental enamel hypoplasia, and keratoconjunctivitis. The "ectodermal dysplasia" features are likely to be secondary to the candidal infections or autoimmunity[44] Patients with APECED often have autoimmune antibodies, including antithyroglobulin, antimicrosomal antibodies, antiadrenal and antimelanocyte antibodies, and rheumatoid factor. Autoantibodies also have been found in patients with CMC who do not have clinical endocrinologic disease.

PROGNOSIS, CLINICAL COURSE, AND TREATMENT Candidal lesions in patients with CMC generally respond to systemically administered azole antifungal agents (itraconazole, fluconazole) or terbinafine.[45] Ketoconazole is no longer used because of the risk of hepatitis. Patients who are resistant usually respond to amphotericin B with or without flucytosine. Cutaneous granulomas often are less responsive despite clearance of infection. Recurrences are common, and the antifungal agents must be used intermittently. The drugs have no effect on the abnormal cell-mediated immunity. All patients with CMC should have an annual endocrine evaluation and patients with documented endocrinopathy or a family history of APECED should be monitored more closely. Patients who have a history of infections other than candidal should have further evaluation of their immune status.

DiGeorge Syndrome

EPIDEMIOLOGY The incidence of DiGeorge syndrome (DGS) is 1 in 4000 live births.[46] Ninety percent of the cases are associated with a deletion in chromosome 22q11.1.

ETIOLOGY AND PATHOGENESIS DGS (congenital thymic aplasia) is a member of a group of disorders that result from deletion of chromosome 22q11 (catch 22/DGS/velocardiofacial syndrome).[47] The disorder results from developmental defects of the third and fourth pharyngeal pouches due to haploinsufficiency of Tbx1, t-box transcription factor.[48]

CLINICAL FINDINGS The thymic shadow is absent or reduced at birth. Infants often have neonatal tetany with hypocalcemia due to the aplastic parathyroid glands. The cardiac anomalies are most commonly truncus arteriosus, septal defects, and abnormal aortic arch vessels. Characteristic facial features of DGS include a short philtrum, low-set malformed ears, and hypertelorism.

Many patients have recurrent mucocutaneous candidal infections as neonates, as well as increased susceptibility to viral infections, *P. carinii*, and other fungal infections. Graft-versus-host disease (GVHD) may develop in infants given nonirradiated blood products. There is an overall increased of malignancy, particularly hepatoblastoma; in a cohort of patients with DGS under the age of 14, the overall risk of malignancy was 900 per 100,000, whereas the overall risk of malignancy in children under 14 years is 3.4 per 100,000.[57]

PROGNOSIS, CLINICAL COURSE, AND TREATMENT Patients with complete DGS usually die within the first 2 years of life.[58] In rare cases, transplant of HLA-matched bone marrow or peripheral blood mononuclear cells restores T-cell function.[59] Postnatal thymus transplant restores T-cell function in patients with complete DGS.[51,60]

Cartilage-Hair Hypoplasia Syndrome

EPIDEMIOLOGY Cartilage-hair hypoplasia (CHH) syndrome is an autosomal recessive disorder that is most common in Amish and Finnish individuals.[61] There is a 4:1 female-male ratio.[62]

ETIOLOGY AND PATHOGENESIS The disorder results from mutations in RMRP, the

CARTILAGE-HAIR HYPOPLASIA SYNDROME AT A GLANCE

- Synonym: Metaphyseal chondrodysplasia McKusick type
- Autosomal recessive disorder, common in Amish and Finnish populations
- Mutations in the RNA component of a ribonucleoprotein endoribonuclease, leading to defective cell-mediated and humoral immunity
- Characterized by fine, sparse hypopigmented hair, short-limbed dwarfism
- Supportive treatment with appropriate antibiotic use, bone marrow transplant corrects immune deficiency but not dermis or cartilage

▲ **FIGURE 144-6** Sparse hypopigmented hair in a woman with cartilage-hair hypoplasia syndrome. (From Brennan TE, Pearson RW: Abnormal elastic tissue in cartilage-hair hypoplasia. *Arch Dermatol* **124**:1411, 1988, with permission.)

RNA component of a ribonucleoprotein endoribonuclease.[63]

CLINICAL FINDINGS Patients have fine, sparse, hypopigmented hair (Fig. 144-6) and metaphyseal dysostosis that results in short-limbed dwarfism. Patients may have soft, doughy skin with degenerated elastic tissue. Chronic oral fungal or viral infections as well as recurrent upper respiratory infections, otitis media, and pneumonias are related to defective cellular and humoral immunity. Associated pleiotropic features include Hirschsprung disease, deficient erythrogenesis, and an increased risk of malignancies[66] particularly non-Hodgkin lymphoma and basal cell carcinomas.

PROGNOSIS, CLINICAL COURSE, AND TREATMENT Supportive therapy with appropriate antibiotic treatment is indicated. Bone marrow transplantation, although rarely performed, has fully corrected the immune deficiency but has no influence on the course of the chondroplasia or elastic tissue. A DNA marker-based analysis provides a useful method for prenatal diagnosis.

COMBINED ANTIBODY AND T-CELL DEFICIENCY

Wiskott-Aldrich Syndrome

EPIDEMIOLOGY Wiskott-Aldrich syndrome (WAS) is an X-linked recessive disorder with an incidence of approximately 4 per million male births.[67]

PATHOGENESIS The defective gene is *WASP*, mapped to Xp11.22–11.23, which encodes WASp, a hematopoietic specific cytoplasmic protein that functions in signaling and cytoskeletal organization. WASp couples signals arising at the cell membrane with reorganization of the cellular cytoskeleton, resulting in cellular activation and promotion of cell motility. Mutations in WASp affect organization of the immunologic synapse and T-cell activation, T and B lymphocyte migration, and initiation of the primary antibody response.[68] There is a strong phenotype–genotype correlation; as classic WAS occurs when WASp is absent or truncated, while X-linked thrombocytopenia occurs when mutated WASp is expressed.[69]

WAS patients have decreased function and number of both T- and B-lymphocytes, beginning in the first years of life.[70] The lymphocytes of patients with WAS lack microvilli formed by actin bundles, resulting in defective chemotaxis and, in some patients, there is decreased expression of sialoglycoproteins (e.g., CD43 and others) on lymphocytes and platelets. Defects in humoral immunity include abnormal serum immunoglobulins and decreased antibody response to polysaccharide antigens. WAS patients also have defects in NK cell cytotoxicity, dendritic cell migration, and activation and impaired macrophage chemotaxis.[68]

CLINICAL FINDINGS The classic triad of WAS is hemorrhage due to thrombocytopenia and platelet dysfunction, recurrent pyogenic infections, and recalcitrant dermatitis, but this triad appears in only 25 percent of patients.[71] The bleeding diathesis is the most common manifestation of mutations in WAS, present in 84 percent of patients[69] and often manifests initially during the first weeks or months of life with bloody diarrhea. Epistaxis, hematemesis, hematuria, mucocutaneous petechiae, and intracranial hemorrhage also may occur. Recurrent bacterial infections begin in infancy as levels of placentally transmitted maternal antibodies diminish. These infections include furunculosis, conjunctivitis, otitis media and externa, pansinusitis, pneumonia, meningitis, and septicemia. Infections with encapsulated bacteria such as *Pneumococcus*, *Haemophilus influenzae*, and *Neisseria meningitidis* predominate. Patients are also susceptible to infections due to herpes and other viruses and to *P. carinii*.

The atopic dermatitis associated with WAS, which occurs in approximately 80 percent of patients,[67] usually develops during the first few months of life and may be quite severe. The face, scalp, and flexural areas are the most severely involved, although patients commonly have widespread involvement with progressive lichenification. The rash is often more exfoliative than that of atopic dermatitis in individuals without WAS, and excoriated areas frequently have serosanguineous crusts (Fig. 144-7). Secondary bacterial infection of eczematous lesions is common, as are eczema herpeticum (see eFig. 144-7.1 in on-line edition) and molluscum contagiosum. IgE-mediated allergic problems, such as urticaria, food allergies, and asthma, are seen in addition to the atopic dermatitis.

As many as 40 percent of patients with WAS develop an autoimmune disorder.[72] The most common are vasculitis (particularly involving the skin, GI tract, brain,

WISKOTT-ALDRICH SYNDROME AT A GLANCE

- X-linked recessive
- Mutations in Wiskott-Aldrich syndrome
- Recalcitrant dermatitis
- Recurrent pyogenic infections

- Therapy: Bone marrow stem cell transplantation

▲ **FIGURE 144-7** Severe atopic dermatitis in a boy with Wiskott-Aldrich syndrome. Note the serosanguineous crusting.

and heart) in 20 percent of patients, autoimmune hemolytic anemia in 14 percent , and IgA nephropathy in up to 10 percent of patients.[73] Other immune-mediated cutaneous manifestations are angioedema, dermatomyositis, pyoderma gangrenosum, and erythema nodosum.[72] Hepatosplenomegaly is common, and lymphadenopathy, transient arthritis, and joint effusions are present occasionally.

The thrombocytopenia of WAS is persistent, and platelet counts may range from 1000 to 80,000 platelets per μL. A platelet count of < 70,000 is required for formal diagnostic criteria. The platelets are small, and platelet aggregation is defective. Levels of IgM and sometimes, IgG, are low, and isohemagglutinins are absent. IgA, IgE, and IgD levels usually are elevated. Eosinophilia, leukopenia, and lymphopenia are also seen. Delayed hypersensitivity skin-test reactivity is diminished, and patients fail to respond to polysaccharide antigens.

PROGNOSIS, CLINICAL COURSE, AND TREATMENT Therapeutic interventions allow some patients with WAS to survive into adulthood; however, a significant proportion die before age 10 years old secondary to hemorrhage, infection, malignancies, or the complications of transplantation.[67,74,75] Thirteen percent of patients with WAS develop lymphoreticular malignancies,[71] especially non-Hodgkin lymphoma, with a predominance of extra-nodal and brain involvement. Development of autoimmune hemolytic anemia is a poor prognostic factor and associated with the development of lymphoid malignancies; overall 25 percent of patients with autoimmunity develop a malignancy[73] Ten percent of patients die from these malignancies, usually as adolescents or young adults.

Female carriers of *WAS* mutations may be detected by the selective inactivation of the abnormal X chromosome in T and B cells and in platelets. Studies of maternal X-chromosome inactivation also have been used to diagnose boys with atypical WAS. Mutation analysis allows for prenatal diagnosis.[76]

Appropriate antibiotics, immunizations, and transfusions of platelets and plasma decrease the risk of fatal infections and hemorrhage. Intravenous infusions of γ-globulin are useful in some patients. Splenectomy has been advocated to ameliorate the bleeding abnormality in patients with recurrent severe hemorrhage, but this procedure increases the risk of infection from encapsulated bacterial organisms in these patients, who cannot mount a response to vaccination. Bone marrow or stem cell transplantation is the treatment of choice for patients with recurrent problems, especially significant autoimmunity. Full engraftment results in normal platelet number and function, normal immunologic status, and clearance of the dermatitis (T lymphocyte engraftment). The 5-year survival rate with HLA-matched sibling donors is 87 percent.[71] Topical glucocorticoid preparations and systemic γ-globulin may improve the dermatitis, and chronic administration of oral acyclovir is appropriate for patients with recurrent eczema herpeticum.

Severe Combined Immunodeficiency

EPIDEMIOLOGY Severe combined immunodeficiency (SCID) includes a group of heterogeneous disorders characterized by similar clinical manifestations and immunologic deficiencies of both humoral and cell-mediated immunity.[77–79] The overall incidence of SCID is 1 in 75,000 births.[80] The mode of inheritance is either X-linked or autosomal recessive.

PATHOGENESIS All patients with SCID share most clinical features and have abnormalities of both cell-mediated and humoral immunity, although the extent of deficiency is variable. The underlying bases of SCID are quite heterogeneous, but the molecular bases correspond to integral steps in the differentiation of T cells (Table 144-4). Ninety-five percent of SCID cases have an identified gene defect.[80] X-linked SCID affects approximately 46 percent of patients,[81] and the genetic defect is a mutation in the gene encoding the γ_c chain of the IL-2 receptor, which is also shared with five other interleukin receptors, thus explaining the severity of the immunodeficiency. Several of these receptors are required for the early development of T cells, so female carriers with the mutation have nonrandom inactivation of T cells, which do not survive if the mutated allele is activated. Similarly, mutations in the gene encoding interleukin 7 receptor α chain (IL-7R) and the signaling protein Janus kinase 3 also affect cytokine receptor development. The most common form of autosomal recessive SCID (16 percent of patients) results from mutations in the gene for the purine-degradation enzyme adenosine deaminase (*ADA*).[81] Mutations in antigen receptor genes account for several other molecular defects. Ten percent of patients have defects in the recombination-activating gene 1 or 2 (*RAG1* or *RAG2*) or *Artemis* gene. These molecular defects all result in total or selective lymphopenia. Additional defects fail to completely block T-cell differentiation but the resultant T cells are functionally impaired. These include ZAP-70 deficiency,[85] CD3γ chain deficiency,[86] major histocompatibility complex (MHC) class II deficiency and MHC class I deficiency/transporter for antigen presentation (TAP) deficiency. The human homologue of the nude mouse with total alopecia and nail dystrophy has been linked to mutations in *WHN* (winged helix nude) (see Table 144-4).[87]

CLINICAL FINDINGS Infants with SCID usually fail to gain weight by 3 to 6 months of age, following the onset of recurrent sinopulmonary and skin infections. Persistent mucocutaneous candidiasis is often present at the time of

SEVERE COMBINED IMMUNODEFICIENCY AT A GLANCE

- Heterogeneous group of X-linked and autosomal recessive disorders with deficient cell-mediated and humoral immunity.
- Failure to thrive in early infancy; diarrhea; recurrent mucocutaneous candidiasis, bacterial and viral infections; risk of graft-versus-host disease.
- Transplantation may prevent death during infancy.

TABLE 144-4
Sub-Types of Severe Combined Immunodeficiency

Disorder	Gene	Lymphocyte Profile	Gene Product Function
Defects in cytokine receptor			
X-linked severe combined immunodeficiency[a,b]	*IL2RG*	T–/B+/NK–	Common γ chain of IL-2, -4, -7,-9,-15, and -21
IL-7 receptor (IL-7R) deficiency	*IL7R*	T–/B+/NK–	α chain of IL-7 receptor; stimulates Janus kinase 3
Janus protein kinase deficiency[b]	*JAK3*	T–/B+/NK–	Tyrosine kinase; primary signal transducer from common γ chain and α chain of IL-7R
Defects in cell receptor			
RAG 1 or 2[c]	*RAG1/ RAG2*	T–/B–/NK+	Required for somatic V, D, and J rearrangements during B- and T-cell development
Artemis deficiency[d,e]	*Artemis*	T–/B–/NK+	Required for DNA repair during somatic V, D, and J rearrangements during B- and T-cell development
T-cell receptor/CD3 complex deficiency	*CD3δ* and *CD3ε*	T–/B+/NK+	Facilitates expression of T-cell receptor/CD3 complex; block at pre–T-cell receptor stage of development
CD45 deficiency[82]	*PTPRC*	T–/B+/NK+	Phosphatase that regulates immune cell signaling
LIG4 syndrome[e,83]	*LIG4*	T–B–NK+	Ligase required for ATP-dependent repair of double-stranded DNA
CD8 deficiency[84]	*CD8A*	$CD4^+CD8^-$/B+/NK+	Promotes survival and differentiation of activated T cells to memory $CD8^+$ T cells
Defects in purine pathway enzymes			
ADA deficiency[a,f]	*ADA*	T–/B–/NK–	Enzyme necessary for detoxification of metabolic products of the purine salvage pathway that cause lymphocytes to undergo apoptosis
PNP deficiency	*PNP*	T–/B–/NK–	Enzyme necessary for detoxification of metabolic products of the purine salvage pathway that cause lymphocytes to undergo apoptosis: located downstream from ADA
Defects that fail to completely block T-cell differentiation. Result in functionally impaired T cells +			
ZAP-70 deficiency	*ZAP-70*	$CD4^+CD8^-$/B+/NK+	Signaling tyrosine kinase
T-cell receptor/CD3 complex deficiency	*CD3γ*	T+/B+/NK+	Chain facilitates expression of T-cell receptor/CD3 complex
MHC class II deficiency (bare lymphocyte syndrome II)	*CIITA* *RFXB* *RFX5* *RFXAP*	T+/B+/NK+ but dysfunctional CD4	Defects in the transactivating factors of MHC II molecules
MHC class I deficiency/TAP deficiency (bare lymphocyte syndrome I)	*TAP1* *TAP2*	$CD4^+CD8^-$/B+/dysregulated NK	Transporter associated with antigen processing, transports peptides to assemble the class I molecule
Defect in thymic development			
Winged helix nude deficiency	*WHN*	T–/B+/NK+	Human homologue of nude mouse with total alopecia and onychodystrophy; critical transcription factor for thymic development

ADA = adenosine deaminase; ATP = adenosine triphosphate; IL = interleukin; MHC = major histocompatibility complex; NK = natural killer cell; PNP = purine nucleoside phosphorylase; RAG = recombination activating gene; TAP = transporter associated with antigen processing.
[a]Most common severe combined immunodeficiency defects. X-linked severe combined immunodeficiency accounts for approximately 50 percent of patients. Adenosine deaminase deficiency accounts for approximately 20 percent of patients.
[b]Highest risk of human papillomavirus infections after transplantation may reflect a persistent abnormality in expression on keratinocytes despite transplantation.[176]
[c]Deletions/frameshift mutations of *RAG1*/*RAG2* genes result in severe combined immunodeficiency phenotype. Less severe mutations result in Omenn syndrome, clinically distinct from other forms of severe combined immunodeficiency. Mutations in other genes may lead to the Omenn phenotype and immunodeficiency.
[d]Common genetic defect seen in Athabascan-speaking Native Americans, the defect is called *SCIDA* in this population. Gene frequency may be as high as 2 percent. These patients have a higher incidence of oral/genital ulcers.[89]
[e]Both *Artemis* and *LIG4* mutations lead to hypersensitivity to irradiation.
[f]Eighty-five percent to 90 percent of patients present in infancy with severe immunodeficiency; one-half have skeletal deformities, neurologic symptoms, behavior problems, and decreased IQ.

diagnosis, and systemic candidal infections occur occasionally. Patients with SCID also may have chronic diarrhea and malabsorption caused by viral infections. *P. carinii* pneumonia is often a presenting feature. Although bacterial infections usually respond to systemic antibiotics, viral infections tend to be fatal. Infants with SCID lack palpable lymphoid tissue despite recurrent infections.

In addition to cutaneous bacterial and candidal infections, the most common cutaneous eruptions are morbilliform or resemble seborrheic dermatitis. In some infants with SCID, biopsy sections show GVHD (see Chap. 28). GVHD may result from the in utero exposure to maternal lymphocytes, from transfusion with nonirradiated blood products, or may follow transplantation. Patients with GVHD most commonly present acutely with morbilliform erythema, papular dermatitis, or diffuse erythroderma. The face, neck, palms, and soles are affected initially, before a generalized eruption. Severe cases are complicated by diffuse bullae or toxic epidermal necrolysis. The clinical presentation of GVHD from maternal engraftment (without transplantation) is indistinguishable from the clinical

presentation of GVHD from transplantation, but histopathologic features differ.[88] Biopsy sections from GVHD secondary to maternal engraftment show psoriasiform hyperplasia with parakeratosis and variable spongiosis in contrast to the vacuolar interface pattern observed in conventional GVHD.[88] Overall, 83 percent of SCID patients with maternal engraftment develop skin manifestations.[88] Oral and genital ulcerations are also seen in SCID, particularly in Athabascan-speaking American Indian children with a defect in the *Artemis* gene.[89] Patients with Omenn syndrome show erythroderma, hepatosplenomegaly and lymphadenopathy with eosinophilia and increased IgE production. B cells tend to be undetectable, and T cells, although often increased in number, are non-functional. Recently, Omenn syndrome has been shown to be a phenotype with several underlying genetic bases. Most patients have RAG1/RAG2 mutations, but the phenotype of Omenn syndrome has been described in patients with mutations in Artemis and IL7R.[90–92] Two individuals with CHH and another with complete DGS also showed features of Omenn syndrome.[93,94]

The sub-type of SCID is determined generally by DNA analysis, although detection of cells by fluorescence-activated cell sorting (e.g., T, B, and NK cells) and by analysis for the presence of surface markers is confirmatory. All sub-types have absent or low T-cell number and function, and total lymphocyte counts are usually < 1500 to 2000 cells (normal is 4000 to 13,500). With maternal engraftment, T lymphocyte counts may be close to normal. The number of B cells and NK cells differs depending on the genetic defect (see Table 144-4). ADA enzyme activity in leukocytes can be measured to confirm ADA-deficient SCID.

In families with a previously affected sibling of a known phenotype, prenatal detection of SCID is possible by DNA analysis, if the specific gene defect is known, by fluorescence-activated cell sorting of fetal blood with monoclonal antibodies, or by analysis of enzyme levels in cultured amniocytes. Carrier mothers of boys with X-linked SCID may be detected by the selective inactivation of the abnormal X chromosome in T and B cells.

PROGNOSIS, CLINICAL COURSE, AND TREATMENT Affected children with most forms of SCID rarely survive beyond 1 year of age without transplantation. The definitive treatment of choice for SCID is a hematopoietic stem cell transplant from HLA-identical or haploidentical T-cell depleted bone marrow.[95] Removal of post-thymic cells from parental marrow may diminish the risk of GVHD in patients with SCID without an HLA-identical donor. Bone marrow transplants done before the age of 3 months have a 95 percent survival rate, whereas after 3 months of age, the survival rate decreases to 75 percent,[96] emphasizing the importance of early diagnosis. Hematopoietic stem cell transplant does not restore complete immune reconstitution in regards to B-cell function and more than one-half of patients remain dependent on IVIG and prophylactic antibiotics. Some patients develop waning T-cell numbers years after transplant. In utero transfer of haploidentical CD34 cells and retroviral gene therapy[95] have been successful for patients with γ_c- and ADA–deficient forms of SCID. The success of gene therapy has been tempered by the development of leukemia in three patients who received retroviral gene therapy for γ_c SCID. Gene therapy is currently restricted to patients who are unlikely to survive allogenic transplantation or who have already undergone standard transplantation but do not have satisfactory T-cell immunity.[95] Patients with IL-2 deficiency have been treated with IL-2 injections. Enzyme replacement therapy with polyethylene glycol modified bovine ADA, administered subcutaneously once weekly, has resulted in clinical and immunologic improvement in patients with ADA deficiency.

Ectodermal Dysplasia with Immunodeficiency

EPIDEMIOLOGY X-linked recessive transmission is most common with an estimated incidence of 1:250,000 live male births.[97] An autosomal dominant form of ectodermal dysplasia with immunodeficiency has also been described.[98]

ETIOLOGY AND PATHOGENESIS Several genetic disorders result from gene mutations in NEMO and lead to abnormal nuclear factor κB (NF-κB) signaling (see Hypohidrotic Ectodermal Dysplasia in Chap. 143, and Incontinentia Pigmenti in Chap. 73). One of these, hypohidrotic ectodermal dysplasia with immunodeficiency, results from hypomorphic mutations in the NEMO gene [also called *ectodermal dysplasia, anhidrotic, with immunodeficiency* (EDA-ID), or *hyperimmunoglobulinemia M, immunodeficiency, X-linked with ectodermal dysplasia*]. NF-κB is recognized as a DNA-binding factor,[99] and its ability to transcribe genes is regulated by a cytoplasmic inhibitor, IκB. NF-κB signaling affects inflammation, apoptosis, development, and immunity.[100,101] NF-κB activation requires phosphorylation of IκB by IκB kinase (IKK). IKK is composed of two catalytic components (IKKα and IKKβ) and a regulatory subunit, IKKγ or NEMO. NEMO has no catalytic function, but is the structural scaffold that supports the IKK complex.[100] When NEMO is absent or defective, no functional IKK complex is formed and, as a result, NF-κB cannot translocate to the nucleus and activate gene transcription.

The hypomorphic mutations that cause EDA-ID allow early survival in males, in contrast to the large deletions in *NEMO* (usually of exons 4 to 10) that lead to incontinentia pigmenti in carrier females and fetal death in affected males (see Chap. 73).

CLINICAL FINDINGS Affected patients present with classic characteristics of hypohidrotic ectodermal dysplasia. These include the characteristic facies (Fig. 144-8), hypotrichosis or atrichia, hypohidrosis (leading to heat intolerance), hypodontia or anodontia with conical incisors, and associated dermatitis (see Chap. 143).[23,97,105–107] A subset of patients has associated osteopetrosis and lymphedema in association with severe immunodeficiency. Boys with immunodeficiency

ECTODERMAL DYSPLASIA WITH IMMUNODEFICIENCY AT A GLANCE

- Mutations in nuclear factor κB essential modulator, leading to abnormal nuclear factor κB signaling
- Characteristic facies of hypohidrotic ectodermal dysplasia
- Often severe immunodeficiency; bacterial, atypical mycobacterial, and viral infections are common
- Therapy: transplantation

▲ **FIGURE 144-8** Ectodermal dysplasia with immunodeficiency gene mutation. This boy with a hypomorphic mutation in *NEMO* showed failure to thrive, slightly exfoliative dermatitis, and the typical facial features of hypohidrotic ectodermal dysplasia. Note the small chin, the "pouty" lower lip, thin upper lip, small pinched nose with malar hypoplasia. His mother had a pigmented streak following a line of Blaschko, typical of that seen in incontinentia pigmenti. (Used with permission from Dr. Anthony Mancini.)

from NEMO mutations without the features of hypohidrotic ectodermal dysplasia have also been described.[108] Bacterial infections early in infancy are common, particularly sepsis, pneumonia, otitis, sinusitis, and lymphadenitis. Recurrent pneumonias may lead to bronchiectasis. Common pathogens include *Streptococcus pneumoniae*, *H. influenzae*, *Klebsiella*, *Salmonella*, and *Pseudomonas*. Infections with atypical mycobacteria and viruses, including cytomegalovirus (systemic and GI involvement), herpes simplex virus, molluscum contagiosum, human papillomavirus, and *P. carinii*, are also reported.[23,97,106]

The immunodeficiency is often severe, but its characteristics are variable. They may include impaired B-cell class switching with hypogammaglobulinemia (and often increased levels of IgM and/or IgA), impaired specific antibody production (particularly to polysaccharide antigens), deficient NK cell cytotoxicity, and poor cytokine production in response to CD40L signaling.[97,107] Biopsy of skin may show evidence of keratinocyte apoptosis, reflecting the dysfunction in NF-κB signaling, and must be differentiated from GVHD.

TREATMENT AND PROGNOSIS Therapy is guided by the patient's clinical and immunologic phenotype. Ectodermal dysplasia is treated supportively (see Chap. 143). Patients with impaired antibody production may benefit from IVIG. All infections (bacterial and viral) should be treated aggressively with the appropriate antibiotics/antivirals. Prophylaxis for both *P. carinii* and Mycobacterium avium intracellulare should be considered.[97] Stem cell transplantation may lead to immune reconstitution.[109] The mother and sisters of these patients should be offered genetic testing for the *NEMO* mutation and counseling.

Ataxia-Telangiectasia

EPIDEMIOLOGY Ataxia-telangiectasia (AT; Online Mendelian Inheritance in Man #208900), also called *Louis-Bar syndrome*, is an autosomal recessive disorder with an incidence of approximately 1:40,000 and a carrier rate of up to 1 percent. Carriers have an increased risk of breast cancer, hematologic malignancies,[110] and ischemic heart disease, with a reduced life expectancy of approximately 8 years.[111] These heterozygotes show increased risk of chromosomal breaks after exposure to irradiation in vitro, suggesting that mammograms in known carriers of AT are contraindicated.

ETIOLOGY AND PATHOGENESIS AT results from mutations in *ataxia-telangiectasia mutated* (*ATM*), which encodes a phosphatidylinositol 3-kinase-like serine/threonine protein kinase that plays a central role in activating apoptotic and cell cycle responses to DNA damage.[112] More than 400 different *ATM* mutations have been identified in patients with AT. The MRE11-RAD50-NBS1 (MRN) complex senses DNA breaks and recruits and activates ATM.[113] The autophosphorylated ATM monomers then phosphorylate and thus activate several targets, among them p53, BRCA1, and NBS1 and MRE11 themselves, leading to cell cycle arrest and facilitated DNA repair. The activation of ATM occurs in response to external damage, such as from ionizing radiation and radiomimetic agents (bleomycin), and in physiologic DNA breaks, such as during meiosis, telomere maintenance, and V(D)J recombination in lymphocytes.[112] These important roles of ATM explain the immunodeficiency, premature aging, progressive neurologic deterioration, and sensitivity to ionizing radiation. Oxidative stress related to ATM dysfunction has also been implicated.

Mutations in the *NBS1* and *MRE11* genes, respectively, cause Nijmegen breakage syndrome (immunodeficiency with microcephaly, chromosomal instability, and a cancer predisposition, but no ataxia[114]) and AT-like disorder (with neurologic manifestations and radiosensitivity, but no telangiectases).

CLINICAL FINDINGS Characteristic oculocutaneous telangiectases begin near the ocular canthi and progress across the bulbar conjunctivae (Fig. 144-9). These tel-

ATAXIA-TELANGIECTASIA AT A GLANCE

- Autosomal recessive disorder with mutations in *ataxia-telangiectasia mutated (ATM)*
- Early onset of ataxia with progressive neurologic deterioration; conjunctival telangiectasis first appears in pre-school years in most patients
- Sinopulmonary infections, lymphoreticular neoplasia
- Deficiency of immunoglobulin A (IgA), IgE, IgG_2, IgG_4; variable manifestations of T-cell deficiency; high levels α-fetoprotein; chromosomal breaks; sensitive to irradiation

▲ **FIGURE 144-9** Bulbar conjunctival telangiectases in a patient with ataxia-telangiectasia. (From Paller AS: Hereditary immunodeficiency disorders, in *Genetic Disorders of the Skin*, edited by Alper JC. Chicago, Mosby Year Book, 1991, p 105, with permission.)

▲ **FIGURE 144-10** Ataxia-telangiectasia. Telangiectases inside and on the helix.

angiectases usually appear when patients are 3 to 6 years of age; rarely have they been described at earlier ages. Cutaneous telangiectases subsequently may develop on the malar prominences, ears, eyelids, anterior chest, popliteal and antecubital fossae, and the dorsal aspects of the hands and feet (Fig. 144-10). The telangiectases may be subtle and resemble fine petechiae, especially in the flexural areas. The development of telangiectases may be related to sun exposure, because ocular, but not cutaneous, telangiectases develop in affected dark-skinned children. The development of telangiectases may relate, at least in part, to the sensitivity of some AT strains to ultraviolet (UV) light.[115]

Progeric changes of the skin, including xerosis and gray hair, occur in 90 percent of patients.[116] During adolescence, the facial skin may become progressively more atrophic and sclerotic, causing a mask-like appearance. Occasionally, the ears, arms, and hands also become scleroderma-tous. The hair may be diffusely gray by adolescence, and subcutaneous fat is generally lost in childhood. Recurrent severe impetigo often develops. Seborrheic dermatitis occurs in many patients, and the associated blepharitis may lead to a diagnosis of blepharoconjunctivitis rather than ocular telangiectasia. Mottled hyper- and hypopigmentation commonly occur and, together with the telangiectases and atrophy, can resemble the poikiloderma of radiodermatitis, actinic damage, or scleroderma. Other pigmentary changes include café-au-lait spots that may be found in a dermatomal distribution,[117] multiple ephelides, and vitiligo. Hypertrichosis of the arms and legs, alopecia areata, multiple warts, atopic dermatitis, keratosis pilaris, nummular eczema, and acanthosis nigricans have also been described in association with AT. Among the most common cutaneous manifestations are non-infectious cutaneous granulomas (Fig. 144-11).[117] These persistent, atrophic, and often ulcerative lesions are often mistaken for other granulomatous processes, including sarcoidosis, necrobiosis lipoidica diabeticorum, granuloma annulare, and granulomatous dermatitis.

Usually, the progressive cerebellar ataxia first becomes apparent during infancy (median age, 1.2 years old) with swaying of the head and trunk and apraxia of eye movements, often years before skin or conjunctival abnormalities develop. In childhood, dysarthric speech, drooling, choreoathetosis, and myoclonic jerks become prominent. The diagnosis of AT is usually made at a median age of 7 years, after appearance of the mucocutaneous telangiectasia. Patients usually require a wheelchair by their teenage years.

Recurrent bacterial and viral sinopulmonary infections occur in up to 80 percent of patients; these are the most common cause of death, which is usually from bronchiectasis and respiratory failure. Approximately 75 percent of patients with AT may have growth retardation and endocrine disorders, especially ovarian agenesis or testicular hypoplasia and insulin-resistant diabetes.

Neoplasia occurs in 40 percent of surviving adolescents or young adults, although lymphoid malignancy has been described as the presenting sign during infancy. Most common are lymphomas (especially B cell; 200-fold increased risk) and leukemia (especially T-cell chronic lymphocytic; 70-fold increased risk).[118,119] Basal cell carcinomas have been reported in young adults.

Among techniques to confirm diagnosis are analysis of radioresistant DNA synthesis (which demonstrates an abnormal S phase checkpoint), radiosensitivity testing with the colony survival assay, immunoblotting for the ATM protein, assessment of ATM kinase activity, and molecular genetic testing.

PROGNOSIS, CLINICAL COURSE, AND TREATMENT The therapy for AT is supportive and includes administration of antibiotics for infection, physiotherapy for pulmonary bronchiectasis, physical therapy to prevent contractures in patients with neurologic dysfunction, and sunscreens and sun avoidance to diminish actinic-like changes. Patients should be aggressively screened for malig-

▲ **FIGURE 144-11** Non-infectious granulomatous dermatitis of a patient with ataxia-telangiectasia. These persistent lesions tend to ulcerate.

nancy, especially after the first decade of life. Intralesional injections of triamcinolone have helped to promote healing of the painful associated ulcerations, although the lesions do not clear completely with treatment. Autopsy findings indicate that approximately 50 percent of the patients die from pulmonary disease, the most common cause of death. Lymphoreticular malignancies, including lymphoid leukemia, are the second most common cause of death, leading to the deaths of 15 percent of patients with AT. The remaining patients tend to die of both pulmonary disease and malignancy. Therapeutic radiation and radiomimetic chemotherapeutic agents, especially bleomycin, may lead to extensive tissue necrosis. The administration of small doses of other chemotherapeutic drugs and low-dose, fractionated radiation is the least harmful means of managing these malignancies. In a small subset of patients with milder AT, treatment with aminoglycosides increased ATM gene function.[121] Death usually occurs by late childhood or early adolescence; the oldest surviving patient died at the age of 50 years. Prenatal diagnosis is currently best achieved by DNA analysis.

DISORDERS OF PHAGOCYTOSIS AND CELL KILLING

Patients with defects in phagocyte function or cell killing typically present during infancy or childhood with recurrent, unusual, and/or difficult to clear bacterial infections. Infections commonly seen include those of skin or mucosa, lung, lymph nodes, deep tissue abscesses, or

childhood periodontitis. The most distinctive disorders of phagocytosis and cell killing are chronic granulomatous disease (CGD), leukocyte adhesion deficiencies, hyperimmunoglobulinemia E syndrome (HIES), and the silvery hair syndromes with immunodeficiency. However, several disorders with neutropenia, neutrophil dysfunction, or cytokine dysfunction also lead to a decreased ability to engulf and/or kill organisms. These are reviewed in Table 144-5.

Chronic Granulomatous Disease

EPIDEMIOLOGY CGD is a heterogeneous group of X-linked and autosomal recessive disorders. Ninety percent of patients with the disorder are male, and the overall incidence is 1 in 200,000 to 250,000 persons. X-linked disease occurs in 70 percent of affected individuals with signs and symptoms manifesting in the first year of life. Individuals with autosomal recessive disease (30 percent) present later in life with milder signs and symptoms; 56 percent of these patients have a deficiency of $p47^{phox}$ and deficiencies in $p22^{phox}$ and $p67^{phox}$ account for the remaining cases.[122]

PATHOGENESIS CGD is caused by defects in the reduced nicotinamide adenine dinucleotide phosphate (NADPH) oxidase, the enzyme complex responsible for the generation of superoxide.[123] Normal bactericidal activity after phagocytosis requires the NADPH oxidase system, which consists of NADPH, an unusual phagocyte cytochrome b (b_{558}), and cytosolic proteins. In patients with CGD, this membrane-associated NADPH oxidase system fails to produce superoxide and other toxic oxygen metabolites.

The types of microbial organisms that cause infections in patients with CGD require intracellular killing and are usually catalase-positive. Only five organisms are

CHRONIC GRANULOMATOUS DISEASE AT A GLANCE

- Group of disorders in which defective production of reactive oxygen intermediates impairs intracellular killing of microorganisms
- X-linked or autosomal recessive
- Mutations in genes that encode components of nicotinamide adenine dinucleotide phosphate oxidase system
- Pneumonias, lymphadenopathy, hepatosplenomegaly, and skin infections
- Granulomas, most commonly of lungs and liver

TABLE 144-5
Other Disorders of Phagocytosis or Cell Killing

Disorder	Genetics	Gene	Functional Consequence	Clinical Findings
Neutropenia				
Cyclic neutropenia	AD	*ELA2*	Defects in neutrophil elastase.	Cycles of neutropenia and monocytopenia, about every 3 wk. Oral ulcers and fever when low.
Severe congenital neutropenia	AD AD	*ELA1* *GF11*	Defects in neutrophil elastase lead to abnormal neutrophil trafficking. Repressor of elastase transcription leads to accumulation of elastase.	Neutropenia, myelodysplastic syndrome, and acute myelogenous leukemia. Neutropenia and lymphopenia. Myeloid progenitors in circulation.
Schwachman-Diamond syndrome (SBDS)	AR	*SBDS*	SBDS protein participates in metabolism of ribosomal RNA.	Pancytopenia with myelodysplastic syndrome and acute myelogenous leukemia. Pancreatic insufficiency. Chondrodysplasia.
WHIM[177]	AD	*CXCR4*	Receptor regulates development and migration of neutrophils; affects viral entry into cells.	Chronic cutaneous and cervical warts, antibiotic-responsive bacterial sinopulmonary infections; often low immunoglobulin levels, peripheral neutropenia in the face of bone marrow hypercellularity (myelokathexis), and distinctive neutrophil morphology.
Cytokine defects				
	AR	*IL12B*	Absence of component of IL-12 and IL-23 that stimulates IFN-γ production.	Severe mycobacterial infections. Disseminated bacille Calmette-Guérin after vaccination. Severe *Salmonella* infections.
	AR	*IL12RB1*	β1 chain of IL-12 and IL-23 receptors.	
	AR, AD	*IFNGR1*	Affects ligand binding to IFN-γ receptor.	
	AR	*IFNR2*	Affects IFN-γ receptor signaling.	
	AR, AD	*STAT1*	Affects transcription in IFN receptor signaling.	Also severe viral infections.
	AR	*STAT5B*	As in Stat1, but also growth hormone receptor signaling.	Also growth hormone insensitivity.
Defects of killing				
Myeloperoxidase deficiency	AR	*MPO*	Myeloperoxidase required for bacterial killing.	Especially *Staphylococcus aureus* and candidal infections. May be asymptomatic.
Specific granule deficiency	AR	*C/EBPE*	C/EBPε transcription factor required for granulocyte differentiation.	Recurrent bacterial infections. Neutrophils with two lobes.

AD = autosomal dominant; AR = autosomal recessive; IFN = interferon; IL = interleukin; WHIM = warts, hypoimmunoglobulinemia, infections, myelokathexis.

responsible for the overwhelming majority of infections in CGD in North America and Europe: *Staphylococcus aureus*, *Serratia marcescens*, *Burkholderia cepacia*, *Nocardia* sp., and *Aspergillus* sp.[123] The intense humoral and granulomatous responses of CGD are thought to be compensatory in the robust but ineffectual response to organisms.

CLINICAL FINDINGS Pyodermas with associated regional lymphadenopathy and dermatitis, especially around the nares and ears, usually occur during infancy and sometimes even in affected neonates. Staphylococcal abscesses are found in 40 percent of patients, particularly of the perianal area. Purulent inflammatory reactions may develop at sites of lymph node drainage or minor cutaneous trauma and heal slowly with scarring. Patients with CGD often develop chronic inflammatory granulomas, most commonly of the lungs and liver. Cutaneous granulomas are nodular and often necrotic. Granulomas can occlude vital structures, especially of the GI and genitourinary systems. Intra-oral ulcerations resembling aphthous stomatitis, chronic gingivitis, perioral ulcers, scalp folliculitis, and seborrheic dermatitis have also been described in many patients. Female carriers for X-linked CGD do not have the increased risk of infections but may have cutaneous lesions of discoid or systemic lupus erythematosus (SLE), Jessner lymphocytic infiltration of the skin, aphthous stomatitis, granulomatous cheilitis, photosensitivity, and/or Raynaud phenomenon.[126]

The lymph nodes, lungs, liver, spleen, and GI tract are the most frequent areas of non-cutaneous involvement. Suppurative lymphadenitis with abscess and fistula formation usually affects cervical nodes. Pneumonia occurs in almost all affected children and may lead to abscess formation, cavitation, and empyema. Hepatosplenomegaly has been reported in 80 percent to 90 percent of patients; more than 30 percent of patients develop hepatic abscesses, and staphylococcal liver abscesses are almost pathognomonic to CGD.

Patients with bacterial and *Nocardia* sp. infections tend to be symptomatic and frequently have leukocytosis, anemia, and elevated sedimentation rate. In contrast, lack of fever, normal erythrocyte sedimentation rate, and few symptoms are more common in *Aspergillus* sp. infections. Thus, lab values within normal limits do not rule out infection in a CGD patient. Patients not uncommonly show an increased erythrocyte sedimentation rate, hypergammaglobulinemia, leukocytosis, and mild anemia; immune functions are otherwise usually normal.

The diagnosis of CGD is made on the basis of assays that rely on superoxide production. The dihydrorhodamine flow cytometry-based test is currently favored and can readily distinguish X-linked from autosomal forms[80]; the ferricytochrome c reduction assay is another quantitative measure of the respiratory burst. The screening test for CGD is the nitroblue tetrazolium (NBT) reduction assay, in which the yellow NBT becomes its soluble, oxidized form (blue formazan) when precipitated with normal oxidative metabolism. Quantitative NBT tests and chemiluminescence assays also may be performed. Immunoblot analysis confirms the absence of the glycoprotein 91^{phox} ($gp91^{phox}$) component; because deficiency of one component of cytochrome b_{558} leads to absence of the other, sequencing of the $gp91^{phox}$ or $p22^{phox}$ gene is necessary if absence is noted by immunoblot analysis. Immunoblots that show the absence of $p47^{phox}$ or $p67^{phox}$ can be diagnostic.

Biopsy of cutaneous granulomas shows histiocytic infiltrates associated with foreign body giant cells and accumulation of neutrophils with necrosis. Although the histopathologic features of lupus erythematosus-like skin lesions in CGD patients and carriers may resemble those of lupus patients, immunofluorescence examination of lesional skin is usually negative.

PROGNOSIS, CLINICAL COURSE, AND TREATMENT Patients with X-linked CGD, $p22^{phox}$ CGD and $p67^{phox}$ CGD tend to have a more severe clinical course compared to patients with $p47^{phox}$ CGD. The mean age of diagnosis of X-linked CGD is 3 years of age, and of autosomal recessive forms 8 years of age. More than 90 percent of patients with non-$p47^{phox}$ CGD have undetectable levels of superoxide production.[82] Some patients will develop severe infections as early as infancy while others will unexpectedly develop a serious infection typical of CGD later during childhood.

Small foci of localized inflammation may not be associated with fever and may be difficult to detect without vigorous investigation of the lungs, liver, and bones by routine screening radiographs, scans, or ultrasound. Cultures should be performed to identify the infectious agent, and invasive procedures may be necessary to obtain adequate tissue samples. Patients with evidence of infection should be treated empirically with broad-spectrum parenteral antibiotics that cover *S. aureus* as well as Gram-negative organisms. Intravenous therapy should be continued for at least 10 to 14 days, followed by a several-week course of oral antibiotics. Surgical interventions (drainage, débridement) may be required for deeper infections. Trimethoprim-sulfamethoxazole therapy decreases the incidence of bacterial infection without increasing the incidence of fungal infection. Itraconazole is an effective agent for prophylaxis for fungal infections.[127] Prophylactic IFN-γ has been shown to decrease the number and severity of infections without increasing the incidence of chronic inflammatory complications in both X-linked and autosomal recessive CGD.[128] Use of IFN-γ is not accompanied by any measurable improvement in NADPH oxidase activity; its clinical benefit is related to enhanced phagocyte function and killing by non-oxidative mechanisms.[129] Leukocyte transfusions have been used for rapidly progressive, life-threatening infections. Although bone marrow transplantation has been performed in some patients with CGD, its use is limited by procedure-related toxicities, GVHD, and death; it should only be considered for those that have severe, life-threatening infections despite appropriate medical care. Systemic glucocorticoids have been helpful for patients with obstructive visceral granulomas. Stem cell gene therapy has been used for patients with the $p47^{phox}$ deficient form (Table 144-6).[84] Prenatal diagnosis has been performed by the NBT slide test and now can be based on molecular analysis.

The prophylactic administration of antibiotics and IFN-γ has reduced the mortality of CGD to about 2 percent per patient-year for autosomal CGD and 5 percent for X-linked CGD.[122] The most common causes of death are pneumonia and/or sepsis due to *Aspergillus* or *B. cepacia*.[75]

Leukocyte Adhesion Deficiency

EPIDEMIOLOGY Three autosomal recessive disorders are grouped under the term *leukocyte adhesion deficiency* (LAD). A dominant form has more recently been described in one patient [LAD type 4 (LAD4)].

ETIOLOGY AND PATHOGENESIS LAD is a rare inherited disorder that affects the

TABLE 144-6
Treatment of Chronic Granulomatous Disease

TREATMENT	INDICATION	DOSE
Trimethoprim-sulfamethoxazole[a] (dicloxacillin if allergic)	Bacterial infections	5 mg/kg/day divided bid
Itraconazole[a]	Fungal infections	100 mg/day if < 50 kg; 200 mg/day if > 50 kg
Interferon-γ[a]	Infections	50 μg/m^2 subcutaneous 3×/wk
Leukocyte transfusion	Life-threatening infections	
Bone marrow transplantation	Life-threatening infections	
Systemic glucocorticoids	Granulomas, particularly if obstructive	
Débridement /drainage/surgical intervention	Abscesses (particularly liver)	

[a]Regardless of genetic subgroup, the current recommendation is to use prophylaxis with trimethoprim-sulfamethoxazole, itraconazole, and interferon-γ.[123]

ability of neutrophils to adhere to the endothelium, tissue matrix, and microbes. Adherence is essential for the ability of leukocytes to emigrate into sites of infection and eliminate pathogens. Adherence of leukocytes relates in part to a group of cell surface glycoproteins (β_2 integrins) that share a common 95-kd β_2 subunit (CD18) encoded on chromosome 21q22.3. This β_2 subunit may be linked to three distinct α chains to form three different surface glycoproteins—the iC3b receptor (CR3), lymphocyte function–associated antigen 1, and p150,95. A mutation in the gene encoding CD18 leads to absent or deficient surface glycoproteins in LAD1. As a result, neutrophil and monocyte chemotaxis and phagocytosis are impaired.

LEUKOCYTE ADHESION DEFICIENCY AT A GLANCE

- Group of three autosomal recessive and one autosomal dominant disorder (see Table 144-6)
- Gingivitis and periodontitis
- Poor wound healing; delayed separation of the umbilical stump and development of pyoderma gangrenosum–like necrotic ulcerations after wounding
- Life-threatening bacterial and fungal infections

CLINICAL FINDINGS Patients have frequent infections of the skin and the respiratory and GI tracts, often caused by *S. aureus* or Gram-negative enteric bacteria. The skin infections are often precipitated by puncture wounds or skin surface trauma and begin as small erythematous or necrotic abscesses, progressing to large ulcerative lesions that resemble pyoderma gangrenosum, but the inflammatory response and production of purulent material are impaired (Fig. 144-12). Histopathology often reveals complete absence of tissue neutrophils. Poor wound healing leads to paper-thin or dysplastic cutaneous scars. Cellulitis of the face and perirectal area is common. Gingivitis with periodontitis results in loss of teeth. Delayed umbilical cord separation and omphalitis are also characteristic features.

Patients with LAD2 have less severe infections but have developmental delay and the Bombay (hh) erythrocyte phenotype. LAD3 is similar to LAD1 but has an associated bleeding tendency.

LABORATORY ABNORMALITIES Laboratory exams reveal a persistent leukocytosis, often out of proportion to the degree of symptoms. Diagnosis is confirmed by showing the reduction of glycoproteins with flow cytometry using monoclonal antibodies specific for the three α subunits, CD15s, and the common CD18 β subunits.

PROGNOSIS, CLINCAL COURSE, AND TREATMENT The severity of clinical involvement is proportional to the degree of glycoprotein deficiency. Patients with severe phenotypes (< 1 percent of normal expression of CD18) present in the newborn period with delayed umbilical cord separation and omphalitis. Life-threatening severe bacterial or fungal infections occur with a mortality rate of more than 75 percent before the age of 5 years old.[98] Patients with moderate phenotype (1 percent to 30 percent of normal expression of CD18) often have a milder course and are diagnosed later in life. More than one-half of these patients die between the ages of 10 and 30 years old.

Antimicrobial therapy is the mainstay of treatment. Skin abscesses/ulcers often require débridement and grafting. Bone marrow transplantation restores leukocyte function and is recommended in patients with the severe phenotype. Successful transplant of cord blood from HLA-identical siblings has also been reported.[130] Gene therapy introducing the normal CD18 subunit gene into affected hematopoietic stem cells has successfully restored CD18 expression. The ex vivo transfer of CD18 into affected cells, followed by infusion of the transduced cells, may represent another therapeutic approach.[131]

Oral fucose replacement has been helpful in some patients with LAD2. Leukocyte adhesion molecules are expressed on fetal leukocytes and make

◀ **FIGURE 144-12** Necrotic ulceration on the leg of a boy with leukocyte adhesion deficiency type 1. Note the heaped-up edge and extensive crusting. Biopsies showed almost no neutrophil invasion.

prenatal diagnosis possible by fetal blood sampling at 20-weeks' gestation.

Hyperimmunoglobulinemia E Syndrome

EPIDEMIOLOGY HIES is rare (incidence 1 in 10^6).[132] It is found equally in males and females. Most cases are sporadic or consistent with an autosomal dominant inheritance. Autosomal recessive inheritance has also been described, but patients show different associated features.

ETIOLOGY AND PATHOGENESIS The gene for HIES has been mapped to the proximal arm of chromosome 4q, although the underlying cause of HIES is still unknown.[133] A neutrophil chemotactic defect was originally implicated as primary, but recent studies indicate that neutrophil dysfunction and abnormalities of chemotaxis are variably expressed and intermittent.[134] Patients with HIES appear to have defective T-cell cytokine responses. IgE synthesis is normally enhanced by the Th2 cytokines (IL-4 and IL-13) and repressed by Th1 cytokines (IFN-γ and IL-12).[132] Given their constitutive expression of IgE, mononuclear cells from patients with HIES fail to exhibit the normal stimulation of IgE production by IL-4[135]; in addition, HIES cells cannot produce normal levels of IFN-γ even after cells are stimulated by IL-12.[136]

CLINICAL FINDINGS The clinical presentation of individual patients with HIES may vary greatly. The neonatal or infantile rash of HIES is often a papulopustular eruption with prominent crusting distributed on the scalp, face, neck, axillae, and diaper area. The most consistent finding on skin biopsy is an eosinophilic spongiotic dermatitis, sometimes centered in the dermal follicles.[137] In other infants, early candidal infections of the skin, mucosae, and nails and/or infantile atopic dermatitis (Fig. 144-13) are alternative presentations; in patients with the eosinophilic papulopustules, the atopic dermatitis commonly follows later in infancy. Superinfection of the dermatitis with *S. aureus* is very common,[138] and patients show high levels of anti-staphylococcal IgE antibodies. Staphylococcal skin infections include impetigo, furunculosis, paronychia, cellulitis, and characteristic "cold" abscesses (see Fig. 144-13) that do not demonstrate the anticipated degree of erythema, warmth, and purulence. The abscesses occur most commonly on the head and neck and in intertriginous areas.

HYPERIMMUNOGLOBULINEMIA E SYNDROME AT A GLANCE

- Synonyms: Job syndrome, Buckley syndrome, hyper-immunoglobulin E (IgE) recurrent infection syndrome.
- Most cases are sporadic or show autosomal dominant inheritance with variable penetrance.
- Classic triad: recurrent staphylococcal skin abscesses, pneumonia with pneumatocele formation, and high serum levels of IgE.
- Other common features are the atopic dermatitis, scoliosis, fractures, and dental abnormalities.
- Sporadic and autosomal dominant cases suffer from a multisystem disorder, affecting the skin, soft tissues, skeletal system, and dentition. Autosomal recessive cases have severe viral infections, lack skeletal and dental involvement, and develop severe neurologic complications.

Pulmonary bacterial pneumonia, abscesses, and empyema are the most frequent systemic infections and may result in pneumatoceles that serve as the nidus for bacterial or fungal superinfection. The most common infecting organisms are *S. aureus* and *H. influenzae*. Other than pneumonias, deep-seated infections, bacteremia, and sepsis are rare.[134]

Facial and skeletal abnormalities are common. Patients develop progressive coarsening of facial features (see Fig. 144-13), probably reflecting the skeletal defects, but the recurrent facial pustulation and lichenification from dermatitis may contribute. Distinctive facial features, including prominent forehead, a broad nasal bridge, and wide nasal tip are universally present by the age of 16 years old. Dental anomalies include retention of primary teeth and lack of eruption of secondary teeth. Osteopenia is common, and 57 percent of patients have had at least three pathologic fractures, especially of the long bones, ribs, and pelvis. Scoliosis occurs in 63 percent of adult patients and hyperextensibility of joints in 68 percent of patients.[132]

▲ **FIGURE 144-13** Coarse facial features, atopic dermatitis furuncles, and a cold abscess at the glabella in a boy with hyperimmunoglobulinemia E syndrome.

By definition, serum IgE levels must be elevated, but normal levels of IgE increase markedly during childhood. Levels of > 2000 IU/mL are seen in adolescents and adults; considerably lower levels during infancy are seen, given that the upper limit of normal in infants < 1 year old is 12.7 IU/mL and by 5 years of age is 47.1 IU/mL; an IgE level 10-fold above the 95th percentile for age is required for diagnosis. Eosinophilia of at least two standard deviations above normal (usually above 700 cells/μL) is also a clinical manifestation. The total white blood cell count is typically normal and often fails to elevate in the setting of acute infection. The most common clinical features and laboratory values of patients with sporadic or autosomal dominant HIES are summarized in Table 144-7.

Autosomal recessive disease is characterized by recurrent bacterial and viral infections, autoimmunity and devastating neurologic complications that are often fatal in childhood. Patients with autosomal recessive HIES show no tendency to form pneumatoceles and have no skeletal or dental abnormalities.[139] Eosinophilia tends to be more severe (e.g., 17,500/μL) and elevated levels of other immunoglobulin isotypes often accompany the increase in IgE level.[132]

PROGNOSIS, CLINICAL COURSE, AND TREATMENT Given the lack of correlation between serum levels of IgE, eosinophilia, and the susceptibility to severe infections, the clinical course is difficult to predict. Patients with autosomal recessive HIES have a more severe course related to the neurologic complications.[139]

TABLE 144-7
Characteristics of Hyperimmunoglobulinemia E Syndrome

	INCIDENCE (%)
Immune System	
• Dermatitis	100
• Skin abscesses	87

• Scoliosis (> 10°)	63
Laboratory Values	
• Immunoglobulin E > 2000 IU/mL or > 10 times the age-specific norm	97
• Eosinophilia (> 2 standard deviations above the norm)	93

Anti-staphylococcal antibiotics are effective for most cutaneous infections in patients with HIE, and oral triazole antifungals treat the mucocutaneous candidiasis. The prophylactic use of anti-staphylococcal antibiotics markedly reduces the incidence of skin abscesses and pneumonia. The cutaneous and pulmonary abscesses often require incision and drainage and may require partial lung resections. IVIG therapy has been used successfully. IVIG may influence IgE levels due to an increased immunoglobulin catabolism or neutralization of the IgE.[132] Ascorbic acid and cimetidine have decreased the number of infections and the chemotactic defect in some patients. Isotretinoin has been reported to eliminate the recurrent staphylococcal abscesses in an isolated patient without any change in immunologic status. Cyclosporin A also been used with good clinical and laboratory response.[140,141] IFN-γ has shown inconsistent effects on IgE levels and infection susceptibility. Bone marrow transplant has been attempted in two cases of typical autosomal dominant HIES with limited success.

Silvery Hair Syndromes: Chédiak-Higashi and Griscelli Syndromes (See Chap. 73)

CHÉDIAK-HIGASHI SYNDROME The silvery hair syndromes comprise a group of autosomal recessive disorders in which a peculiar metallic sheen to hair and often skin is noted. Of these, Chédiak-Higashi and Griscelli syndromes have associated immunodeficiency (Table 144-8). The other syndrome with silvery hair, Elejalde syndrome, does not have associated immunodeficiency. Elejalde syndrome may be allelic with the myosin 5a-deficient form of Griscelli syndrome (GS), with severe associated CNS dysfunction.

Epidemiology. Chédiak-Higashi syndrome (CHS) is a rare autosomal recessive disorder. Parental consanguinity is often reported, and there are approximately 300 reported cases worldwide.

Etiology and Pathogenesis. CHS is caused by mutations in the LYST gene, located on chromosome 1q42, which encodes a protein required for the final steps of vesicle trafficking and secretion.[142,143] The LYST gene is expressed in lysosomes and other secretory organelles (melanosomes, cytolytic granules, and platelet dense granules). Characteristic giant granules are thought to result from altered granule maturation and fusion.[144] Enlarged melanosomes are unable to be transferred to keratinocytes. NK cells and cytotoxic T lymphocytes do not release proteolytic enzymes necessary for target cell killing. Cytotoxic T lymphocyte–associated antigen is trapped in abnormally large vesicles rather than on the cell surface and thus may be unable to regulate T-cell activation, increasing the risk of lymphoproliferative disease.[145] Platelet dense granules are delayed in secretion of storage pools required for normal coagulation. Diminished chemotaxis of neutrophils and monocytes and delayed intracellular microorganism killing are often associated.

Clinical Findings. Patients usually first show manifestations during infancy or early childhood. Pigment abnormalities occur in 75 percent of patients, particularly the silver sheen to the hair (Fig. 144-14A). Ocular hypopigmentation may cause photophobia, and strabismus and nystagmus are common. Visual acuity does not tend to be reduced. The skin is typically fair, but slate-colored areas of pigmentation may be present. Diffuse speckled hypopigmentation and hyperpigmentation may be seen in the sun-exposed skin of dark-skinned individuals.[146]

Infections can be observed in the newborn period and continue through the lifetime of the patient. Infections most commonly involve the skin, lungs, and respiratory tract where microbes such as *S. aureus*, *S. pyogenes*, and *pneumococcus* are prevalent. Deep ulcerations resembling pyoderma gangrenosum have been described.

Neurologic manifestations include muscle weakness, cranial and peripheral neuropathy, and progressive neurologic deterioration. CHS patients have also been observed to exhibit a mild coagulation defect. Patients bruise easily, manifest petechiae, and have some mucosal bleeding, although platelet numbers remain normal.

The finding of large cytoplasmic granules in blood leukocytes is highly diagnostic. Hair shafts have evenly distributed granular pigment granules (see Fig. 144-14B), in contrast to the irregular, large pigmentary clumping of GS (see Fig. 144-14C). Skin biopsy shows pigmentary dilution in both melanocytes and keratinocytes and electron microscopy reveals giant melanosomes.

Prognosis, Clinical Course, and Treatment. Hemophagocytic syndrome, an accelerated phase of the disease that resembles lymphoma, occurs by late childhood. Hemophagocytic syndrome is characterized by widespread visceral infiltration by atypical lymphoid and histiocytic cells.

CHÈDIAK-HIGASHI SYNDROME AT A GLANCE

- Autosomal recessive disorder of vesicle trafficking that results in giant organelles, including melanosomes, leukocyte granules, and platelet-dense granules
- Mutations in LYST
- Silvery hair, often hyperpigmentation on nose and ears, and a variable degree of photophobia and nystagmus
- Recurrent pyogenic infections and a mild bleeding diathesis
- An "accelerated phase" with pancytopenia and organomegaly due to lymphohistiocytic infiltration (fatal without hematopoietic stem cell transplantation)
- Progressive neurologic deterioration
- Therapy: Transplantation

TABLE 144-8
Characteristics of Griscelli and Chédiak-Higashi Syndromes

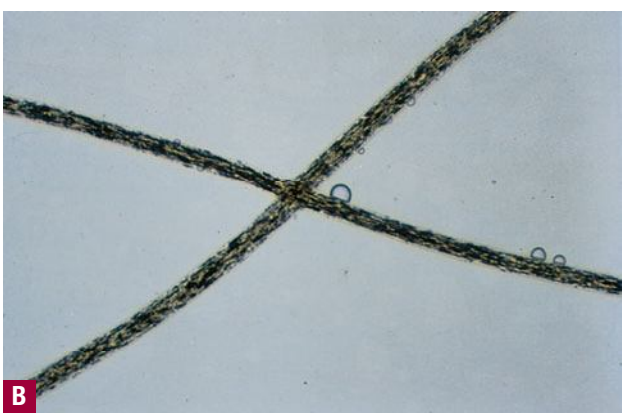
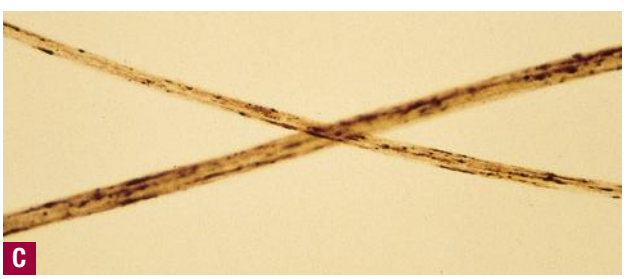
Gene defect/ protein	*MYO5A*/myosin5a.	*RAB27A*/Rab27a.	a. *Slac2-a/mlph.* b. *MYO5A* F-exon deletion.	*LYST/lysosomal transport protein.*
Functional consequence	Intracellular organelle transport and neurotransmitter secretion; Interacts with Slac2-a/mlph.	GTPase for organelle movement and transfer. Essential for T and NK lymphocyte cytotoxic granule release and target cell death. Interacts with Slac2-a/mlph.	Interacts with both myosin 5a and Rab27 to form a protein complex essential for melanosome movement to melanocytes.	Protein required for final steps of membrane fusion and vesicle trafficking.
Tissue expression	Brain. Not in cytotoxic cells.	Cytotoxic cells. Not in brain.	Slac2-a/mlph is not in cytotoxic cells.	
Clinical features	Silvery metallic hair. Mild skin pigment dilution. Onset of neurologic disorder in infancy.	Silvery metallic hair. Mild skin pigment dilution. Severe immune disorder with hemophagocytic syndrome. Neurologic symptoms are associated with hemophagocytic syndrome and central nervous system infiltration.	Silvery metallic hair.	Silvery metallic hair and skin. Recurrent infections. Bleeding tendencies. Progressive neurologic defects. Immune disorder with hemophagocytic syndrome.
Immune defects	None.	T and NK cell function; hypogammaglobulinemia.	None.	T and NK cell function, diminished neutrophil chemotaxis and bactericidal activity.
Hair mount	Large, uneven clusters of pigment.	Same as GS1.	Same as GS1.	Granular, evenly distributed pigment.
Skin light microscopy	Pigmentary dilution in keratinocytes, accumulation of melanosomes in melanocytes.	Same as GS1.	Same as GS1.	Pigmentary dilution in both keratinocytes and melanocytes.
Skin electron microscopy	Mature melanosomes filling epidermal melanocytes.	Same as GS1.	Same as GS1.	Reduced numbers of giant melanosomes.
Leukocyte granules	None.	None.	None.	Large, cytoplasmic.

GTPase = guanosine triphosphatase; mlph = melanophilin; NK = natural killer.





▲ **FIGURE 144-14** Silvery hair syndromes. **A.** Silvery sheen to the hair in a black infant; the patient had darkly pigmented eyes and skin. Note the accentuation of pigmentation on the ear helix. **B.** Small, evenly clumped pigment granules in the hairs of Chédiak-Higashi syndrome. **C.** Larger aggregates of irregularly spaced pigmentation in the hairs of a patient with Griscelli syndrome.

This lymphoma-like stage is precipitated by viruses, particularly by EBV infection. Hepatosplenomegaly, lymphadenopathy, pancytopenia, jaundice, fever, a leukemia-like gingivitis, and pseudomembranous sloughing of the buccal mucosa are common features.

The hemophagocytic syndrome associated with lymphohistiocytic proliferation of silvery hair syndromes needs to be distinguished from massive lymphoproliferation in other immunodeficiency disorders, particularly X-linked lymphoproliferative disorder (see Antibody Deficiency Disorders), familial hemophagocytic lymphohistiocytosis, autoimmune lymphoproliferative syndrome, and immunodeficiency due to mutations in the IL-2R. *Familial hemophagocytic lymphohistiocytosis* is a group of autosomal recessive disorders with hemophagocytosis and absence of NK cell cytotoxicity that tends to be fatal without early stem cell transplantation.[147]

The mean age of death for patients with Chédiak-Higashi syndrome is 6 years old, usually from overwhelming infection or hemorrhage during the lymphoma-like accelerated phase. Prenatal diagnosis has been achieved by examination of hair from fetal scalp biopsies and of leukocytes from fetal blood samples.

The treatment of choice for patients with Chédiak-Higashi syndrome is early transplantation, which corrects the immunologic status but does not affect the pigment abnormality nor inhibit the development of neurologic disorders that grow increasingly worse with age. Acyclovir, high-dose intravenous γ-globulin, vincristine, cyclosporine, and prednisone have been used to control the accelerated phase, but it is usually fatal. Ascorbic acid corrects the microtubular defects in vitro but has no clinical ameliorative effects.[150] Interferon has been demonstrated by some authors to partially restore NK cell function.[151]

GRISCELLI SYNDROME ***Epidemiology.*** The majority of affected patients with this autosomal recessive disorder are of Mediterranean or Middle Eastern origin and born into consanguineous families.

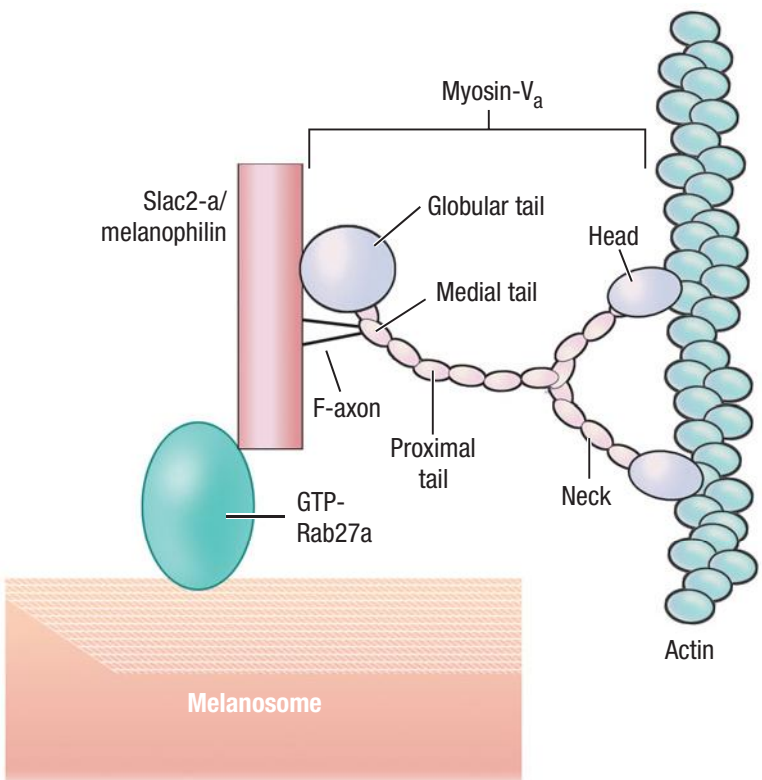
Etiology and Pathogenesis. Mutations in three genes may underlie GS. GS1 is caused by a mutation in the *MYO5A* gene that encodes myosin 5a, a motor protein responsible for intracellular organelle transport. *MYO5A* is abundantly expressed in brain tissue and is important for neurotransmitter secretion. It is not expressed in cytotoxic cells. GS2 is caused by a mutation in the *RAB27A* gene, which encodes Rab27a, a guanosine triphosphatase protein involved in the function of the intracellular-regulated secretory pathway. It is essential for T and NK lymphocyte cytotoxic granule release and cell death. This defective cytotoxic activity most likely leads to the uncontrolled activation of lymphocytes and macrophages in the hemophagocytic syndrome. Both *MYO5A* and *RAB27A* have been mapped to chromosome 15q21.1.[152] A third type of Griscelli syndrome (GS3) is the result of a homozygous missense mutation in *Slac2-a/mlph* (melanophilin, mlph) or a deletion of the *MYO5A* F-exon. Melanophilin encodes a member of the Rab effector family and interacts with both myosin 5a (through the F-exon) and *RAB27A* to form a triprotein complex essential for the capture and local transport of melanosomes to the melanocytes (Fig. 144-15).[152,153] All three genetic sub-types share the inability to construct this complex for melanosome transport, thus leading to the characteristic pigmentary abnormality of GS.

Clinical Findings. The pigmentary dilution of GS is often limited to the hair, characterized by a silver-gray sheen with a few cases of skin involvement.

GRISCELLI SYNDROME AT A GLANCE

- Autosomal recessive group of disorders
- Mutations in *MYO5A* (more neurologic), *RAB27A* (hemophagocytosis), or *Slac-2a*
- Silvery hair is a hallmark
- Hemophagocytosis often precipitated by Epstein-Barr virus infection
- Treatment: Transplantation

The hair shaft shows large uneven clusters of pigment (see Fig. 144-14C) and the skin shows pigmentary dilution in keratinocytes but accumulation of melanosomes in melanocytes. Electron microscopy reveals numerous stage IV melanosomes in epidermal melanocytes. In contrast to Chédiak-Higashi syndrome, smears of leukocytes do not



▲ **FIGURE 144-15** Protein interactions required for melanosome transfer. GTP = guanosine triphosphate. [Adapted from Menasche G et al: Griscelli syndrome restricted to hypopigmentation results from a melanophilin defect (GS3) or a MYO5A F-exon deletion (GS1). *J Clin Invest* **112**:450, 2003.]

show giant granules. The additional clinical features present in each subtype are dependent on the function and tissue expression of the defective protein. Patients with GS1 have a primary neurologic disorder that presents in infancy with hypotonia and developmental delay. Severe immune disorder characterized by hemophagocytic syndrome or an "accelerated phase of the disease" is seen in GS2. Hemophagocytic syndrome is characterized by infiltration of various organ systems by activated lymphocytes and macrophages. It develops by a mean age of 36 months, and often is precipitated by a virus, particularly EBV. Patients have fever, hepatosplenomegaly, neurologic impairment, coagulopathy, and pancytopenia.[154] Patients with GS3 present solely with the pigmentary abnormalities.

Prognosis, Clinical Course, and Treatment. GS has been uniformly fatal but now can be reversed by successful bone marrow transplantation. Eighty-five percent of patients with GS2 have mutations in the *RAB27A* gene that lead to early protein truncation. They have the most severe form of the disease with early development of hemophagocytic syndrome and rapid progression. The median survival from the onset of the accelerated phase to death in these patients is 5 months. Most patients die by 5 years of age secondary to progressive CNS disease or recurrent infections.[154] Missense mutations in the *RAB27A* gene show a milder phenotype with later age of hemophagocytic syndrome onset and a good response to chemotherapy treatment.[155] Patients with GS1 do not develop hemophagocytic syndrome. Prenatal diagnosis has been achieved by examination of hair from fetal scalp biopsies and DNA from leukocytes of fetal blood samples.[156]

COMPLEMENT DEFICIENCY DISORDERS

The complement system represents an enzymatic reaction cascade that involves three major initial pathways (classical—C1, C4, C2; lectin; and alternative—C3, factors B, D, H, and I, properdin) and a shared terminal pathway (membrane attack complex—C5–C9) (see Chap. 36). Complement proteins regulate humoral and cellular immune functions, and participate in the killing of bacterial organisms. Abnormalities of the complement system tend to manifest as increased susceptibility to bacterial organisms or autoimmune disorders.[157,158]

COMPLEMENT DEFICIENCY DISORDERS AT A GLANCE

- Deficiency or dysfunction of early complement components is associated with autoimmune disorders, particularly systemic lupus erythematosus.
- Deficiency or dysfunction of early complement components leads to risk of infections caused by encapsulated bacteria.
- Deficiency of late complement components markedly increases susceptibility to neisserial infections.

Epidemiology

The most common hereditary complement disorder is C2 deficiency, which can result from a defect in either protein synthesis (type 1) or secretion (type 2); 1 percent to 2 percent of the Caucasian population is heterozygote[159] and 0.005 percent are homozygote.[160] The deficiency is usually caused by a 28-base pair deletion in the C2 gene. Homozygous deficiencies of C1q, C1r, C1s, and C4 (C4A or C4B) are rare, but manifest with autoimmune disease more frequently than homozygous C2 deficiency. The incidence of SLE in patients with C1q, C4, and C1r is 93 percent, 75 percent, and 57 percent, respectively; whereas it is 10 percent with C2 deficiency (25 percent if homozygous).[157] Total deficiency of mannan-binding lectin (MBL) is the most common among homozygote states (approximately 3 percent), although clinical penetrance is low.[161] In addition, approximately 0.01 percent of individuals have a homozygous deficiency in the MBL-associated serum protease, which is activated by MBL binding to the surface carbohydrates of bacteria and generates classical pathway C3 convertase via cleavage of C4 and C2. Excluding deficiency of MBL; however, homozygote forms of complement deficiency represent 0.03 percent of the population. In general, heterozygotes produce sufficient complement to ensure function and remain asymptomatic, so individuals who manifest complement disorders tend to be homozygotes. Hereditary angioedema (HAE), on the other hand, manifests in heterozygotes with deficiency or dysfunction of the C1 inhibitor (C1 INH) (see Hereditary Angioedema). Despite the rarity of homozygous deficiency, the incidence of complement deficiency in patients with recurrent neisserial infection has been found to be as high as 20 percent. In patients with autoimmune disorders, such as SLE, the incidence of C2 deficiency is approximately 7 percent[159] and of MBL deficiency is increased two- to threefold. Properdin deficiency is the only X-linked complement deficiency, and all known patients are male.

Etiology and Pathogenesis

Defects involving the early components of the classical complement pathway (C1, C4, C2) manifest with an increased incidence of autoimmune disorders, especially SLE (Table 144-9). The reason for the increased incidence of autoimmune disorders and particularly lupus in patients with complement deficiency is unclear. The genes that encode C4A, C4B, C2, and factor B are localized to the MHC region on chromosome 6; just as HLA types have been linked to SLE (e.g., HLA A1, B8, DR3), gene alterations in this region may play a role in generation of autoimmunity.

The variety of recurrent infections associated with complement deficiencies underscores the key role of complement in bacterial clearance. Patients with a deficiency of the early classical components, especially C2, have a mildly increased susceptibility to infections with encapsulated bacteria. Opsonization of bacteria and fungi may be ineffective in disorders of the classical pathway because of the slow, inadequate formation of C3b. However, the development of infection is likely mitigated by the ability of the lectin and alternative pathways to generate C3, thus bypassing the early classical pathway (see Chap. 36). C5 deficiencies result in impaired generation of chemotactic factors, which may lead to inadequate neutrophil function. Individuals with C5 to C9 (membrane attack complex) deficiencies typically develop chronic recurrent neisserial infections as teenagers, reflecting the role of the terminal complement pathway in the destruction of these organisms. Similarly, the effect of properdin in stabilizing the alternative C3 convertase is critical for killing of organisms because properdin deficiency leads to fulminant neisserial infections. Manifestations of complement deficiency may also result from alterations in the regulators of the complement cascade that lead to uncon-

TABLE 144-9
Clinical Manifestations of Hereditary Deficiency or Dysfunction of Complement Components

MANIFESTATION	COMPONENT	PATHWAY	ASSOCIATIONS
Infection	C1q, C1r, C1s, C4, C2	Classical	Autoimmune disorders, especially SLE Increased encapsulated bacterial infections
	Mannan-binding lectin	Lectin	Pyogenic infections in neonates and children SLE
	Factors H, I	Inhibitors, alternative	Recurrent pyogenic infections (C3 depletion)
	Properdin	Stabilizer, alternative	Fulminant neisserial infections
	CR3	Receptor for iC3b	Leukocyte adhesion defect (see LAD type 1)
	C5–C9	Terminal (membrane attack complex)	Recurrent neisserial infections; milder with C9 deficiency
Autoimmune disorders	C1, C4, C2	Classical	Autoimmune disorders, especially SLE Increased encapsulated bacterial infections
	Mannan-binding lectin	Lectin	Pyogenic infections in neonates and children SLE
Exfoliative erythroderma	C3, C5	Shared, terminal	Failure to thrive, diarrhea, infections
Angioedema	C1 esterase inhibitor	Inhibitor, classical	Angioedema
Renal disease and/or hemolysis	Factor H	Inhibitor, alternative	Glomerulonephritis, atypical hemolytic uremic syndrome
	Decay accelerating factor (CD59)	Inhibitor, alternative	Hemolysis, thrombosis
	Membrane co-factor protein (CD46)	Inhibitor, alternative	Atypical hemolytic uremic syndrome
	C3	Shared	Membranoproliferative glomerulonephritis Severe bacterial infections

LAD = leukocyte adhesion deficiency; SLE = systemic lupus erythematosus.

trolled activation of the complement cascade (see Chap. 36).

Clinical Features

Cutaneous and joint findings of lupus erythematosus (see Chap. 156) are the most common autoimmune manifestation of deficiency of the early complement components (see Table 144-9), and often first show manifestations during childhood. Manifestations of deficiency of C2 are seen most commonly, given its prevalence, but deficiency of homozygous C1q deficiency is the strongest single genetic risk factor for SLE identified to date. In general, the lupus associated with C2 deficiency is milder than that associated with deficiency of other classical complement components (Fig. 144-16), which have an earlier onset, and increased risk of associated glomerulonephritis. In addition to patients who meet criteria for lupus erythematosus, undifferentiated connective tissue disease and vasculitis are the most common autoimmune manifestations in individuals with C2 deficiency. C2 deficiency has also been found in patients with dermatomyositis, juvenile rheumatoid arthritis, atrophoderma, Henoch-Schönlein purpura, cold urticaria, and inflammatory bowel disease.

The most common feature of lupus in persons with C2 deficiency is photosensitivity, and lesions typical of subacute cutaneous lupus are seen more often than those of acute cutaneous lupus (see Fig. 144-16) or discoid lupus. Oral ulcerations are present in approximately 50 percent of affected individuals, and cicatricial alopecia may occur. In general, the lesions may be more resistant than those of lupus without complement deficiency, but noncutaneous manifestations tend to be less

▲ **FIGURE 144-16** Systemic lupus erythematosus in a child with C4 deficiency. This boy eventually died of an overwhelming Gram-negative coccal infection.

severe. Arthralgias or arthritis is seen in 80 percent, but renal disease tends to be mild or occult. C2 deficiency lupus but also C4 deficiency lupus is unlikely to be associated with elevated antinuclear antibody titers or anti-DNA antibodies, but 75 percent of patients have detectable anti-Ro antibodies. Direct immunofluorescence may show deposition but is more likely to be negative than in lupus unrelated to C2 deficiency. Leukopenia has been described in 50 percent of affected individuals and rheumatoid factor in 40 percent.

Although most individuals with MBL deficiency show no clinical manifestations, deficiency of MBL or its associated serum protease is also associated with an increased risk of SLE, and MBL deficiency has been described with dermatomyositis. In patients with SLE, having MBL deficiency is associated with a higher risk of bacterial complications. The risk of SLE is also increased in individuals with deficiencies in C3 or regulators of the complement pathway, such as factor H or factor I (C3b inactivator). Approximately 5 percent of individuals with deficiency of the late complement components have evidence of immune complex or autoimmune disease, and these manifestations have not been described with properdin deficiency.

The bacterial organisms that cause problems in complement deficiency of classical components are encapsulated bacteria, including *Pneumococcus* and *H. influenzae*. Infections can be severe with an onset during infancy and childhood.[166,167] A recent retrospective study of 40 patients with homozygous C2 deficiency over a mean of 39 years (range, 1 to 77 years) found that severe infection was the predominant clinical manifestation[157]; 23 patients had a his-

tory of septicemia or meningitis caused by *Pneumococcus*, and in 12 the infections were recurrent. Nineteen patients had at least one episode of pneumonia, with recurrence in 10 affected individuals.

With deficiency of components of the membrane attack complex or regulators of the alternative pathway, particularly properdin deficiency, infections most commonly begin in teenage years and are caused by neisserial organisms, particularly meningococcus. Properdin deficiency is associated with fulminant meningococcal disease that can lead to death in up to 28 percent of patients and usually manifests as a single episode, but the neisserial disease with deficiency of the late complement components tends to be recurrent and of lesser severity, only occasionally leading to death.

Laboratory Abnormalities

In complement deficiencies other than HAE, total hemolytic complement (CH50) is markedly decreased (e.g., in C9 deficiency) or undetectable (most complement deficiencies). The alternative pathway lytic test (AP50) is less sensitive than the CH50, but may be useful to screen for deficiencies in the alternative pathway components. Levels of specific complement components and MBL are generally measured by enzyme-linked immunosorbent assay or radial immunodiffusion assays.[158] Although usually absent with C2 deficiency itself, anti-Ro antibodies are present in three-fourths of patients with C2 deficiency who have SLE.

Differential Diagnosis

Secondary decreases in complement levels may be seen in patients with a variety of disorders, most commonly in SLE and hypocomplementemic vasculitis. Complement levels may also be reduced by bacterial (particularly endocarditis) and viral infections, hepatic disease, myeloma, malnutrition including anorexia nervosa, and medications that may cause a lupus-like syndrome (especially hydralazine, penicillamine, and procainamide). The "Leiner phenotype" has been described in patients with HIES, SCID, and X-linked agammaglobulinemia.

Treatment

Traditional management of lupus erythematosus is appropriate for patients with complement deficiency and should be chosen based on clinical manifestations. Topical anti-inflammatory medications and sun protection may adequately treat milder cases with cutaneous findings, but antimalarial medications, systemic corticosteroids, and other immunosuppressive drugs may be required for more severe cases; given the increased risk of infections in patients with complement deficiency, careful monitoring is critical.

HEREDITARY ANGIOEDEMA

HAE is almost always inherited in an autosomal dominant fashion with a spontaneous mutation rate of 25 percent.[171] It occurs in 1 in 150,000 persons and has no racial or ethnic predilection. Seventy-five percent of patients report a positive family history. There are three types of HAE. Type I is characterized by low antigenic levels of C1 INH and affects 85 percent of patients, whereas the remainder of patients have Type II, with low functional levels but normal/high antigenic levels of C1 INH.[172] A third type of HAE does not show a deficiency of C1 INH.[173] This type of HAE was previously thought to only affect women, although recently, a family was described in which three male family members were affected.[174] One family has been identified in which the disease is transmitted as an autosomal recessive trait due to a mutation in the promoter region of the gene.[175] See Chap. 37 for a complete discussion of HAE.

SECTION 25

SKIN MANIFESTATIONS OF BONE MARROW AND BLOOD DISORDERS

CHAPTER 145

Hematologic Diseases

Bina A. Rashid
Elizabeth Bahar Houshmand
Michael P. Heffernan

Mucocutaneous changes are often an indicator of underlying hematologic diseases. The skin and mucous membranes are highly vascular and are susceptible to abnormalities in the blood. Mucocutaneous manifestations may result from alterations in hemoglobin concentration, oxygenation, and plasma volume. Likewise, genetic diseases, such as sickle cell and thalassemia, present with significant skin changes, as do bone marrow disorders such as the leukemias and lymphomas.[1–3] This chapter focuses on the cutaneous findings associated with non-malignant hematologic disorders.[4]

Routine laboratory tests have now made it easier to detect common hematologic disorders. In some parts of the world where laboratory tests are not easily accessible or affordable, pallor, cyanosis, and jaundice are useful in detecting an underlying disease and assessing its management. In such areas of the world, anemia and other hematologic conditions are more prevalent.[5] A comprehensive listing of these associations is presented in Table 145-1. Selected associations are covered in more detail in the text. The emphasis, in this chapter, is the differential diagnosis of mucocutaneous discoloration (pallor, erythroderma, cyanosis, jaundice, and extramedullary hematopoiesis) and blood extravasation (cutaneous hemostasis and purpura).

CUTANEOUS SIGNS AND SYMPTOMS ASSOCIATED WITH HEMATOLOGIC DISEASES

Pallor

Pallor of the mucocutaneous tissue is observed most readily in the palms, nail beds, face, and conjunctivae. In these areas, the microvascular bed is visible through the skin. Pallor is the result of lowered hemoglobin content.[75,76]

There are multiple causes for pallor. They include acute and chronic hemorrhage, emotion, drugs (i.e., vasopressors), cold, shock, and pathophysiologic adjustments that lead to anemia. Cutaneous edema can also produce pallor. Treating the underlying etiology of pallor corrects both the pallor and the cause.

ANEMIA The palmar creases are a good indicator of the severity of anemia. Unless the hemoglobin level drops below the normal range, palmar creases appear pink.

The definition of anemia is dependent on the patient's age and sex. Anemias are best approached through a morphologic classification based on red blood cell (RBC) size or volume, which can be assessed by a blood smear.[77,78] This allows us to classify the anemias into microcytic, normocytic, and macrocytic anemias. Each morphologic type of anemia is associated with specific causes such as blood loss, genetic disorders, decreased red blood cell production, or increased red blood cell destruction.[79,80]

Constitutional signs and symptom of anemia include malaise, fatigue, dizziness, postural hypotension, dyspnea on exertion, and tachycardia. Obviously, these symptoms and signs become more apparent as the oxygen demand is increased. Red blood cells carry oxygen linked to hemoglobin from the lungs to tissue capillaries.[81,82] Oxygen is then released from hemoglobin according to the characteristics of the oxyhemoglobin dissociation curve.[82]

Laboratory evaluation should be based on the suspicion of the underlying cause of anemia; it includes complete blood count with white blood cell differential, iron studies (iron, total iron blood

HEMATOLOGIC DISEASES AT A GLANCE

- Mucocutaneous changes (i.e., pallor, jaundice, flushing, erythema, and cyanosis) often predict underlying hematologic pathology.
- Anemia is best differentiated by mean corpuscular volume value.
- Megaloblastic anemia of vitamin B_{12} deficiency is distinguished from folate deficiency by lack of neurologic signs in folate deficiency.
- Carcinoid tumor results in flushing, typically for 10 minutes or less; in comparison, flushing from mastocytosis lasts 30 minutes or more.
- Polycythemia vera presents with acrocyanosis, aquagenic pruritus, urticaria, Sweet syndrome, and purpura.
- The morphologic diagnosis of purpura begins with three P's: Is the lesion *p*urpuric, is it *p*rimary, and is it *p*alpable?
- Leukemia cutis is a localized or disseminated skin infiltration by leukemic cells. It is a sign of dissemination or systemic disease or relapsing leukemia.

TABLE 145-1
Cutaneous Findings with Hematologic Associations[6–9]

Pigmentary changes
- Generalized hyperpigmentation
  - POEMS syndrome (*p*olyneuropathy, *o*rganomegaly, *e*ndocrinopathy, *M*-protein, *s*kin lesions)[10,11]
    - ~ Hyperpigmentation, 93%–98%; apparent skin thickening, 77%–85%; hypertrichosis, 78%–81%; peripheral edema, ~90%; digital clubbing, 56%; white fingernails; verrucous angiomata, telangiectasia
  - Hemochromatosis may have bronze or grayish pigmentation of the skin
  - Megaloblastic anemia of vitamin B_{12} or folate deficiency
  - Fanconi anemia[12,13]
    - ~ Begins age 4–10 yr with skin or hematologic presentation
    - ~ Generalized hyperpigmentation, especially lower trunk, flexures, neck, 85%
    - ~ Scattered darker and lighter macules within hyperpigmented areas
    - ~ Progressive hypoplastic anemia with pancytopenia
    - ~ Death from leukemia, other neoplasms, or infections 2–5 yr after onset
  - Dyskeratosis congenita[14]
    - ~ Nail dystrophy, beginning 5–13 yr of age
    - ~ Fine reticulate gray-brown hyperpigmentation, especially neck, thighs, and trunk
    - ~ Atrophic skin with telangiectasis
    - ~ Oral leukoplakia
    - ~ Mucocutaneous carcinomas, occasional pancreatic carcinoma, Hodgkin disease
    - ~ Frequent blood dyscrasias, aplasias, refractory anemias, pancytopenias
- Localized hyperpigmentation
  - Hypermelanosis and hemosiderosis may develop on the lower legs in hemolytic anemia, may develop focally in vitamin B_{12} or folate deficiency
  - Porphyria cutanea tarda, variegate porphyria, erythropoietic porphyria, occasionally hereditary coproporphyria cause hyperpigmentation, primarily in sun-exposed areas (see Chap. 149)
- Generalized hypopigmentation
  - Chédiak-Higashi (see Recurrent cutaneous infections)
  - Hermansky-Pudlak[15]
    - ~ White, red, or brown hair; cream-gray to light normal skin
    - ~ Blue-gray to brown iris
    - ~ Platelet bleeding diathesis
    - ~ Ceroid-like deposits in reticuloendothelial system, gastrointestinal tract, lung, and kidney that lead to pulmonary interstitial fibrosis, nephritis, granulomatous colitis
- Localized hypopigmentation
  - POEMS syndrome (see Generalized hyperpigmentation)
  - Pernicious anemia with vitiligo
  - Vitamin B_{12} deficiency associated with poikilodermatous hypopigmentation
  - Anemia of autoimmune hypothyroidism may be associated with vitiligo
  - Adult Gaucher disease[16]
    - ~ Brown chloasma-like macules on face, neck, and hands
    - ~ Symmetric hyperpigmentation of lower legs
  - Niemann-Pick disease[17,18]
    - ~ Indurated discolored patches, especially on checks, café-au-lait spots
    - ~ Mongolian on skin and oral mucosa
  - Porphyria cutanea tarda, variegate porphyria, erythropoietic porphyria, usually in areas of scarring

Recurrent cutaneous infections
- Neutropenia
  - Severe neutropenia (counts of 500/μL usually associated with fever, erythema without pus, painful ulcers). Causes include congenital and cyclic neutropenia; leukemia, lymphoma; marrow toxicity, failure, infiltration; and immune and autoimmune neutropenias.
- Functional leukocyte defects (counts may be low, normal, or elevated; defects identified in adherence, chemotactic response, phagocytosis, and killing)[19,20]
  - Chédiak-Higashi syndrome[15,21]
    - ~ Autosomal recessive
    - ~ Defect in cytoplasmic granule function
    - ~ Fair skin, light blond or silvery hair, and pale retina; translucent irises due to abnormal melanosomes
    - ~ Large neutrophil inclusion on Wright-stained blood smear
    - ~ Usually die in childhood
  - Griscelli syndrome[22] (see Chap. 115)
    - ~ Pigmentary dilution with silvery-gray hair
    - ~ Autosomal recessive
    - ~ Hypogammaglobulinemia, defective cell-mediated immunity
    - ~ Neutropenia, thrombocytopenia, lymphohistiocytosis, hepatosplenomegaly
    - ~ Neurologic deterioration
  - Chronic granulomatous disease of childhood (see Chap. 115)
    - ~ Leukocytes ingest bacteria normally but fail to kill them because of defects in H_2O_2 and oxygen radical production
    - ~ Multiple types, most X-linked; overall sex ration, male-female 6:1
    - ~ Skin lesions eczematous and purulent initially, transition to chronic cutaneous granulomas
    - ~ Catalase-positive microbes (e.g., *Staphylococcus aureus*, *Salmonella*, *Aspergillus*) can multiply intercellularly, whereas catalase-negative microbes (e.g., pneumococci or streptococci) that generate their own H_2O_2 are killed
    - ~ Nitroblue tetrazolium dye helpful in diagnosis
    - ~ X-linked carriers may develop lupus-like skin lesions, aphthous stomatitis, or granulomatous cheilitis
  - Myeloperoxidase deficiency
    - ~ Autosomal recessive affecting neutrophils but not eosinophils
    - ~ Functional impairment not severe
    - ~ Occasional difficulty with pyogenic infections, persistent fungal infection more common
- Membrane and cytoskeletal defects (see Chap. 115)
  - Leukocyte adherence disorders due to congenital lack of defect or some component of CD11/CD18 surface glycoproteins
    - ~ Neutrophils unable to adhere firmly to surfaces or complement-opsonized microorganisms
    - ~ Possible persistent leukocytosis
    - ~ Failure to develop much neutrophil response at inflammatory or infectious sites
  - Cytoskeletal defect in polymerizable actin[23]
    - ~ Similar presentation to leukocyte adherence defects, but with normal CD11/CD8 but impaired motility
  - Complement abnormalities
    - ~ C3 deficiency, C3b inactivator deficiency
  - Hyperimmunoglobulin E (IgE) syndrome
    - ~ Job and Buckley syndromes are subsets
    - ~ Elevated IgE, defective neutrophil chemotaxis
    - ~ No clear relationship between IgE levels and neutrophil motility defect
    - ~ Cold abscesses

(continued)

TABLE 145-1
Cutaneous Findings with Hematologic Associations[6–9] (Continued)

Recurrent cutaneous infections—*continued*
- Leiner disease
  - ~ Severe seborrheic dermatitis
  - ~ Diarrhea, failure to thrive
  - ~ Gram-negative bacterial and candidal infection during infancy
- Wiskott-Aldrich syndrome[24,25]
  - ~ X-linked
  - ~ Thrombocytopenia, small but dysfunctional platelets, hemorrhage
  - ~ Eczema
  - ~ Recurrent infections: Initially bacteria such as *Pneumococcus*, *Haemophilus influenzae*, *Neisseria meningitidis*; over time, T-cell function deteriorates and patient becomes susceptible to opportunistic viral, bacterial, and fungal infections
  - ~ Immunologic abnormalities and lymphoreticular malignancies
  - ~ CD43, a ligand for intercellular adhesion molecule-1, is defective; however, probably not primary defect because CD43 gene is on chromosome 16, not X
- Persistent or extensive herpes simplex or recurrent or disseminated herpes zoster suggest underlying immune defect or hematologic malignancy

Neutrophilic cutaneous reactions
- Acute febrile neutrophilic dermatosis (Sweet syndrome): Less than 10% of reported patients have heme association, usually acute myelogenous leukemia, myeloproliferative disorder, myelodysplastic syndrome, multiple myeloma, or monoclonal gammopathy
- Pyoderma gangrenosum: Often atypical or bullous—hematologic association similar to those in Sweet syndrome
- Antineutrophil cytoplasmic autoantibody (ANCA)–positive neutrophilic dermatosis
- Polymorphic disease with monoclonal IgA ANCA[26]
- Erythema elevatum diutinum (see Vascular disorders and coagulopathies)
- Leukocytoclastic vasculitis (see Vascular disorders and coagulopathies)

Vesiculobullous disease
- Pemphigus vulgaris: Lymphoproliferative diseases[27,28]
- Paraneoplastic pemphigus: Lymphoproliferative diseases, thymoma[29]
- Acquired immunobullous disease with skin fragility: Waldenström macroglobulinemia[30]
- Linear IgA dermatosis: Associations include Hodgkin lymphoma, non-Hodgkin lymphoma, polycythemia vera, chronic lymphocytic leukemia, plasmacytoma[31]
- IgA pemphigus: Occasional monoclonal gammopathy or myeloma, most often IgA
- Sub-corneal pustular dermatosis: IgG or IgA monoclonal gammopathy or myeloma[10,11]
- Dermatitis herpetiformis: Frequent polyclonal IgA gammopathy, occasional myeloma, lymphomas, angioimmunoblastic lymphadenopathy
- Porphyria cutanea tarda, variegate porphyria, hereditary coproporphyria, and erythropoietic porphyria (see Pruritus, prurigo, and burning, and Generalized hyperpigmentation)
- Bullous mastocytoma, bullous urticaria pigmentosa of infancy[32]
- Hypereosinophilic syndrome can induce vesiculobullous lesions[33]

Skin cancers
- Basal cell and squamous cell carcinoma increased in non-Hodgkin lymphoma and chronic lymphocytic leukemia (CLL)[34]
- Kaposi sarcoma increased in lymphoma, CLL, some immune deficiencies

Vascular disorders and coagulopathies
- Vasculitis
  - Usually cutaneous leukocytoclastic vasculitis (including urticarial vasculitis) and polyarteritis nodosa; ~5% of patients with vasculitis have an underlying malignancy[35]; lymphoproliferative disease most common, especially hairy cell leukemia, other hematologic associations include cryoglobulinemia, Hodgkin disease, non-Hodgkin lymphoma, myelodysplastic syndrome, chronic myelogenous leukemia, and multiple myeloma[27,36]
  - Erythema elevatum diutinum: Gammopathy or myeloma, frequently IgA[10,11]
  - Urticaria and angioedema
    - ~ Lymphoproliferative disease, sometimes with decreased C1-esterase inhibitor function[10]
    - ~ Cryoglobulinemia; can also cause cold-induced urticaria[10]
    - ~ Lymphocytic vasculitis: Angioblastic lymphadenopathy, non-Hodgkin lymphoma, CLL[37]
    - ~ Vasculitis panniculitis: Children, non-Hodgkin lymphoma[38]
    - ~ Hypereosinophilic syndrome[33]
- Vasculopathies and altered vascular reactivity
  - Flushing, erythroderma
  - Plethora, ruddy cyanosis
  - Erythema annulare centrifugum: Lymphoma, "malignant histiocytosis," hypereosinophilic syndrome[39]
  - Erythralgia/erythromelalgia[40–42]
    - ~ Polycythemia vera, essential thrombocytopenia; less commonly myelofibrosis, chronic myelogenous leukemia, cryoglobulinemia
  - Raynaud phenomenon
    - ~ Waldenström macroglobulinemia[10]
    - ~ Cryoglobulinemia[10]
  - Livedo reticularis[43,44]
    - ~ Plasma cell dyscrasias with hyperviscosity, cryoglobulinemia, or cold agglutinin disease, macroglobulinemia[45]
    - ~ Hyperleukocytosis
    - ~ Polycythemia vera, thrombocythemia[46]
    - ~ (for the following, see also Tables 145-2 to 145-4)
    - ~ Anti-phospholipid antibody, lupus anticoagulant[47]
    - ~ Hereditary protein C deficiency[48]
    - ~ Antithrombin III deficiency[48,49]
    - ~ Heparin-associated thrombocytopenia[50]
  - Acral cyanosis
    - ~ Coumadin or other anticoagulant-enhanced tendency for cholesterol embolization: Blue toe syndrome
    - ~ Polycythemia vera, thrombocythemia, rarely with myeloblast leukostasis syndrome of chronic myelogenous leukemia[51]
    - ~ Cryoglobulinemia[10,52]
    - ~ Cold agglutinins[10,45]
    - ~ Crystal globulin vasculopathy: Multiple meloma[53,54]
- Vascular changes
  - POEMS syndrome: Telangiectasias or angiomas
  - Langerhans cell histiocytosis: Telangiectasias, petechial hemorrhage
  - Telangiectasia macularis eruptive perstans variant of urticaria pigmentosa[32]

(continued)

TABLE 145-1
Cutaneous Findings with Hematologic Associations[6–9] (Continued)

Vascular disorders and coagulopathies—*continued*
- Bleeding or coagulopathy secondary to dysproteinemia
  - Mucocutaneous hemorrhage
    - ~ Hyperviscosity syndrome, usually Waldenström macroglobulinemia, occasionally myeloma, cryoglobulinemia[55]
    - ~ Abnormal platelet function from dysproteinemias[10]
    - ~ Factor deficiencies or inhibitors: factor V or VIII with IgM or IgA36l factor VII with IgG[10]; factor X adsorptive depletion in amyloidosis[55]
    - ~ Low-grade disseminated intravascular coagulation with protein C dysfunction secondary to IgG gammopathy[10]

Cutaneous deposition/induration[10,11]/altered texture
- AL (light-chain related) systemic amyloidosis: Papules, plaques, nodules, bullae, sclerotic plaques, urticaria-pigmentosa-like lesions, alopecia, macroglossia; occurs with idiopathic or disease-associated monoclonal gammopathies
- Nodular cutaneous amyloidosis: Local monoclonal plasma cell infiltrate; atrophic outpouchings of abdominal skin[56]
- Storage papule disease (translucent, often crusted or purpuric centers, buttocks and lower extremities): Waldenström macroglobulinemia[57]
- Cutaneous swelling associated with crystalline protein deposition: myeloma[58]
- Follicular spicules of the nose: Multiple myeloma, cryglobulinemia[59]
- Scleromyxedema variant of lichen myxedematosus: usually IgGγ gammopathy[60]
- Scleroderma: usually IgG monoclonal gammopathy, occasionally myeloma
- Niemann-Pick: Waxy induration with transient xanthomas overlying enlarged lymph nodes[18,61]
- Thickened, doughy, skin of diffuse cutaneous mastocytosis[62]
- Anetoderma: Cutaneous plasmacytoma, benign lymphoid hyperplasia[63]

Xanthomas[10,11]
- Necrobiotic xanthogranuloma with paraproteinemia
  - Usually periorbital xanthoma, typically ulcerative
  - Leukopenia
  - Monoclonal gammopathy or multiple myeloma
- Xanthoma disseminatum—occasional association with monoclonal gammopathy, multiple myeloma, Waldenström macroglobulinemia
- Generalized plane xanthomatosis
  - Multiple myeloma, monoclonal gammopathies, leukemias
  - Xanthomas and café-au-lait spots: juvenile chronic granulocytic leukemia
  - Eruptive or tuberous xanthomas rarely reports with dysproteinemias

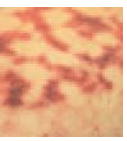
Cutaneous sarcoidal or histiocytic tissue reactions
- Cutaneous sarcoidal reactions: Lymphoma[64]
- Multicentric reticulohistiocytosis: Lymphoproliferative disorders[65]

Epidermal changes
- Acquired ichthyosis: Lymphoproliferative malignancies, primarily Hodgkin disease[66]
- Sign of Lesser-Trélat: Lymphomas comprise one-fifth of cases[67]

Hypertrichosis
- Porphyria cutanea tarda, erythropoietic porphyria

Pruritus, prurigo, and burning
- Severe itching occurs in 1%–11% of patients with Hodgkin disease even in the absence of any visible skin lesions; occasional complication of non-Hodgkin lymphoma and leukemia[27]
- Mycosis fungoides, Sézary syndrome, or other lymphomas with skin involvement may also present as itching
- Eosinophilic folliculitis after marrow transplant or chemotherapy for heme malignancies[68]
- Aquagenic pruritus: Polycythemia vera, hypereosinophilic syndrome, myelodysplastic syndrome, juvenile xanthogranuloma[69]
- Hypereosinophilic syndrome: Pruritic, erythematous papules or nodules, and angioedematous or urticarial plaques common[33]
- Mastocytosis: Pruritic and usually pigmented papules or diffuse pruritis[32]
- Erythropoietic protoporphyria: Pruritus and burning within minutes of sun exposure; may develop urticaria, edema, erythema, purpura
- Angioimmunoblastic lymphadenopathy: Macular and popular eruptions, petechial, purpuric, nodular, ulcerative, and erythrodermic eruptions described[70,71]

Ulcerations
- Non-malignant red blood cell disorders and leg ulcers
  - α or β thalassemias
  - Hemoglobin (Hb) SS, Hb-s-β thal, Hb SC
  - Hereditary spherocytosis and elliptocytosis
  - Paroxysmal nocturnal hemoglobinuria
- Cutaneous lesions of leukemia, lymphoma, and some histiocytoses may ulcerate
- Lymphomatoid papulosis
- Polycythemia vera and essential thrombocytopenia
- Kaposi sarcoma
- Reactive hemophagocytic syndrome
- Angioimmunoblastic lymphadenopathy[70]
- Necrobiotic xanthogranuloma with paraproteinemia, xanthoma disseminatum
- Sweet syndrome
- Cryoglobulinemia[10]
- Hypereosinophilic syndrome, especially mucosal ulcerations and erosions[33,72]
- Protein C deficiency, inherited and acquired (including Coumadin necrosis, some disseminated intravascular coagulation)
- Heparin necrosis
- Anti-phospholipid antibody syndrome
- Neutropenic and immune deficiency–related infections
- Pyoderma gangrenosum or pyoderma gangrenosum–like ulcers,[73,74] Chédiak-Higashi
- Leukocyte adhesion deficiency
- Chronic granulomatous disease
- Hyperimmunoglobulinemia E
- Felty syndrome
- Acute myelogenous leukemia



count, percent saturation of iron), ferritin, B_{12}, lactate dehydrogenase (LDH), haptoglobin, folate levels, platelet and reticulocyte counts.[83]

IRON DEFICIENCY Sixty percent to 70 percent of the body stores of iron are in the RBCs in the form of hemoglobin. Heme-containing proteins are essential for metabolic processes in virtually all cells.[84] Hemoglobin, myoglobin, and the cytochromes are all heme-containing proteins and enzymes.[85] The average life of an erythrocyte is 120 days, after which it is phagocytized by macrophages of the liver, spleen, and bone marrow. The iron is then stored in the form of ferritin to be recycled.[86,87]

Iron deficiency anemia can result from increased iron demand in the setting of inadequate iron stores. This is

most commonly seen during pregnancy when increased blood volume is necessary for the growth and development of the fetus.[90]

Clinical signs and symptoms of iron deficiency include fatigue, pallor, koilonychia, tinnitus, irritability, and pica (the craving to eat substances such as dirt, clay, ice, laundry starch, salt, or cardboard).[91] Akathisia (restless legs syndrome), blue sclera, angular stomatitis, and glossitis can also be seen. Generalized fatigue often disrupts the patient's ability to focus on daily activities at work, home, and school, resulting in poor performance.[92]

Treatment of iron deficiency anemia requires replacing lost iron and maintaining the daily iron dietary requirement. The recommended daily dose for treatment of iron deficiency is between 150 to 200 mg/day of elemental iron (325 mg ferrous sulfate = 65 mg of elemental iron), usually continued until the hemoglobin reaches a normal value.[93]

MEGALOBLASTIC ANEMIA In contrast to iron deficiency anemia, megaloblastic anemia is classified as a macrocytic anemia characterized by enlarged erythroid precursor cells. There are numerous etiologies for macrocytic anemia; folate and cobalamine (vitamin B_{12}) deficiency are the most common. Their deficiency leads to impaired purine and pyrimidine synthesis, preventing normal DNA replication. The macrocytic cells are a result of nuclear-cytoplasmic asynchronization.[94]

Clinical findings of megaloblastic anemia develop slowly and vary, depending on the level of hemoglobin concentration and the etiology. The commonly shared signs and symptoms are malaise, fatigue, palpitation, glossitis, shortness of breath, and light-headedness. Mild jaundice can also be seen when ineffective erythropoiesis leads to hyperbilirubinemia. Folate and vitamin B_{12} deficiencies are impossible to distinguish by hematologic findings; however, their clinical presentations differ as discussed below.

Vitamin B_{12} is found only in meat and dairy products, making vegetarians prone to deficiency.[98] In non-vegetarian populations (especially of Scandinavia, Turkey, and Israel), vitamin B_{12} deficiency is caused by a rare genetic disorder of malabsorption, the Imerslund-Grasbeck syndrome. Pernicious anemia (PA) is the most common cause of vitamin B_{12} deficiency. It is an autoimmune disorder that attacks intrinsic factor in the ileum, which is essential to absorb vitamin B_{12}. The second cause of PA, chronic atrophic gastritis, results in autoantibodies against gastric parietal cells, which produce intrinsic factor.

It is common to have other autoimmune disorders along with PA, such as vitiligo and Hashimoto thyroiditis.[99] Hyperpigmentation is a common cutaneous manifestation of vitamin B_{12} deficiency.[100] Hyperpigmentation is usually prominent on the knuckles of the hands and feet, especially in darkly-pigmented individuals.[101,102]

Folate is found in animal products and in green leafy vegetables. Its deficiency is usually attributed to dietary inadequacy, alcohol abuse, malabsorption, and drugs that interfere with folate metabolism, i.e., methotrexate, phenytoin, trimethoprim. The demand for folate by the placenta and fetus usually doubles. Therefore, it is now standard care to give prophylactic folic acid supplements to all pregnant women to reduce the risk of neural tube defects in newborns.[103] Exfoliative skin disease and hemolysis can also lead to folate deficiency due to increased demand. Hereditary folate malabsorption results in impaired folate transport in the gastrointestinal tract and the blood-brain barrier. Neurologic findings in vitamin B_{12} deficiency, but not folate deficiency, help to clinically distinguish between the two causes of megaloblastic anemia. Memory loss, dementia, tremor, Lhermitte's sign, irritability, atrophic glossitis, and neuropathy may occur. Specifically, patients with vitamin B_{12} deficiency develop subacute combined degeneration of the dorsal and lateral spinal columns—paresthesia (initial presentation), loss of vibration and position sense, shuffling gait, ataxia, spasticity, and paraplegia. The signs are symmetric in presentation and affect the lower extremities more than the upper extremities.

Typically, patients with folate deficiency are malnourished and often have diarrhea. Patients with alcoholism are prone to folate deficiency. Another distinguishing marker is that vitamin B_{12} deficiency takes many years to occur, given the large liver stores. Folate deficiency, on the other hand, can occur in a few months.

Correcting the underlying etiology usually resolves the anemia and reverses the signs and symptoms. Vitamin B_{12} is best administered parenterally. Prophylactic folic acid supplementation of 400 μg/day is recommended for all women of childbearing age. In folate deficient patients, 50 to 100 μg of oral folic acid is recommended with subsequent maintenance therapy.

Box 145-1

Differential Diagnosis of Flushing

- Toxins: Scombroid poisoning, drugs—ethanol, calcium channel blockers
- Rosacea
- Malignant carcinoid
- Mastocytosis
- Frey syndrome
- Fever
- Benign cutaneous flushing (blushing, exercise, temperature changes, spicy foods)
- Climacteric flushing (hot flashes)
- Chromaffin tumor
- Anaphylaxis
- Renal cell cancer
- Vasoactive intestinal polypeptide tumor
- Medullary carcinoma of thyroid
- Polyneuropathy, organomegaly, endocrinopathy, M protein, and skin changes
- Neurologic diseases (brain tumors, migraine headache, orthostatic hypotension, Parkinson)

ANEMIA OF ENDOCRINE DISORDERS Panhypopituitarism, hypothyroidism, and Addison disease are the most common endocrine disorders in association with anemia, although anemia may occur in hyperthyroidism and gonadal disease as well (see Chap. 152).

Flushing

DIFFERENTIAL DIAGNOSIS Flushing occurs as a result of cutaneous vasodilation, as opposed to pallor by vasoconstriction. Flushing associated with sweating is mediated through the sympathetic cholinergic fibers (Box 145-1; see Chap. 152).

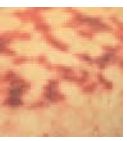
Polycythemia Vera

The hallmark cutaneous finding of polycythemia vera (PV) is acrocyanosis (ruddy cyanosis) and plethora. Other skin findings are aquagenic pruritus, neutrophilic dermatosis and pyoderma gangrenosum, and purpura. Acrocyanosis is seen in conditions with elevated hemoglobin levels, but deoxygenated blood through the dilated vessels in the skin. Increased red cell mass is either a direct result of compensation for hypoxia or from primary disorders such as polycythemia vera. These changes lead to an increase in blood viscosity and vascular volume, resulting in a hypercoagulable state and paradoxic hemorrhage from platelet dysfunction.[114]

POLYCYTHEMIA VERA

AT A GLANCE

- Myeloproliferative disorder that involves all cell lines, with dominant erythropoietin proliferation and, subsequently, increased plasma volume and hematocrit.
- Presents with acrocyanosis, aquagenic pruritus, urticaria, and Sweet syndrome.
- Diagnostic criteria are (1) elevated red cell mass, (2) normal arterial O_2, and (3) splenomegaly.
- Treatment: Concomitant therapy of aspirin and phlebotomy, cytoreductive therapy with hydroxyurea; narrowband ultraviolet B phototherapy for pruritus.



Other symptoms are headache, paresthesia, and erythromelalgia. Erythromelalgia is a thrombotic syndrome of small vessels of the hands and feet, resulting in erythema and burning pain due to congestion.[115] If not treated, this can lead to acrocyanotic ischemia and potentially gangrene of the tissue. The catastrophic symptoms include large vessel arterial cerebrovascular (stroke) or cardiovascular (myocardial infarction) events, and peripheral arterial occlusion. PV has an unusually high incidence of portal and hepatic vein thrombosis (Budd-Chiari syndrome), lower extremity deep venous thrombosis, leg ulcers, Raynaud phenomenon, and pulmonary emboli. Bleeding manifestation is assumed to be a direct cause of dysfunctional platelets or von Willebrand disease. Defective primary hemostasis manifests with ecchymosis, menorrhagia, epistaxis, gingival hemorrhage and, less frequently, gastrointestinal hemorrhage. Risk factors for PV are age (more than 60 years of age), history of thrombosis, cardiovascular risk factors (hypertension, smoking, hypercholesterolemia, diabetes), hereditary and acquired thrombophilic states (congenital deficiency of anticoagulants: antithrombin III, protein C and S; genetic mutation in factor V Leiden, prothrombin G20210A, or methylenetetrahydrofolate reductase); and acquired conditions (anticardiolipin antibodies and/or lupus anticoagulants).[116]

The major diagnostic criteria are (1) elevated red cell mass, (2) normal arterial O_2, and (3) splenomegaly. In the absence of splenomegaly, two of the following minor criteria must occur: (1) leukocytosis more than 12,000/uL, (2) thrombocytosis more than 400,000/uL, (3) leukocyte alkaline phosphatase more than 100 units, and (4) vitamin B_{12} more than 900 pg/mL. Increased platelet consumption and elevated von Willebrand factor (VWF) are associated findings with thrombosis.[117]

There is no specific therapy for PV. Treatment is directed toward preventing thrombohemorrhagic episodes and progression to myelofibrosis or leukemia.[118] Even though the role of low-dose aspirin is still under investigation, a recent randomized trial demonstrated value in using low-dose aspirin in PV. Aspirin is currently recommended in patients with ischemic stroke, myocardial infarction, and erythromelalgia. Those not benefiting symptomatically from aspirin usually require platelet cytoreduction.[119]

Phlebotomy is used to maintain hematocrit levels at less than 45 percent in males and less than 42 percent in females. Concomitant therapy of aspirin and phlebotomy is highly recommended. In high-risk patients, cytoreductive therapy with hydroxyurea may reduce recurrent thrombosis. The standardized treatment with heparin followed by anticoagulant therapy is generally used for venous thrombosis; however, recurrent venous thromboses may be prevented with hydroxyurea. Patients with severe thrombosis and/or hemorrhage benefit greatly from platelet apheresis followed by cytoreductive therapy. Narrowband ultraviolet B phototherapy provides optimum treatment for pruritus associated with PV.[120]

Cyanosis

Cyanosis refers to discoloration of the mucocutaneous tissue that results in a blue or purple tinge, particularly in the peripheral tissues such as lips, ears, and nail beds. It results from low levels of hemoglobin in the microvasculature, reducing oxygen supply to the tissues. *Central cyanosis* refers specifically to the lingual and sublingual regions, and is more reflective of reduced hemoglobin in the blood; in peripheral cyanosis (skin, hands, feet, earlobes, etc.), the cause is often vasoconstriction. Cyanosis may be difficult to detect and is often missed on physical examination. Many factors, including natural skin pigment, thickness of the skin, and blood flowing through the cutaneous capillaries, determine the degree of cyanosis.

When cyanosis is suspected, a complete and careful examination of the skin includes the mouth, conjunctivae, hands and feet, nose, and ears. Cyanosis is detectable when at least 5 grams of deoxygenated hemoglobin are circulating in the capillary blood. Total concentration of hemoglobin in respect to deoxyhemoglobin determines the presence of cyanosis. A patient with severe anemia may never present with cyanosis, whereas a patient with PV can manifest peripheral cyanosis (Box 145-2). Fluorescent light is also used to best observe cyanosis. If cyanosis is positional, an intracardiac mass must be considered.[121]

Box 145-2

Differential Diagnosis of Cyanosis

- Deoxyhemoglobin
  - Acquired and inherited methemoglobinemia
  - Sulfhemoglobinemia
  - Low oxygen-affinity hemoglobin
- Abnormal hemoglobin
  - Congenital heart defects
    - Transposition of the great vessels
    - Tetralogy of Fallot
    - Ebstein's anomaly
  - Arteriovenous fistulae, e.g., in Osler-Weber-Rendu syndrome or dyskeratosis congenital.
  - Disorders of the central nervous system, respiratory system, musculoskeletal and circulatory systems can disrupt the oxygen supply to the tissues.

The diagnostic workup for a complete assessment of cyanosis includes complete blood cell count, arterial blood gas, pulse oximetry, partial arterial pressure of oxygen (PaO_2) level, arterial oxygen saturation. Central cyanosis can be detected reliably when the arterial oxygen saturation has fallen to 85 percent, but in dark-skinned persons, it may not be detected until it has declined to 75 percent.

The causes of cyanosis are broad, but best if characterized into two groups; disorders involving deoxygenated hemoglobin and disorders of abnormal hemoglobin.[122,123] The latter includes acquired and inherited methemoglobinemia, sulfhemoglobinemia, and low oxygen-affinity hemoglobin. Abnormal hemoglobin, such as hemoglobin M (Hb M) or methemoglobinemia, is caused by oxidation of ferrous iron to ferric iron, debilitating the oxygen-carrying capacity of hemoglobin. Consequently, the affinity for oxygen in the remaining binding sites increases and the oxygen-saturation curve shifts to the left. The offending agents are nitrates (found in drinking water, drugs, and food), topical anesthetic agents (lidocaine, benzocaine, and prilocaine), drugs (i.e., dapsone,

phenazopyridine, sulfamethoxazole), and aniline dyes. Congenital methemoglobinemia is caused by deficiency in nicotinamide adenine dinucleotide (reduced form)–cytochrome b_5 reductase.[124] Treatment of choice for methemoglobinemia is intravenous methylene blue; oxygen is not useful.[125,126]

Methemoglobinemia is caused by the hemoglobin in RBCs becoming unable to bind and carry oxygen. It can be clinically suspected when cyanosis occurs in the presence of a normal PaO_2, as obtained by arterial blood gas.

Methemoglobinemia causes clinically discernible cyanosis when the absolute level of methemoglobin exceeds 1.5 g/dL; this correlates with approximately 10 percent to 15 percent methemoglobin. Sulfhemoglobin in concentrations greater than 1.5 g/dL also causes "cyanosis" with a normal PaO_2 and may be erroneously measured as methemoglobin.[127]

Offending agents in cases of acquired methemoglobinemia should be discontinued. No other therapy may be required. But if the patient is symptomatic, methylene blue, 1 to 2 mg/kg over 5 minutes, provides an artificial electron acceptor for the reduction of methemoglobin via the NADPH-dependent pathway. Response is usually rapid; the dose can be repeated in 1 hour, but frequently this is unnecessary. Caution should be exercised to avoid an overdose because large (more than 7 mg/kg) cumulative doses have been reported to cause dyspnea, chest pain, and hemolysis. Because co-oximetry detects methylene blue as methemoglobin, it cannot be used in following methemoglobin levels after treatment with methylene blue; however, the specific Evelyn-Malloy method allows for the discrimination of methemoglobin from methylene blue. Methylene blue should not be administered to patients with glucose-6-phosphate dehydrogenase deficiency.[131] If methylene blue is contraindicated, ascorbic acid can be given. RBC exchange transfusion has also been reported to be an effective treatment in symptomatic methemoglobinemic patients with co-existent glucose-6-phosphate dehydrogenase deficiency.

Sulfhemoglobinemia occurs as sulfur binds to hemoglobin, resulting in irreversible deoxyhemogobinemia. It produces cyanosis at levels of only 0.5 g/dL capillary blood. Etiologies are drugs (sulfonamides, phenacetin, acetanilide, and phenazopyridine), constipation, and purging.

Low oxygen hemoglobin-affinity occurs at altitude of 5000 m (16,000 ft) or higher and can cause hypoxemia severe enough to result in cyanosis. Emotion, cold exposure, Raynaud phenomenon, and cryoglobulins (cold agglutinins) are some nonhematologic causes of peripheral cyanosis.[132]

Disorders involving deoxygenated hemoglobin include congenital heart defects in the newborn (i.e., transposition of the great vessels, tetralogy of Fallot, and Ebstein's anomaly). X-linked dyskeratosis congenita presents with abnormal pigmentation, telangiectasias, nail dystrophy, leukoplakia; rarely, arteriovenous fistulas with central cyanosis occur. Arteriovenous fistulas are a feature of Osler-Weber-Rendu syndrome as well. Other disorders of the central nervous system, respiratory tract, and musculoskeletal and circulatory systems can also disrupt the oxygen supply to the tissues.[133]

Jaundice

Jaundice (icterus) refers to the yellowish discoloration of the skin, caused by elevated bilirubin levels. The discoloration is a direct result of the bile pigment that stains the skin, suggesting an abnormality in bilirubin clearance or increased production due to hepatobiliary disease (see Chap. 151) or a hemolytic disorder.[134] Kernicterus or permanent damage to the neonatal brain associated with hyperbilirubinemia is a serious risk.

Infiltrative Lesions/Extramedullary Hematopoiesis

Extramedullary hematopoiesis usually takes place in the spleen and liver but can also affect the skin. The dermis is a normal site of hematopoiesis during early fetal development. Cutaneous lesions of extramedullary hematopoiesis include nodules (can be sclerosing), ulcers, erythematous papules, violaceous plaques, and diffusely erythematous induration. Neonates with dermal hematopoiesis present as blueberry muffin babies with dark blue-colored to violaceous nodules. In neonates, the causes are erythroblastosis fetalis, chromosomal abnormalities, infections, congenital hemolytic anemia, thalassemia, and twin-to-twin transfusion.[139] Older individuals may show dermal hematopoiesis from hemolytic anemias, myeloproliferative syndromes such as chronic idiopathic myelofibrosis and PV, thalassemia, and osteoporosis. The histologic findings are intradermal proliferation of immature granulocytes, megakaryocytes, and erythroid and myeloid precursor cells.[140]

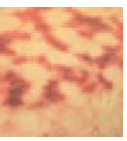
JAUNDICE AND EXTRAMEDULLARY HEMATOPOIESIS AT A GLANCE

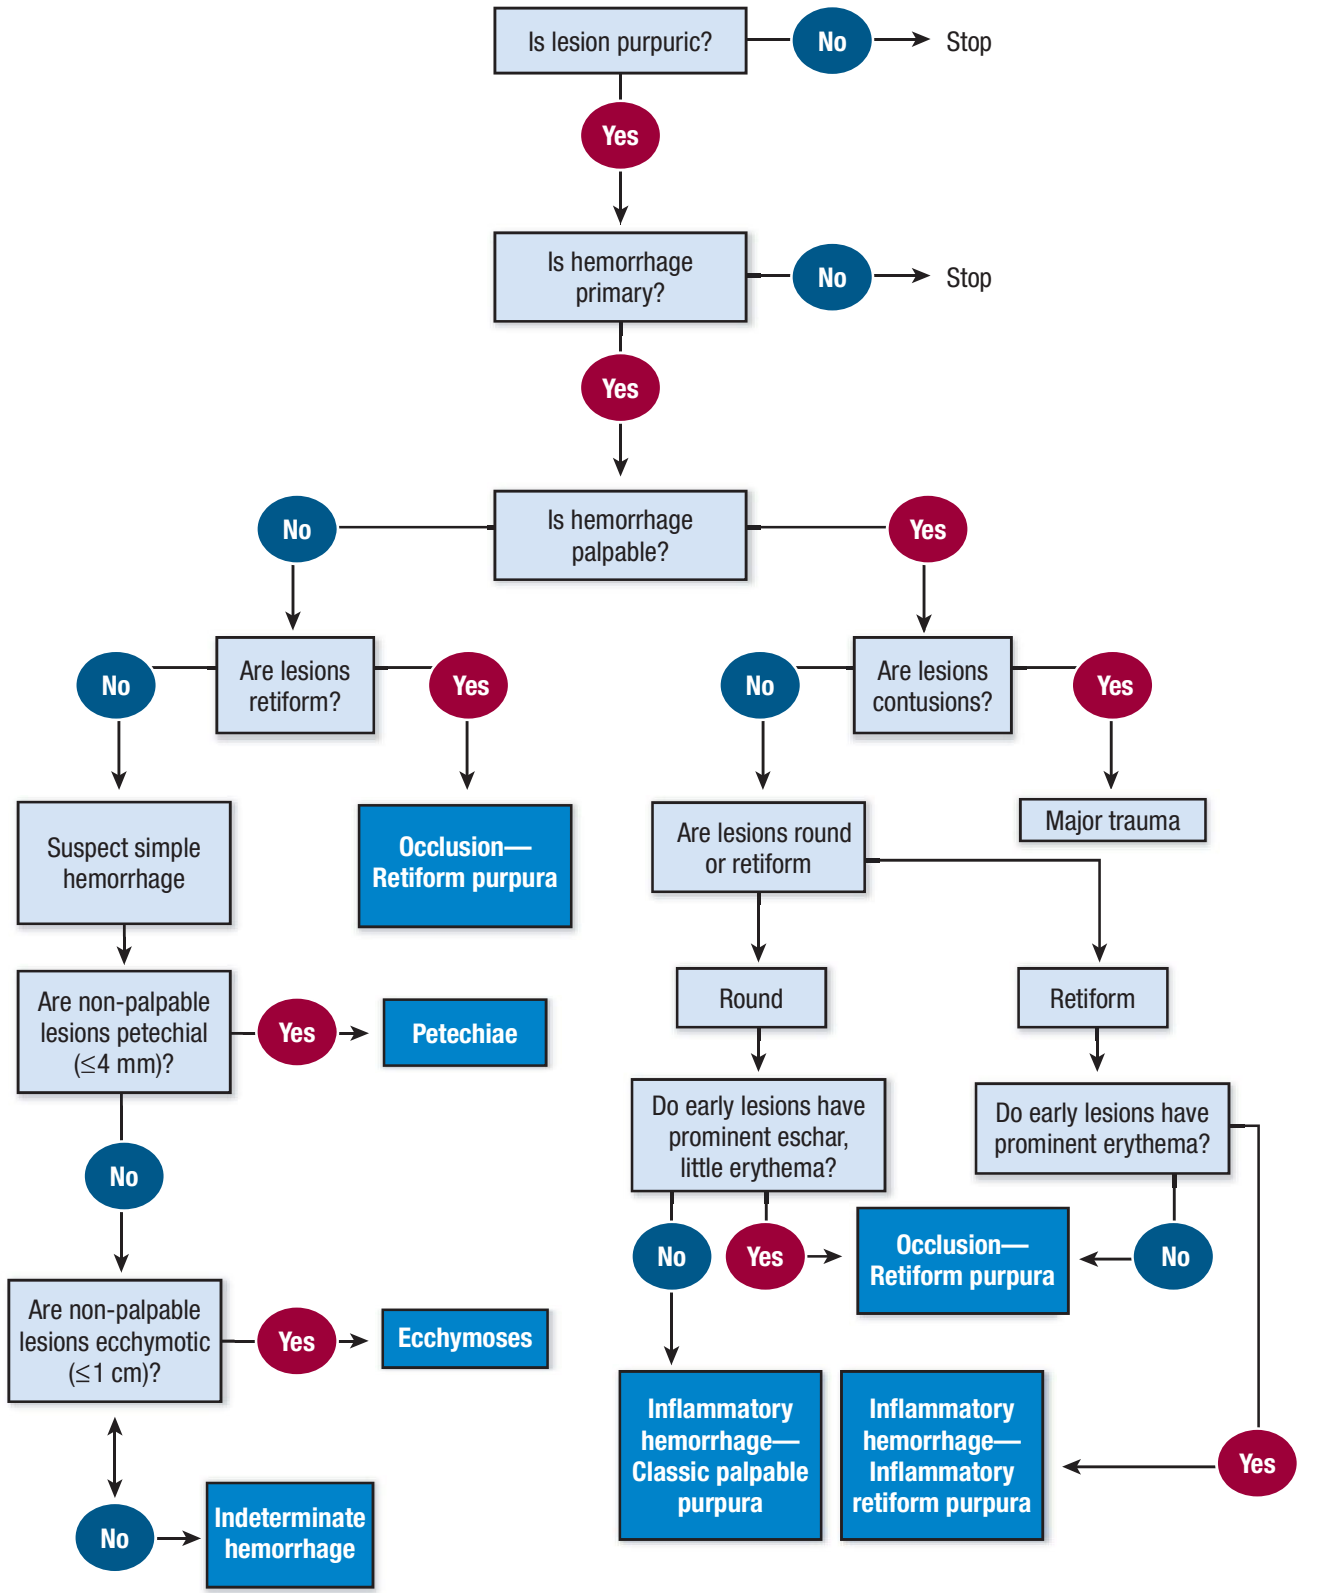
- Jaundice is detectable when bilirubin levels are approximately 51 *M* (3.0 mg/dL) under non-fluorescent lighting, especially in the sclerae and sublingual region
- Differential diagnosis of jaundice: Carotenemia causes yellow pigment in palms, soles, forehead, and nasolabial folds; quinacrine leads to yellowing of skin, but not sclera.
- Extramedullary hematopoiesis: Cutaneous lesions include nodules ulcers, erythematous papules, violaceous plaques, and diffusely erythematous induration; biopsy confirms diagnosis but underlying cause needs to be determined.

HEMOSTASIS AND DIFFERENTIAL DIAGNOSIS OF PURPURA

Hemostasis

Hemostasis results from damage to the blood vessels and manifests as bleeding into the skin and soft tissues. Hemostasis has two phases, primary and secondary. Primary hemostasis is characterized by vascular contraction, platelet adhesion and activation, and subsequent development of a plug at the site of vessel injury. Vascular contraction leads to slowing of the blood flow, so the platelets can adhere to the injured site and diminish blood loss. Primary hemostasis begins immediately and is a critical mechanism involved in repairing minor defects in the microvasculature.[141] The secondary hemostasis phase promotes vascular integrity when primary hemostasis is insufficient and when larger vessels are involved. This phase maintains vasoconstriction through the secretion of prostaglandins, thromboxane, and serotonin. It also solidifies the platelet plug formed during the primary hemostasis. This occurs through a series of clotting cascade pathways that involve platelets, coagulation factors, proteins, and enzymes. Purpura, petechiae, epistaxis, and ecchymo-





▲ **FIGURE 145-1** Algorithm for assessing purpura.

sis are commonly seen in platelet abnormalities, whereas clotting factor defects or deficiency (hemophilia A and B and von Willebrand disease) can lead to palpable ecchymoses, hematomas, hemarthrosis, or unstoppable bleeding during minor surgeries.[142] Further workup in suspected patients for disordered hemostasis requires evaluation of platelet count, bleeding time, prothrombin time, activated partial thromboplastin time, and thrombin time.[143] Additionally, peripheral blood smear, platelet release assays, and coagulation factor assays are helpful.

DIFFERENTIAL DIAGNOSIS OF PURPURA (Fig. 145-1; Tables 145-2, 145-3, and 145-4) Purpura is mucocutaneous hemorrhage measuring at least 5 to 10 mm in diameter and categorized as palpable or non-palpable. These lesions do not blanch with pressure by finger or dias-

TABLE 145-2
Partial Differential Diagnosis of Non-Palpable, Nonretiform Purpura by Size of Lesion

- Petechiae: ≤ 4 mm[144,145]
  - Platelets < 50,000/μL
    - Immune thrombocytopenia
    - Thrombotic thrombocytopenic purpura
    - Disseminated intravascular coagulation
    - Acquired thrombocytopenia (including drug-related)[145]
      - ~ Peripheral destruction (especially quinine)
      - ~ Marrow failure
      - ~ Marrow infiltration, fibrosis, failure
  - Abnormal platelet function
    - Congenital/hereditary platelet function defects[146]
    - Acquired platelet function defects
      - ~ Aspirin, nonsteroidal anti-inflammatory drugs
      - ~ Renal or hepatic insufficiency
      - ~ Gammopathy
      - ~ Myeloproliferative thrombocytosis
  - Non-platelet etiologies
    - Mildly inflammatory conditions
      - ~ Chronic pigmented purpura
      - ~ Waldenström hypergammaglobulinemic purpura
    - Intravascular pressure increase
      - ~ Valsalva-like spikes (nondependent); repetitive vomiting, coughing, childbirth
      - ~ Relatively fixed increased pressure: Ligature, strangulation, stasis
      - ~ Trauma: Usually linear arrangement
- Mid-size macules: 5–10 mm
  - Waldenström hypergammaglobulinemic purpura
  - Immunocompromised patients with sepsis
- Ecchymoses: ≥ 1 cm
  - Procoagulant defect and minor trauma[147,148]
    - Anticoagulant use
    - Vitamin K deficiency
    - Disseminated intravascular coagulation
    - Hepatic diagnosis, poor factor synthesis
    - von Willebrand disease (rarely hemophilia)
  - Poor dermal vessel support and minor trauma[149–151]
    - Actinic (senile) purpura
    - Glucocorticoid treatment, topical/systemic
    - Vitamin C deficiency—scurvy
    - Systemic amyloidosis (mostly light chain–related amyloidosis)
    - Ehlers-Danlos syndrome (some types)
    - Pseudoxanthoma elasticum
  - Other pathophysiology
    - Major trauma
    - Waldenström hypergammaglobulinemic purpura

copy, reflecting the loss of blood from vessels into the dermis. The cause of purpura can be of hematologic, dermatologic, infectious, rheumatologic, traumatic, and vascular in origin. The cause can often be determined by taking a history and performing a thorough physical examination.[178,179]

The morphologic diagnosis of purpura begins with three P's: Is the lesion *p*urpuric, is it *p*rimary, and is it *p*alpable? Manifestations of purpura include petechiae, purpuric macules, ecchymoses (Fig. 145-2), contusions, and variant presentations (target lesion, telangiectatic lesions, small angiomas, and inflammatory lesions). Purpuric lesions typically are red, blue, or a purple tone; however, greenish or yellowish hues on the skin can also be seen because of hemoglobin breakdown. Furthermore, colors help determine pathophysiology. Red-colored purpura results from saturated hemoglobin with adequate blood flow and perfusion of the cutaneous tissues.[180,181] Bright red color indicates superficial hemorrhage. Blue is indicative of restricted blood flow (presumably deoxygenated hemoglobin) and is commonly seen in hemorrhagic lesions and cyanosis. Livedo reticularis has a purplish-blue color in a net-like pattern that is a result of limited blood flow to the cutaneous tissue.

Lesions that are non-blanching are seen when there is extravasation of RBCs. Blanching of a lesion further helps to determine the erythema to hemorrhage ratio. For example, inflammation and flushing of the skin blanches completely; combination hemorrhage with inflammation blanches partially and pure hemorrhage is non-blanchable.[182]

Palpability reflects the amount of cutaneous hemorrhage, resulting in a hematoma. Obviously, the more hemorrhage, the more likely a lesion is to be palpable. Palpable purpura is due to the edema and inflammation that accompanies purpuric lesions (Fig. 145-3). The edema is often a result of inflammation or preceding microvascular ischemia.[183,184]

Retiform purpura is a branching, net-like purpura that is indicative of microvascular occlusion due to vaso-occlusive processes from cryoglobulinemia or anti-phospholipid antibodies, as well as vasculitis[185] or disseminated intravascular coagulation (DIC) (Figs. 145-4 and 145-5).

IDIOPATHIC THROMBOCYTOPENIC PURPURA

Idiopathic thrombocytopenic purpura (ITP) usually has an insidious onset in which diffuse localized petechiae are seen on the lower extremities in association with epistaxis, gingival bleeding, and menorrhagia. Treatment is based on the severity of the thrombocytopenia. ITP may be triggered by viral infection or vaccination against rubella and, rarely, measles.[186,187]

ITP is a common bleeding disorder in children caused by autoantibodies against platelet surface antigens, especially glycoproteins IIb/IIIa and Ib. It presents with increased immunoglobulin (Ig) M, IgG, and IgA autoantibodies with decreased platelet surface antigens (CD41, CD61, and CD42b).[188,189] Patients are usually asymptomatic with only ecchymoses and petechiae found on their physical examination.[190] Oral blood blisters with gastrointestinal or mucocutaneous bleeding can also occur and are referred to as *wet purpura*. As in ITP, immunothrombocytopenic purpura can be associated with recent viral illness and vaccination.[191]

ALLOIMMUNE THROMBOCYTOPENIC PURPURA Alloimmune thrombocytopenic purpura occurs when alloantibodies

TABLE 145-3
Partial Differential Diagnosis of Palpable or Retiform Purpura with Prominent Early Erythema by Lesion, Shape, and Degree of Erythema

- Palpable purpura
  - Morphology of early lesion: Prominent erythema with palpable purpura suggests inflammatory hemorrhage
  - Classic palpable purpura[144,152] (round, port-wine, partially blanchable)
  - Leukocytoclastic vasculitis and immune complex disease[152,153] (lesions usually cluster in dependent areas)
    - Small vessels only
      - ~ Idiopathic, or infection/drug-associated immunoglobulin G (IgG) or IgM complexes[154,155]
      - ~ Idiopathic IgA complexes (Henoch-Schönlein purpura, or IgA with drugs, infection
      - ~ Subacute bacterial endocarditis—hands
      - ~ Waldenström hypergammaglobulinemia
      - ~ Urticarial vasculitis—often random localization
      - ~ Pustular vasculitis—often random localization
    - Small and medium-size cutaneous vessels may be involved
      - ~ Mixed cryoglobulinemia
      - ~ Rheumatic vasculitis (lupus erythematosus, dermatomyositis, rheumatoid arthritis)
  - Leukocytoclastic vasculitis and pauci-immune vasculitis (lesions usually localize randomly)
    - Antineutrophil cytoplasmic antibodies (ANCA)–associated
      - ~ Wegener granulomatosis
      - ~ Microscopic polyangiitis
      - ~ Churg-Strauss rarely
    - Other
      - ~ Erythema elevatum diutinum—hands/feet/elbows/buttocks
      - ~ Sweet syndrome (rarely vasculitic)
  - Not leukocytoclastic (lesions usually localize randomly)
    - Small vessels only
      - ~ Erythema multiforme—acral early
      - ~ Pityriasis lichenoides et varioliformis acuta
      - ~ Chronic pigmented purpura—often legs
      - ~ Waldenström hypergammaglobulinemia—usually dependent
      - ~ Urticarial lymphocytic "vasculitis"
  - Classic target lesion
  - Usually erythema multiform—expect acral and mucosal involvement, as well as elsewhere
- Retiform purpura
  - Morphology of early lesion: Prominent erythema with retiform purpura suggests subset of inflammatory hemorrhage (and, rarely, ischemic syndromes)
  - Inflammatory retiform purpura (retiform, partially blanchable)
  - Leukocytoclastic vasculitis and immune complex disease (lesions usually cluster in dependent areas)
    - Small vessels only
      - ~ IgA (Henoch-Schönlein purpura) vasculitis[154,156]
    - Small and medium-sized cutaneous vessels may be involved
      - ~ Mixed cryoglobulinemia
      - ~ Rheumatic vasculitides
  - Leukocytoclastic vasculitis, dermal and subcutaneous vessels, pauci-immune
    - ANCA-associated—random location
      - ~ Wegener granulomatosis
      - ~ Microscopic polyangiitis
      - ~ Churg-Strauss
    - ANCA-negative syndromes
      - ~ Benign cutaneous polyarteritis nodosa, often legs
  - Nonvasculitic
    - Usually lower leg
      - ~ Livedoid vasculitis
    - Usually fingers/toes
      - ~ Chilblains (pernio)
    - Usually random location
      - ~ Pyoderma gangrenosum
      - ~ Sweet syndrome/atypical pyoderma gangrenosum

against human platelets form during blood or platelet transfusion, or maternal-fetal blood exchange, leading to posttransfusion purpura and fetal and neonatal alloimmune thrombocytopenia, respectively.[192] CD109 is a protein expressed on platelets, T lymphocytes, and endothelial cells. Antibodies against HPA-1, HPA-5, and HPA-15 on CD109 should be sought.[192]

THROMBOTIC THROMBOCYTOPENIC PURPURA Thrombotic thrombocytopenic purpura (TTP) is most commonly seen in adults, whereas hemolytic-uremic syndrome (HUS) is more commonly seen in children.[193,194] TTP can result from pregnancy, cancer, drugs (chemotherapeutic and immunosuppressives, oral contraceptives, ticlopidine, and quinine), bone marrow transplantation, and autoimmune diseases. The pathogenesis is known to be from abnormal functioning of VWF that result in platelet-fibrin thrombotic microangiopathies.[195,196] Patients have increased levels of LDH with associated schistocytes, helmet cells, and megakaryocytes; clinical signs include fever, renal (especially in HUS), and central nervous system (headache, seizures, hemiparesis, disorientation) abnormalities. HUS is commonly caused by *Escherichia coli* O157:H7 infection; it presents with bloody diarrhea and hemorrhagic colitis. Deficiency of ADAMTS13 has been shown in familial TTP. The treatment of choice is fresh frozen plasma.

Other diseases associated with thrombus formation are DIC and purpura fulminans (see the section Purpura Fulminans).[197]

PURPURA FULMINANS Purpura fulminans is a severe skin disorder associated with DIC that mainly affects children and infants. Extensive areas of skin develop blue-black hemorrhagic necrosis, and biopsy typically reveals small-vessel microthrombi and vasculitis.[198,199] Distribution of necrotic areas typically depends on the clinical setting. Patients are acutely ill with fever and hemorrhage from multiple sites, are hypotensive, and manifest typical laboratory signs of DIC. The pathogenesis of purpura fulminans is unknown, but histologic findings have been likened to the animal model of consumptive coagulopathy, the local Shwartzman reaction.[200,201] It has also been suggested that the development of purpura fulminans in meningococcemia may result from acquired defects in the protein C pathway because similar lesions are seen in two

TABLE 145-4
Differential Diagnosis of Palpable or Retiform Purpura with Minimal Early Erythema by Lesion, Shape, and Degree of Erythema

- Morphology of early lesion: Minimal erythema with retiform purpura or with necrosis suggests occlusion with ischemic hemorrhage or infarction.
- Platelet plugs[157]
  - Heparin necrosis[50,64] (distant or injection sites)
  - Myeloproliferative thrombosis[158]
  - Paroxysmal nocturnal hemoglobinuria[159,160]
  - Thrombotic thrombocytopenic purpura[161] (plugs mainly visceral vessels, skin lesions usually simple hemorrhage)
- Cold-related gelling or agglutination (lesions localize to acral, cold-exposed areas)
  - Cryoglobulinemia, usually monoclonal[52,162]
  - Cryofibrinogenemia[163,164] (often incidental finding in ill patients)
  - Cold agglutinins[165] (rarely occlusive, usually hemolytic)
- Embolization or crystal deposition (lesions localize to dependent or acral areas)
  - Cholesterol emboli[166]
  - Oxalate crystal deposition[167]
  - Both usually have extensive livedo
  - Hypereosinophilic syndrome[33]
  - Embolus from atrial myxoma, septic,[33] or marantic endocarditis
  - Crystal globulin vasculopathy[53,54]
- Local or systemic changes in coagulation control
  - Coumarin necrosis (altered protein C function)[168,169]
  - Disseminated intravascular coagulation with severe protein C deficiency or dysfunction[170]
  - Homozygous protein C or S deficiency[171,172]
  - Anti-phospholipid antibody/lupus coagulant[47]
  - Livedoid vasculitis atrophie blanche[173,174]
- Occlusion caused by organisms growing in vessel and vessel walls (usually immunocompromised host)
  - Vessel-invasive fungus (*Mucor*, *Aspergillus*, *Cephalosporium*, *Rhizopus*, etc.)
  - Ecthyma gangrenosum (*Pseudomonas*)[164]
  - Disseminated strongyloidiasis[165]
- Uncertain pathophysiology
  - Cutaneous calciphylaxis[175–177]
  - Hemoglobinopathy occlusion (sickle cell, severe thalassemia): Probably sticky reticulocyte occlusion, sickling
  - Lucio phenomenon in leprosy
  - Degos disease—not purpuric
  - Reperfusion necrosis
  - Interferon injection
  - *Loxosceles* spider bite

other protein C deficiency states, namely, neonatal purpura fulminans and warfarin-induced skin necrosis.[202]

Purpura fulminans occurs in three clinical settings. In acute sepsis-associated or secondary purpura fulminans, the initial presentation is one of overwhelming infection that is most commonly meningococcemia (see Chap. 180) but has been reported with many other Gram-positive and Gram-negative organisms.[203,204] Patients are hypotensive with reduced peripheral perfusion contributing to skin necrosis on distal extremities and elsewhere (Fig. 145-6); alternatively, skin necrosis can occur in a patchy distribution. Idiopathic purpura fulminans can manifest within 10 days of an antecedent illness, most commonly scarlet fever and varicella in children. Most skin lesions are localized to the breasts or lower half of the body. Third, purpura fulminans can be seen in association with homozygous protein C deficiency in affected neonates, in whom massive intravascular thrombosis and abdominal wall gangrene can also develop.[205,206] Acquired inhibitors of the protein C pathway can also be associated with this presentation.[207] Patients with warfarin-induced skin necrosis may present with a similar but usually less severe form of purpura fulminans and warrant consideration of protein C or protein S deficiency.[208] The mortality rate has recently been significantly reduced in purpura fulminans, largely because of more widespread use of therapeutic heparinization in these patients and aggressive transfusion support factor replacement.[209]

DISSEMINATED INTRAVASCULAR COAGULATION DIC is a syndrome characterized by a systemic activation of coagulation leading to the intravascular deposition of fibrin in the (micro) vasculature and the simultaneous consumption of coagulation factors and platelets.[210,211] The occurrence of microvascular thrombosis as a consequence of DIC is underscored by pathologic and clinical findings, demonstrating a link between DIC and organ dysfunction. Pathogenetic pathways that play a role in the development of DIC include tissue factor–dependent activation of coagulation, defective physiologic anticoagulant pathways (such as the antithrombin system and the protein C system), and impaired fibrinolysis, caused by elevated levels of plasminogen activator inhibitor type 1.[212,213] New therapeutic strategies are based on current insights into the pathogenesis of DIC, and include anticoagulant strategies (e.g., directed at tissue factor) and strategies to restore physiologic anticoagulant pathways (such as activated protein C concentrate).[214]

DIC is not a disease in itself but is always secondary to an underlying disorder. The disorders most commonly associated with DIC are listed in Table 145-5. Hyperglobulinemic purpura of Waldenström is characterized by recurring nonthrombocytopenic purpura, hy-

◀ **FIGURE 145-2** Non-palpable ecchymoses in a patient on chronic oral glucocorticoid therapy. Note the rectangular and linear lesions that suggest the minor trauma component; the distal lesion shows that the ecchymosis surrounds a linear traumatic injury. (From Piette W: Myeloma, paraproteinemias, and the skin. *Med Clin North Am* 70:155, 1986, with permission.)

▲ **FIGURE 145-3** Classic palpable purpura on the leg of a patient with immunoglobulin A vasculitis. Partial blanching of an early lesion on compression supports the clinical impression of inflammatory hemorrhage.

▲ **FIGURE 145-5** Noninflammatory retiform palpable purpura on the thigh in a patient with disseminated intravascular coagulation secondary to sepsis. None of the lesional color faded on compression. The biopsy showed multiple dermal vessels occluded by clot without inflammation.

pergammaglobulinemia, and an increased sedimentation rate.[215] Hyperglobulinemic purpura of Waldenström may present alone as a primary entity or as a secondary form associated with diseases, such as Sjögren syndrome or systemic lupus erythematosus.[216] Multiple therapies including corticosteroids, antimalarials, plasmapheresis, and other anti-inflammatory and/or immunosuppressive agents have led to variable results.[217]

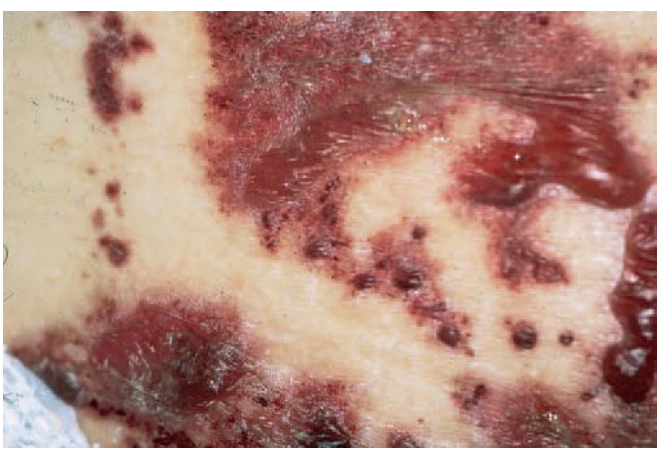
The cutaneous lesions associated with scurvy are characterized by purpura that surrounds corkscrew hairs on the lower extremities (see Chap. 130). Senile purpura results from the loss of elasticity of the skin and weakened capillary walls. RBC extravasation occurs with minor trauma to the hands and other sites (see Chap. 108).[218] Solar purpura usually occurs on the extensor surfaces of the forearm. The pigmented purpuric dermatoses are discussed in detail in Chapter 169.

PALPABLE PURPURA Any process that occludes or damages the cutaneous vasculature results in purpura.

Palpable purpura is either due to vasculitis (see Chaps. 164 and 165) or vasoocclusion (embolic, systemic, and infectious; see Chap. 174). A summary of these syndromes is listed in Table 145-3. Figure 145-3 provides examples of classic palpable purpura; see Figures 145-4 and 145-5 for inflammatory retiform purpura and necrosis. Table 145-4 summarizes the most common differential diagnoses for microvascular occlusion when characterized by noninflammatory retiform, area of purpura/necrosis, and histologically by noninflammatory occlusion of dermal vessels.

LEUKEMIA CUTIS Leukemia cutis (LC) is a localized or disseminated skin infiltration by leukemic cells. It is usually a sign of dissemination of systemic disease or relapse of existing leukemia. Reported incidence varies from less than 5 percent to 40 percent, depending on the type of leukemia, both acute and chronic, including the leukemic phase of non-Hodgkin lymphoma and hairy cell leukemias. It most commonly occurs with acute monocytic leukemia, M5, and acute myelomonocytic leukemia, M4.

Pattern of presentation of skin lesions in LC is variable and may have features that overlap with other (inflammatory) eruptions. Most common lesions are small (2 to 5 mm) papules (Figs. 145-7 and 145-8), nodules (Fig. 145-9), or plaques. LC lesions are usually somewhat more pink, violaceous, or darker than normal skin, always palpable, indurated, firm, or guttate psoriasiform or lymphomatoid papulosis-like lesions, but usually not tender. They are localized or disseminated; usually on trunk (see Fig. 145-7), extremities, and face (see Fig. 145-8) but may occur at any site. They may be hemorrhagic when associated with thrombocytopenia or may ul-



▲ **FIGURE 145-4** Inflammatory retiform palpable purpura in a patient with immunoglobulin A vasculitis. The initial erythematous phase is still present but fading in these lesions; also, blisters have formed.

▲ **FIGURE 145-6** Disseminated intravascular coagulation: Purpura fulminans. Extensive geographic areas of cutaneous infarction with hemorrhage involving the face, breast, and extremities; although the patient looked alert, she died within several days. This catastrophic event followed sepsis after abdominal surgery.

TABLE 145-5
Clinical Conditions Associated with Disseminated Intravascular Coagulation

- Sepsis/severe infection (any microorganism)
- Trauma (e.g., polytrauma, neurotrauma, fat embolism)
- Organ destruction (e.g., severe pancreatitis)
- Malignancy
  - Solid tumors
  - Myeloproliferative/lymphoproliferative malignancies
- Obstetric calamities
  - Amniotic fluid embolism
  - Abruptio placentae
- Vascular abnormalities
  - Kasabach-Merritt syndrome
  - Large vascular aneurysms
- Severe hepatic failure
- Severe toxic or immunologic reactions
  - Snake bites
  - Recreational drugs
  - Transfusion reactions
  - Transplant rejection

▲ **FIGURE 145-8** Leukemia cutis. Multiple skin-colored and erythematous papules in a 38-year-old febrile woman that had erupted approximately 1 week before this picture was taken. The patient had acute myelogenous leukemia.

cerate (see Fig. 145-9). Erythroderma may (rarely) occur. Leukemic gingival infiltration (hypertrophy) occurs with acute monocytic leukemia. Similar lesion morphologies occur with different types of leukemia or specific types of leukemia may present with a variety of morphologies.

Inflammatory disorders occurring in patients with leukemia are modified by the participation of leukemic cells in the infiltrate, resulting in unusual presentations of such disorders (e.g., psoriasis with hemorrhage or erosions/ulcerations). Also, there are a number of cutaneous inflammatory diseases that may be associated with leukemia: Sweet syndrome (see Chap. 31), bullous pyoderma gangrenosum (see Chap. 32), urticaria (see Chap. 37), and necrotizing vasculitis (see Chap. 164).

Systemic symptoms are those associated with hematologic malignancy. Not infrequently, cutaneous manifestation may be the initial presenting symptom and may contribute importantly to the diagnosis.

The diagnosis is made by suspicion and verified by skin biopsy, immunophenotyping, and B- or T-cell receptor rearrangement studies. Hematologic studies with complete analysis of bone marrow aspirate and peripheral blood smear are then needed to make the diagnosis. If cutaneous findings precede any systemic disease, careful assessment of peripheral blood smears and bone marrow biopsies must be made.

The prognosis of LC is directly related to the prognosis for systemic disease. Therapy is usually directed at the leukemia itself.

▲ **FIGURE 145-7** Leukemia cutis. Hundreds of tan-pink papules and a nodule on the trunk of a female with acute myelogenous leukemia arose during a 1-week interval. Per se, these lesions are "non-specific" and do not represent a diagnosis; but when such an eruption is seen, one should perform a peripheral blood count and a biopsy.

▲ **FIGURE 145-9** Leukemia cutis: Chloroma. Large, ulcerated, green-hued tumors (chloromas) in the inguinal and perineal regions of a female with acute myelogenous leukemia; similar lesions were also present in the axillae and on the tongue.

CHAPTER 146

Cutaneous Lymphoma

Chalid Assaf
Wolfram Sterry

INTRODUCTION

Cutaneous lymphomas represent clonal proliferations of neoplastic T or B lymphocytes and rarely of natural killer (NK) cells or plasmacytoid dendritic cells. They have been recognized as a heterogeneous group with distinct variability in clinical presentation, histopathology, immunophenotyping, and prognosis.

Primary cutaneous lymphomas often show a completely different clinical behavior and prognosis than do histologically similar systemic lymphomas, which may involve the skin secondarily. Therefore primary cutaneous lymphomas require different approaches to treatment. For this reason, a new consensus classification has been created based on both the European Organisation for Research and Treatment of Cancer (EORTC) classification for primary cutaneous lymphomas and the World Health Organization (WHO) classification for tumors of hematopoietic and lymphoid tissues. This first common classification (WHO-EORTC)[1] categorizes the entities according to lineage and then according to a combination of morphology, immunophenotype, genetic features, and clinical syndromes (Table 146-1). This chapter discusses the most frequent cutaneous T-cell lymphomas (CTCLs)—mycosis fungoides (MF), Sézary syndrome (SS), primary cutaneous anaplastic large-cell lymphoma (cALCL), and lymphomatoid papulosis (LyP)—and the most frequent cutaneous B-cell lymphomas (CBCLs)—primary cutaneous follicle center lymphoma (PCFCL), primary cutaneous marginal zone lymphoma (PCMZL), and primary cutaneous diffuse large B-cell lymphoma (PCLBCL), leg type. These seven types of cutaneous lymphoma represent nearly 90 percent of all cutaneous lymphomas.[2] Rare entities occurring primarily in the skin are also described.

EPIDEMIOLOGY

Cutaneous lymphomas represent the second most common group of extranodal lymphomas after the primary gastrointestinal lymphomas.[3] The annual incidence is estimated to be 1 per 100,000.[4]

ETIOLOGY

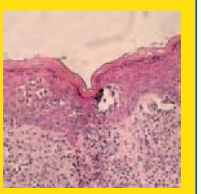
For many years, CTCL was thought of as a disease of long-term antigen stimulation in which an initial inflammatory response in the epidermis leads to T-cell proliferation and, finally, to the emergence of a malignant clone. Despite much effort to identify a unifying antigen, the etiology remains unknown.

A viral etiology for CTCL was an attractive hypothesis given the cutaneous similarities to adult T-cell lymphoma/leukemia which is associated with human T-cell lymphotrophic virus type 1 (HTLV-1) infection (see Chap. 197). The results of studies to determine an association between CTCL and HTLV-1 are contradictory. An early study reported detection of a partially deleted HTLV-1 provirus by polymerase chain reaction (PCR) analysis in a cell line established from a patient with MF.[5] However, studies of American and European populations found no association of MF with HTLV-1 infection. PCR, Southern blot, and reverse transcriptase assays have been used, but no HTLV-1 has been demonstrated.[6–9] These data suggest that HTLV-1 does not play an important role in the etiology of CTCL and that the only reason to screen patients for antibodies is suspicion that the diagnosis is adult T-cell lymphoma/leukemia rather than MF. Epstein-Barr virus (EBV) has also been proposed as a causative pathogen.[10] Given its association with other lymphoproliferative disorders and lymphomas, such as Burkitt lymphoma, this seemed logical. However, the possibility that EBV infection can lead to the proliferation and activation of T cells in the epidermis has only been suggested and has not yet been definitively proven.

Bacterial infections have also been implicated in CTCL.[11] An association with *Staphylococcus aureus* has been suggested.[12] Of the CTCL patients studied, 75 percent had positive results for *Staphylococcus* on culture of blood or skin samples, and one-half of these cultures tested positive for *S. aureus* carrying enterotoxin genes, such as toxic shock toxin-1. The patients with positive blood culture results had SS or progressive plaque and tumor MF, but only four had monoclonal expansion of a specific Vβ gene. The results of this study, which have received support from research on microdissected tumor cells, suggested that *S. aureus* superantigen enterotoxins could provide or potentiate lymphocytic infiltration and long-term antigenic stimulation, leading to T-cell clonal expansion in CTCL.

The suggestion has been made that occupational risk factors also play a causative role in CTCL, because an indolent dermatitis often precedes the diagnosis. Exposure to carcinogens in the work environment could provide the long-term antigenic stimulation needed to initiate clonal expansion. An occupational exposure to chemicals considered hazardous was recorded in 30 percent of patients examined by the Mycosis Fungoides Study Group.[13] However, a case-control study in California and Washington state demonstrated no correlation between MF and occupation or chemical exposure.[14]

CUTANEOUS LYMPHOMA AT A GLANCE



- Second most common group of extranodal lymphomas; estimated annual incidence is 1 in 100,000.
- Clonal proliferations of neoplastic T or B lymphocytes, and rarely of natural killer cells or plasmacytoid dendritic cells, arising in mid and late adulthood.
- Clinical behavior and prognosis are completely different from those of histologically similar systemic lymphomas.
- Most common form of cutaneous lymphoma is mycosis fungoides (MF), a cutaneous T-cell lymphoma, which is categorized as patch, plaque, or tumor stage. Related features include severe pruritus, alopecia, palmoplantar hyperkeratosis, and bacterial superinfection
- Histologically the patch/plaque stage of MF is characterized by an epidermotropic band-like infiltrate of neoplastic T lymphocytes with hyperconvoluted cerebriform nuclei involving the upper dermis variably with exocytosis and formation of intraepidermal Pautrier's microabscesses. The tumor stage consists of a dermal nodular infiltrate sparing the epidermis.

TABLE 146-1
WHO-EORTC Classification of Primary Cutaneous Lymphomas

Cutaneous T-Cell and NK-Cell Lymphomas
- Mycosis fungoides
- Mycosis fungoides variants and sub-types
  - Folliculotropic mycosis fungoides
  - Pagetoid reticulosis
  - Granulomatous slack skin
- Sézary syndrome
- Adult T-cell leukemia/lymphoma
- Primary cutaneous CD30-positive lymphoproliferative disorders
  - Primary cutaneous anaplastic large-cell lymphoma
  - Lymphomatoid papulosis
- Subcutaneous panniculitis-like T-cell lymphoma
- Extra-nodal NK/T-cell lymphoma, nasal type
- Provisional entities of cutaneous T-cell lymphoma
  - Primary cutaneous aggressive epidermotropic $CD8^+$ T-cell lymphoma
  - Cutaneous γ/δ T-cell lymphoma
  - Primary cutaneous $CD4^+$ small or medium-sized pleomorphic T-cell lymphoma

Cutaneous B-Cell Lymphomas
- Primary cutaneous marginal zone B-cell lymphoma
- Primary cutaneous follicle center lymphoma
- Primary cutaneous diffuse large B-cell lymphoma, leg type
- Primary cutaneous diffuse large B-cell lymphoma, other
  - Intravascular large B-cell lymphoma (provisional)
- Precursor hematologic neoplasm
- $CD4^+/CD56^+$ hematodermic neoplasm (blastic NK-cell lymphoma)

NK = natural killer; WHO-EORTC = World Health Organization and European Organisation for Research and Treatment of Cancer.

Even though the hypothesis that CTCL is a disease caused by long-term antigenic stimulation with ultimate emergence of a malignant T-cell clone appears to be logical, the etiology of CTCL, including the identity of some possible initiating events, has yet to be determined.

PATHOGENESIS

The clinical entities encompassed by the term *cutaneous T-cell lymphoma* share several components, including a T-cell clonal population, a modulated antitumor response, and an epidermal microenvironment.[3,15,16]

CTCL is a malignancy of skin-homing T cells that are primarily distinguished from other T cells by a unique cell surface receptor called *cutaneous lymphocyte-associated antigen* (CLA). CLA is expressed on memory T cells that have the ability to home to the skin by binding to E-selectin, which is expressed on vascular endothelial cells and is superinduced during cutaneous inflammation. As these T cells circulate through high endothelial venules, they respond to as yet unknown signals from the epidermis by tethering and rolling on P-selectin and E-selectin and finally extravasating into inflamed skin.

CLA is a cell surface glycoprotein that is defined by its reactivity with a monoclonal antibody, HECA-452. It has now been discovered that CLA is actually an inducible carbohydrate modification of a ubiquitously expressed T-cell surface protein, P-selectin glycoprotein ligand 1. CLA is produced by a post-translational modification of P-selectin glycoprotein ligand 1 by $\alpha(1,3)$-fucosyltransferase, which is found in lymphocytes that bind E-selectin.

CLA is also expressed on cells of myeloid lineage, including monocytes, neutrophils, and dendritic cells. Fewer than 20 percent of peripheral T cells express CLA, which suggests that these cells can be readily recruited to the skin. More than 85 percent of T cells participating in a cutaneous inflammatory response express CLA. However, CLA-expressing lymphocytes are not found in inflammatory infiltrates in the kidney, synovium, or other tissues. In vitro studies show that CLA can be induced in all peripheral blood T-cell populations, which implies that all T cells have the capacity to home to the skin, depending on as yet undetermined regulatory signals.[17]

The second similarity unifying CTCLs is the presence of a modulated antitumor response. Lesions of CTCL often have a $CD8^+$ T-cell component. Although they were once thought to be innocent bystanders in the epidermis, data have now defined the responsibility of $CD8^+$ T cells in the antitumor response. The first insight into defects in the integrity of normal T-cell function in advanced CTCL patients came from observations in patients who had been treated with extracorporeal photochemotherapy (ECP).[18] Responding patients had significantly lower CD4/CD8 T-cell ratios and higher absolute numbers of $CD8^+$ T cells in their peripheral blood at the outset of treatment than did nonresponders. In general, skin biopsy specimens of MF lesions in early stages (T1 and T2) harbor a higher proportion of $CD8^+$ cells than lesions in advanced stages. Improved long-term prognosis was correlated with the presence of these $CD8^+$ tumor-infiltrating lymphocytes (TIL) in MF.[19] It is now believed that these $CD8^+$ cytotoxic T cells play an important part in the pathogenesis of CTCL, mainly in mediating an antitumor response.

One possible mechanism for this antitumor response may be the Fas receptor/Fas ligand (FasL) pathway, which can also provide neoplasms with immune privilege and protection. Fas receptor and FasL are transmembrane proteins of the tumor necrosis factor family and are expressed on cells of lymphoid and myeloid lineage. On binding of the ligand to the receptor, a cascade of events occurs that leads to apoptosis. In melanoma, loss of Fas expression by tumor cells has been correlated with tumor progression, which suggests that the absence of this apoptotic initiator mediator leads to escape of immunosurveillance.

Aberrations of the Fas/FasL pathway have been studied in CTCL. Immunohistochemical studies of Fas and FasL expression in frozen and paraffin-embedded skin biopsy specimens from CTCL patients demonstrated loss of Fas expression in advanced MF and aggressive forms of CTCL and strong expression in early stages of MF. The Fas/FasL pathway may contribute to the immunosuppression seen in MF patients and provide immune advantage or privilege to tumor cells, rendering them immunologically tolerated.

The third unifying concept in the pathophysiology of CTCL is the participation of the epidermis as a microenvironment for malignant cells. Within the skin, cytokines have an important role in maintaining the milieu and initiating immune responses. It is well established that patients with CTCL have variable production and response to T helper 1 and 2 (Th1, Th2) cytokines. Early studies that measured the messenger RNA (mRNA) levels of Th1 and Th2 cytokines showed that, at any stage of disease, mRNA of interleukins 5 and 4 (IL-5, IL-4), Th2 cytokines, could be found, with the persistence of Th2 cytokine mRNA in skin more frequent in the tumor stage. The decline in interferon-γ (IFN-γ) and predominance in Th2 cytokines might be responsible for the loss of immunosurveillance, which allows CTCL to progress.

Other cytokines are also likely to play a role in the pathogenesis of CTCL. Culture studies and immunohistochemical analyses on skin biopsy specimens from in CTCL lesions demonstrate the presence of IL-15 and IL-7. IL-7 is a cytokine produced by keratinocytes that has been identified as a T-cell growth factor. IL-15, also produced in the skin by keratinocytes, has functional properties similar to those of IL-2, a growth-stimulating cytokine for both B and T cells and a potent T-cell chemoattractant.[16]

To better define the microenvironment and cellular components of the epidermis, a new technique of micromanipulation to obtain single immunolabeled T cells in tissue sections followed by single-cell PCR was developed.[20] When this technique is used, the exact location and immunophenotype of clonal and nonclonal (likely reactive) T cells in the different skin compartments can be determined. Once single cells are obtained, their genetic material can be precisely analyzed by PCR without reactive T-cell component contamination. This has allowed insight into the microanatomic preferences of the tumor cells. In addition, these techniques can be performed simply on skin punch biopsy specimens from patients at any stage of disease. Initial experiments with single-cell micromanipulation found that clonal $CD4^+$ T cells, especially in early stages of CTCL, were localized to the epidermis and that nonclonal $CD4^+$ T cells had a preference for the dermis rather than the epidermis. This suggests that the polyclonal $CD4^+$ T cells in the sub-epidermal infiltrate establish a barrier of lymphocyte-mediated antitumor response. Further investigations using this novel technique will bring us closer to an understanding of the unique epidermal sanctuary that harbors, preserves, and perpetuates CTCL.

▲ **FIGURE 146-1** Patch lesion of cutaneous T-cell lymphoma with poikiloderma and scale in a typical location on the breast.

▲ **FIGURE 146-2** Large plaque/patch of cutaneous T-cell lymphoma on the right flank. Annular and arcuate configurations on the border with more atrophy centrally are seen.

PRIMARY CUTANEOUS T-CELL LYMPHOMAS

CTCLs are non-Hodgkin lymphomas characterized by a dominant skin-homing T-cell clone. They represent approximately 80 percent of all cutaneous lymphomas. The most common forms are MF and SS, with an annual incidence of three or four new cases per million people. After MF and SS, the primary cutaneous $CD30^+$ lymphoproliferative disorders comprising LyP and cALCL represent the second most common group of CTCLs (approximately 30 percent).

Mycosis Fungoides

DEFINITION MF is the most frequent variant of CTCL, usually arising in mid to late adulthood (median age at diagnosis, 55 to 60 years) with a male predominance of 2:1.

CLINICAL MANIFESTATIONS ***Skin Signs.*** Clinically MF is categorized as being in the patch, plaque, or tumor stage, but patients may simultaneously have more than one type of lesion. In early patch-stage MF (Figs. 146-1, 146-2), there are single or multiple erythematous, scaly macules and patches that vary in size and are usually well defined. The color of the lesions may vary from orange to a dusky violet-red. The distribution classically favors non–sun-exposed sites, with the "bathing trunk" and intertriginous areas predominant early in the course of the disease. The eruption may be intensely pruritic or asymptomatic and occasionally may be transitory, disappearing spontaneously without scarring. Diagnosis at this stage may be difficult. Often a patient will recall a preceding "chronic dermatitis" for 10 to 20 years that may have been considered to be therapeutically resistant contact dermatitis, atopic dermatitis, psoriasis, or eczema. In any patient with a dermatosis that is refractory to the usual modalities of treatment, multiple biopsy specimens should be taken to pursue a diagnosis.

Patches may last for months or years before progressing to the plaque stage (Fig. 146-3), or plaques may arise de novo. Plaques appear as sharply demarcated, scaly, elevated lesions that are dusky red to violaceous and variably indurated (Figs. 146-4 and 146-5). Lesions in this stage may regress spontaneously or may coalesce to form large plaques with annular, arcuate, or serpiginous borders, and may clear centrally with disease activity remaining at the periphery of the lesion. There may be purpuric hyperpigmentation or hypopigmentation (Fig. 146-6) and poikiloderma (see Figs. 146-1, 146-2).

The tumor stage may occur anywhere, but tumors have a predilection

▲ **FIGURE 146-3** Patches and plaques of cutaneous T-cell lymphoma on the back and arm.

▲ **FIGURE 146-4** Confluent plaques with scaling and developing nodules.

▲ **FIGURE 146-6** In the pigmented purpuric variant of mycosis fungoides, the lesions are the typical size of mycosis fungoides lesions but are distributed in areas that are not usually affected by pigmented purpura, as shown here in the periaxillary skin. (Used with permission from Kathy Zug, MD.)

for the face (Figs. 146-7 and 146-8) and body folds: axillae, groin, antecubital fossae, and, in women, the inframammary area. These may occur in pre-existing plaques or patches of CTCL, which suggests the development of a vertical growth phase (Fig. 146-9). At this point, the neoplastic cells behave in a more biologically malignant manner, with vertical spread that leads to the clinical appearance of an expanding dermal nodule (see Fig. 146-8). De novo occurrence suggests metastatic spread by cells of a malignant T-cell clone. The nodules are reddish brown or purplish red and smooth surfaced, but they often ulcerate and may become secondarily infected (Fig. 146-10). Growth rate is variable. Patients with tumors tend to have a more aggressive form of the disease than patients with patch and plaque disease.

Erythroderma may start de novo or follow MF. The nomenclature for erythrodermic phases of CTCL varies. It has been proposed that erythroderma be defined as the involvement of 80 percent of body surface area with lesions of ill-defined borders and that patients with a history of pre-existing MF be defined as having a separate syndrome of "erythrodermic MF."

The skin is diffusely bright red with readily apparent scaling, but there may be characteristic symmetric islands of uninvolved skin (Fig. 146-11). There may be sparing of the areas of skin that are frequently folded, such as the abdomen and antecubital and axillary areas. This sparing produces a finding often called the *deck chair* or *folded luggage* sign, as shown in Fig. 146-12. Some patients with the erythrodermic form of CTCL develop tumors.

Other Symptoms. Patients may complain of fever, chills, weight loss, malaise, in-

▲ **FIGURE 146-5** Polymorphic nature of mycosis fungoides type of cutaneous T-cell lymphoma. On the right buttock is a large violaceous plaque, whereas further down the thigh is a pink psoriasiform annular lesion. Smaller atrophic lesions can also be noted in the surrounding skin.

▲ **FIGURE 146-7** Leonine facies characterized by infiltrated plaques and tumors of cutaneous T-cell lymphoma.

▲ **FIGURE 146-9** A mixture of plaque and tumor stage lesions on the face of a patient with cutaneous T-cell lymphoma. **A.** Patch and plaque on the cheek and infected centrofacial ulcer. **B.** Ulcerated nodules on the trunk. **C.** Annular and crusted tumors and ulcers on the legs.

somnia secondary to the overwhelming pruritus, and poor body temperature homeostasis. There may be hyperkeratosis, scaling and fissuring of the palms and soles, alopecia, ectropion, nail dystrophy, and ankle edema, with the integument being shiny and hidebound. These changes result in pain on walking and extreme difficulty with tasks requiring manual dexterity. Such patients become cutaneous cripples, severely debilitated by the skin manifestations of this fatal disease. Pruritus is often intense, which results in excoriation, exudation, and secondary infection that may dominate the clinical picture.

DIFFERENTIAL DIAGNOSIS The differential diagnosis of MF is summarized in Box 146-1.

HISTOPATHOLOGY In the patch, plaque, and also in the erythrodermic stage, there is an epidermotropic band-like infiltrate of neoplastic T lymphocytes with hyperconvoluted cerebriform nuclei involving the upper dermis with exocytosis and formation of intraepidermal Pautrier's microabscesses (Figs. 146-13 and 146-14). In the tumor stage a nodular infiltrate in the dermis is found, and the epidermal component is much less pronounced (Fig. 146-15). Immunohistologically the malignant cells express a mature peripheral T-cell ($CD4^+$) phenotype. Partial loss of pan–T-cell antigens such as CD7 and CD3 may be a feature of MF but is not pathognomic of the disease. Analysis of T-cell receptor genes (TCR) typically shows a clonal rearrangement as demonstrated by PCR or Southern blot techniques.[21,22]

TREATMENT AND PROGNOSIS Treatment should be symptom oriented and stage adapted (see Staging of Cutaneous T-Cell Lymphoma and Principles of Treatment of Cutaneous T-Cell Lymphoma later).[23] The prognosis depends on the type and extent of skin involvement (plaques, tumors, or erythroderma), the presence of palpable lymph node involvement, and the presence of visceral disease. Overall, patients with MF limited to the skin have a 5-year survival rate of 80 to 100 percent. In contrast, patients with lymph node involvement show a 5-year survival rate of 40 percent.[24]

Mycosis Fungoides Variants

FOLLICULOTROPIC MYCOSIS FUNGOIDES Folliculotropic MF represents a distinct variant of MF characterized by preferential involvement of the head and neck by folliculotropic T-cell infiltrates, with or without mucinous degeneration of the hair follicles (Fig. 146-16B).[21,22] Previously this variant was called *follicular mucinosis* or *alopecia mucinosa*. Folliculotropic MF occurs mostly in adults but may occasionally affect children and adolescents. Pa-

▲ **FIGURE 146-11** Cutaneous T-cell lymphoma erythroderma (in this case, Sézary syndrome). Note coppery redness and infiltration of the skin as reflected by increased skin folds and scaling.

▲ **FIGURE 146-12** In patients with cutaneous T-cell lymphoma and erythroderma, there may be sparing of areas where the skin folds, as shown here. This finding is often called the *deck chair* or *folded luggage* sign.

tients may have grouped follicular papules (see Fig. 146-16A), acneiform lesions, indurated plaques, and sometimes tumors, which usually involve the head and neck region. The occurrence of alopecia, pruritus, and secondary bacterial infections is common. Infiltrated plaques in the eyebrows with concurrent alopecia are a frequent and highly characteristic finding. Pruritus is often severe.

HYPOPIGMENTED MYCOSIS FUNGOIDES Patients with dark skin develop hypopigmented MF, a variant of patch MF. In darker-skinned individuals, this may be the most common presentation of the disease. Patients respond to therapy by repigmentation, and a relapse often presents as hypopigmentation.

PAGETOID RETICULOSIS Pagetoid reticulosis (Woringer-Kolopp disease) is a distinct variant of MF that is characterized by the presence of localized patches or plaques with an intraepidermal proliferation of neoplastic cells. Patients present with a solitary psoriasiform or hyperkeratotic patch or plaque, which is usually localized on the extremities (Fig. 146-17) and is slowly progressive. Unlike in classic MF, extra-cutaneous dissemination has not been observed.

The disseminated form (Ketron-Goodman type) is much more aggressive and is now considered to be an aggressive primary cutaneous epidermotropic $CD8^+$ T-cell lymphoma (see the section Primary Cutaneous Aggressive Epidermotropic $CD8^+$ T-Cell Lymphoma).

GRANULOMATOUS SLACK SKIN Granulomatous slack skin is a rare sub-type of MF characterized by the slow development of folds of lax skin in the major skinfolds, with a predilection for the axillae and groins (Fig. 146-18). Light microscopy reveals a dense granulomatous infiltrate in the dermis. In addition to small atypical cells with cerebriform nuclei, macrophages and numerous multinucleated giant T cells occur and palisade around necrobiotic areas, where destruction of the elastic tissue is observed. The neoplastic cells express a $CD3^+CD4^+CD8^-$ phenotype.[21,22]

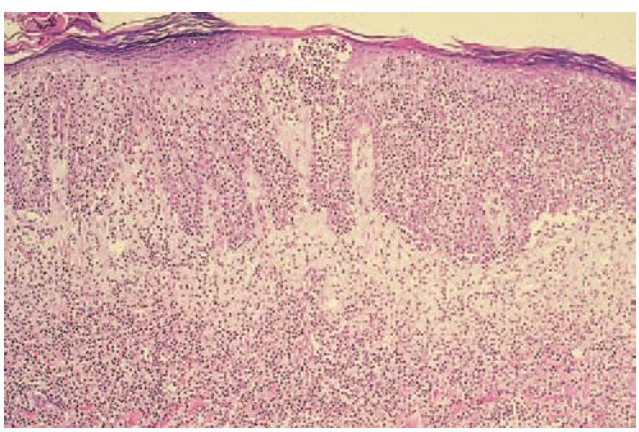
- Drug eruption
- Seborrhoic dermatitis

Sézary Syndrome

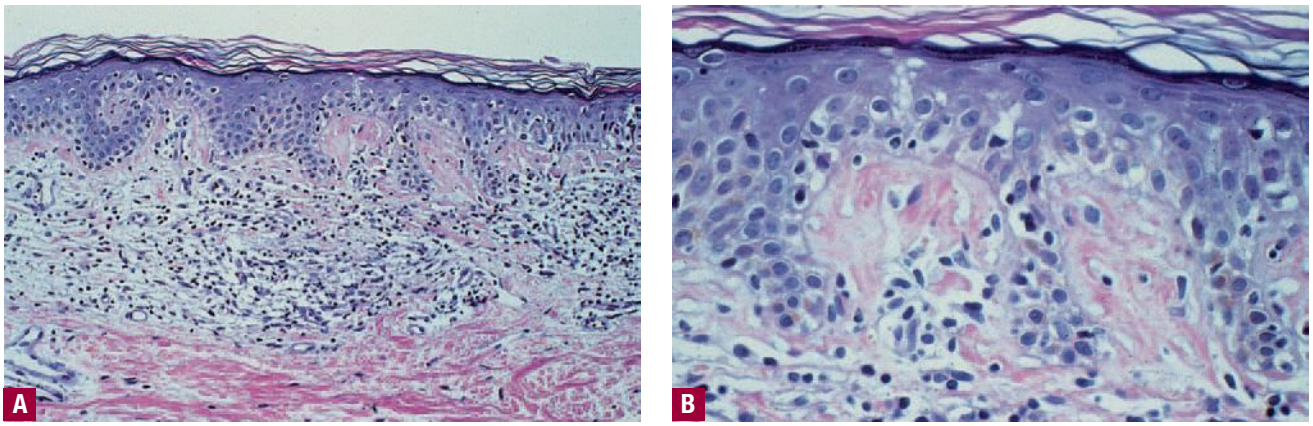
DEFINITION SS is a leukemic variant of CTCL that occurs exclusively in adults. It is characterized by the triad of diffuse erythroderma, generalized lymphadenopathy, and circulating malignant T cells with cerebriform nuclei, the so-called *Sézary cells*.

CLINICAL MANIFESTATIONS Clinical findings include severe scaling or fissuring of the palms and soles, alopecia, and onychodystrophy. The erythroderma may be associated with marked exfoliation, edema, and lichenification and is extremely pruritic (see Fig. 146-11).

LABORATORY FINDINGS SS demonstrates histologic features similar to those of MF.[21,22] Therefore, several diagnostic criteria proposed by the International Society for Cutaneous Lymphoma—including biopsy findings consistent with CTCL, absolute Sézary cell count in the peripheral blood of at least 1000 cells/mm^3, and, by fluorescence-activated cell-sorting analysis, an increased CD4/CD8 ratio of more than 10, a $CD7^-$ phenotype (more than 40 percent), and evidence of a circulating T-cell clone—were included



▲ **FIGURE 146-13** Dense mononuclear cell infiltrate extending from the papillary dermis into the epidermis. The epidermis is completely permeated by these cells, which form a Pautrier's abscess.



▲ **FIGURE 146-14** Patch stage of cutaneous T-cell lymphoma. **A.** Single atypical mononuclear cells in epidermis with sparse superficial perivascular infiltrate in the papillary dermis. (Hematoxylin and eosin–stained section.) **B.** High-power view of atypical cells in epidermis of same section.

in the WHO-EORTC classification.[1] Patients lacking the atypia on the peripheral blood smear or the corroborating evidence are considered to have erythrodermic CTCL.[1,2,25]

TREATMENT AND PROGNOSIS Compared with patients with patch- or plaque-stage MF, patients with SS have a markedly decreased 5-year survival rate of 33 percent. By the time the SS appears, there is very little normal immunity left. Indeed, Sézary's patients have died from infectious complications, not from progressive disease.[26]

Primary Cutaneous CD30⁺ Lymphoproliferative Disorders

Primary cutaneous CD30⁺ lymphoproliferative disorders consist of LyP and cALCL. Both entities are now recognized to form the ends of a spectrum which includes borderline cases that, on histomorphologic grounds alone, cannot be clearly assigned to LyP or cALCL.[1,2]

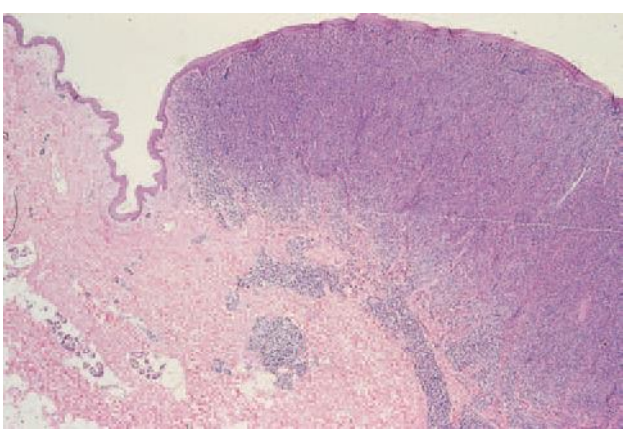
LYMPHOMATOID PAPULOSIS ***Definition.*** LyP was first described by Macauly in 1968. It is an uncommon chronic disorder (incidence of 1.2 to 1.9 cases in 1,000,000) characterized by recurrent self-healing crops of papules and papulonodules.[1,2]

Clinical Manifestations. Disseminated recurrent self-healing papules and papulonodules occur that may become necrotic in the center (Fig. 146-19) and often erupt over a period of months or several years. The lesions typically involve the trunk and extremities, and lesions in various stages of evolution may be present concurrently.

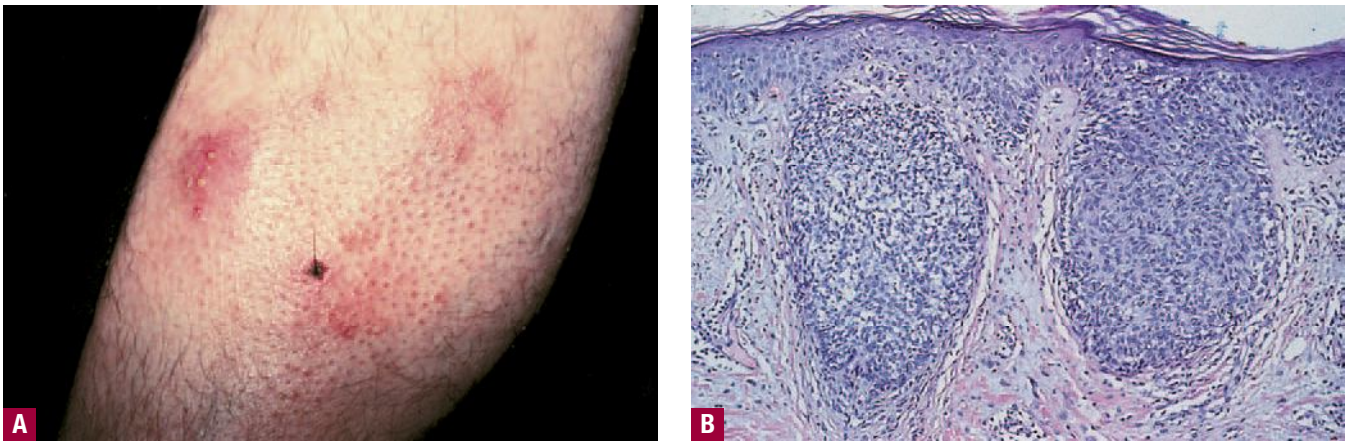
Histopathology. LyP shows a highly variable histologic picture that closely mimics that of malignant lymphoma.[1,2] Three major histologic types, designated as *A*, *B*, and *C*, have been recognized.[21,22] Types A and C are characterized by the presence of large atypical blasts, including mononucleated and binucleated or multinucleated cells resembling Reed-Sternberg cells characteristic of Hodgkin lymphoma. The atypical blasts express one or more T-cell antigens as well as the lymphoid activation antigen CD30 (Fig. 146-20). Although in type A these cells are embedded in a dense inflammatory background consisting of histiocytes, small lymphocytes, neutrophils, and/or eosinophils, in type C they form large sheets closely simulating cALCL. LyP type B is composed of small to medium-sized CD30⁻ T cells showing epidermotropism and thus closely resembles classic MF. Importantly, different histologic types of LyP can be present in one patient, because the histologic picture also correlates with the age of the individual lesion.

Treatment and Prognosis. Because a curative therapy is not available and none of the available treatment modalities affects the natural course of the disease, the short-term benefits of active treatment should be balanced carefully against the potential side effects. Low-dose oral methotrexate (5 to 20 mg/week) is the most effective therapy to suppress the development of new skin lesions. Treatment with psoralen plus ultraviolet A light (PUVA) has been reported to yield beneficial effects. However, after discontinuation of treatment the disease generally relapses within weeks or months. Therefore, in patients with relatively few and non-scarring lesions, long-term follow-up without active treatment should be considered.[27]

In general LyP shows a benign clinical course and a favorable 10-year survival rate of nearly 100 percent. However, in a proportion of patients, estimated at 10 percent to 20 percent of cases, LyP can precede, co-exist with, or follow malignant lymphoma, especially MF, Hodgkin lymphoma, or nodal anaplastic large cell lymphoma. In many of these cases the



▲ **FIGURE 146-15** Low-power view of a cutaneous T-cell lymphoma tumor. The dense infiltrate extends deep into the dermis.



▲ **FIGURE 146-16** **A.** Folliculotropic mycosis fungoides. Note follicular localization and resulting hair loss. **B.** Outer root sheath of hair follicle is disrupted by T cells and mucin deposition, which leads to small cystic spaces.

same clonal TCR rearrangements have been found in the LyP as well as in the associated lymphoma, identifying LyP as a precursor lesion. In the majority of LyP cases, despite the sometimes extremely long course of the disease, there is no evolution of a secondary lymphoma.

CUTANEOUS ANAPLASTIC LARGE CELL LYMPHOMA ***Definition.*** The cutaneous lymphoma cALCL is characterized by large tumor cells, of which the majority express the CD30 antigen, with no evidence or history of MF or another type of primary CTCL. Regardless of the morphology of the tumor cells (anaplastic, immunoblastic, or pleomorphic large cells), the clinical presentation and behavior are identical.

▲ **FIGURE 146-17** Pagetoid reticulosis. Hyperkeratotic plaque localized on the lower leg of a male patient.

Clinical Manifestations. $CD30^+$ cutaneous large-cell lymphomas occur in adults and rarely in children and adolescents, with a male-female ratio of 1.5:1. The clinical picture is characterized by the solitary or locoregional occurrence of reddish to brownish nodules and tumors, which frequently ulcerate (Fig. 146-21A). Although secondary involvement of the regional lymph nodes is observed in roughly 25 percent of the patients, it is not necessarily associated with an unfavorable prognosis.[27]

Histopathology. A nodular or diffuse nonepidermotropic infiltrate of large cells is seen in the dermis (see Fig. 146-21B). In the majority of cases, the neoplastic cells show an anaplastic morphology with oval or irregularly shaped nuclei, prominent nucleoli, and an abundant cytoplasm. Less commonly, a pleomorphic or immunoblastic appearance is observed. Atypical mitotic figures are frequent. In the periphery of the lesions, inflammatory cells (T cells, eosinophils, and neutrophils) are present, sometimes imitating the histologic picture seen in Lyp.

▲ **FIGURE 146-18** Granulomatous slack skin. Note skinfolds due to secondary elastolysis.

By definition, at least 75 percent of the large cells are $CD30^+$. In addition, they express a $CD4^+$ phenotype with variable loss of pan–T-cell antigens such as CD2, CD3, and CD5. Cases with $CD8^+$ neoplastic cells occur rarely. Unlike nodal $CD30^+$ lymphomas, $CD30^+$ large-cell lymphomas of the skin test negative for CD15 and epithelial membrane antigen, and expression of the aplastic lymphoma kinase ALK is also absent in most cases of cALCL. Clonal TCR rearrangements are detected in most cases.[28]

For diagnosis clinico-pathologic correlation is crucial. The histologic picture may suggest Lyp, but lesions of $CD30^+$ cutaneous large cell lymphoma are clinically larger and localized, and they usually do not tend to disappear spontaneously.

Treatment and Prognosis. In cases of solitary or localized skin lesions, radiotherapy is the preferred mode of treatment. Successful treatment with PUVA in combination with IFN-α has been reported. In cases of more generalized skin lesions or extra-cutaneous dissemination, multiagent chemotherapy should be considered.[29] In contrast to extracutaneous large-cell lymphomas, $CD30^+$ cutaneous large-cell lymphomas of the skin have a favorable prognosis, with a disease-related 5-year survival rate of 90 percent.[27]

Subcutaneous Panniculitis-Like T-Cell Lymphoma

DEFINITION Subcutaneous panniculitis-like T-cell lymphoma is defined as a cytotoxic T-cell lymphoma characterized

▲ **FIGURE 146-19** Lymphomatoid papulosis. **A.** Papular papulonecrotic and modular skin lesions. Note that lesions in various stages of development are present at the same time. **B.** Lymphomatoid papulosis. Crusted erythematous papulonodule.

by the presence of primarily subcutaneous infiltrates of small, medium-sized, or large pleomorphic T cells and many macrophages, predominantly affecting the legs and often complicated by a hemophagocytic syndrome.[1]

CLINICAL MANIFESTATIONS Subcutaneous panniculitis-like T-cell lymphoma is characterized by subcutaneous nodules and plaques, which usually involve the legs and, less commonly, the trunk. Patients often have B symptoms—that is, weight loss, fever, and fatigue—which are due to a frequently associated hemophagocytic syndrome.

HISTOPATHOLOGY Histologic examination shows subcutaneous infiltrates simulating a panniculitis. Infiltrates contain a mixture of neoplastic pleomorphic cells of various sizes and macrophages. Usually, tumor cell necrosis, karyorrhexis, and erythrophagocytosis are found. Rimming of individual fat cells by neoplastic T cells is a helpful diagnostic feature. Immunophenotyping shows that the neoplastic cells express CD3, CD8, CD43, CD45RO, T cell–restricted intracellular antigen 1 (TIA-1), perforin, granzyme B, the TCR α/β , and, rarely, CD56. The neoplastic T cells show clonal TCR gene rearrangements.[21,22]

TREATMENT AND PROGNOSIS Even with aggressive chemotherapy, the disease shows a rapidly progressive course, and the prognosis is generally poor, although dissemination to extra-cutaneous sites rarely occurs. In a small number of patients the disease shows an indolent clinical course and may be controlled by systemic steroid treatment.

Extra-Nodal Natural Killer/T-Cell Lymphoma, Nasal Type

DEFINITION Extra-nodal NK/T-cell lymphoma, nasal type, is a nearly always an EBV-positive lymphoma of small, medium, or large cells, usually with an NK-cell or, more rarely, a cytotoxic T-cell phenotype. The skin is the second most common site of involvement after the nasal cavity.[1]

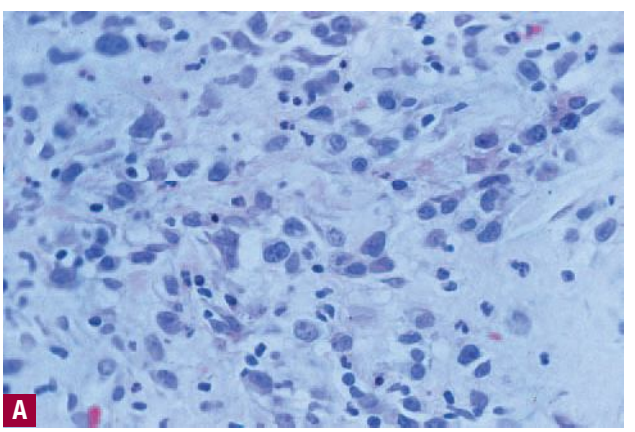
CLINICAL MANIFESTATIONS Extra-nodal NK/T-cell lymphoma either affects the naso-oropharynx, which leads to destruction of the nasal region (formerly described as *lethal mid-line granuloma*) or manifests in skin, subcutis, lungs, viscera, and testes. Skin lesions enclose subcutaneous tumors, erythematous plaques, ulcers, or an exanthematous eruptions with macules and papules. The clinical course is often aggravated by a hemophagocytic syndrome with pancytopenia.

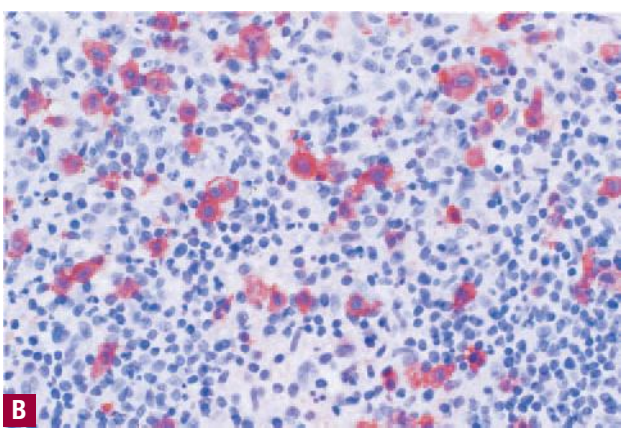
HISTOPATHOLOGY This type of lymphoma shows dense infiltrates involving the dermis and, often, the subcutis. Epidermotropism may be present. Prominent angiocentricity and angiodestruction are often accompanied by extensive necrosis. Immunophenotypically the neoplastic cells strongly express cytoplasmic CD3ε, CD56, and cytotoxic proteins (TIA-1, granzyme B, perforin) but lack surface CD3, and are characteristically positive for EBV.[21,22]

TREATMENT AND PROGNOSIS Even with aggressive chemotherapy, the disease is often lethal within months.[30] A study of the EORTC cutaneous lymphoma group suggested that bone marrow transplantation may be the treatment of choice.[29]

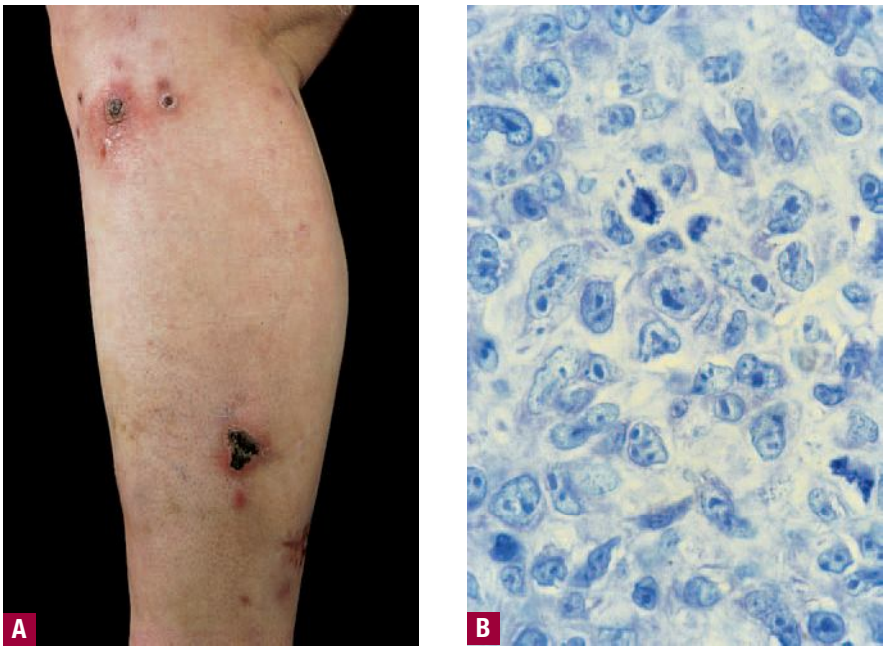
Provisional Entities of Cutaneous T-Cell Lymphoma

In addition to the diseases discussed in the preceding sections, a number of provisional entities are included in the WHO-EORTC classification system. These primary CTCLs display characteristic histologic features, but no dis-





▲ **FIGURE 146-20** **A.** Lymphomatoid papulosis. Dermal infiltrate contains several large lymphoid cells with nuclei showing evenly dispersed chromatin and variably prominent nucleoli (so-called *type A cells*). **B.** Type A with large CD30$^+$ T cells (*red*) among admixed inflammatory cells.



▲ **FIGURE 146-21** Primary cutaneous anaplastic large-cell lymphoma. **A.** Localized nodules, some with ulcerations. **B.** Pleomorphic large-cell lymphoma T-cell infiltrate.

tinct clinical presentation and/or outcome has been defined so far.

PLEOMORPHIC SMALL OR MEDIUM-SIZED CUTANEOUS T-CELL LYMPHOMA ***Definition.*** A neoplastic proliferation of pleomorphic, small or medium-sized T cells in the skin without any clinical signs of classic MF defines the pleomorphic, small or medium-sized CTCL.

Clinical Manifestations. Patients have one or several red-purplish papules or nodules at any location. Because histologic differentiation from MF and MF-associated follicular mucinosis can raise problems, the absence of patches and plaques in pleomorphic small or medium-sized CTCL is the decisive criterion.

Histopathology. Histologically, a dense, diffuse or nodular infiltrate containing small to medium-sized pleomorphic cells is observed within the dermis and, sometimes, the subcutis. Epidermotropism may be present. The neoplastic cells express a T-helper cell phenotype with frequent loss of pan–T-cell markers. In some cases that show a more aggressive clinical course, expression of $CD8^+$ is observed. Demonstration of an aberrant phenotype and of T-cell clonality, as well as predominance of pleomorphic T cells in the infiltrate, serve as useful criteria for the exclusion of pseudolymphomas, which often show an identical histologic pattern. MF is excluded by the absence of a dominant cerebriform tumor cell population.[31]

Therapy and Prognosis. In cases with solitary or localized lesions, radiotherapy is the preferred mode of treatment. PUVA therapy, possibly in combination with IFN-α, is useful in cases with disseminated lesions.

A 5-year survival rate of between 60 percent and 90 percent is reported for this type of lymphoma.[1,31]

PRIMARY CUTANEOUS AGGRESSIVE EPIDERMOTROPIC $CD8^+$ T-CELL LYMPHOMA ***Definition.*** Primary cutaneous aggressive epidermotropic $CD8^+$ T-cell lymphoma is a CTCL characterized by a proliferation of epidermotropic $CD8^+$ cytotoxic T cells and an aggressive clinical behavior. Differentiation from other types of CTCL expressing a $CD8^+$ cytotoxic T-cell phenotype, as observed in pagetoid reticulosis and rare cases of MF, LyP, and cALCL, is based on the clinical presentation and clinical behavior.[1]

Clinical Manifestations. Primary cutaneous aggressive epidermotropic $CD8^+$ T-cell lymphoma is characterized clinically by patches, plaques, papulonodules, and tumors mimicking those of disseminated pagetoid reticulosis and by a metastatic spread to unusual sites such as the lung, testis, central nervous system, and oral cavity, but not to the lymph nodes.

Histopathology. Histologically, band-like infiltrates consisting of pleomorphic lymphocytes or immunoblasts are observed, displaying a diffuse infiltration of an acanthotic epidermis with variable degrees of spongiosis, intraepidermal blistering, and necrosis. The neoplastic cells express the Ki67 antigen at a high frequency and are positive for CD3, CD8, CD7, CD45RA, and TIA, whereas CD2 and CD5 are frequently lost. Expression of TIA identifies these lymphomas derived from a cytotoxic T-cell subset.[29]

Treatment and Prognosis. Even with multiagent chemotherapy, the disease shows an aggressive course, and median survival is 32 months.

CUTANEOUS γ/δ T-CELL LYMPHOMA ***Definition.*** Cutaneous γ/δ T-cell lymphoma encompasses the peripheral T-cell lymphomas with a clonal proliferation of mature, activated γ/δ T cells with a cytotoxic phenotype. This group includes cases previously termed *subcutaneous panniculitis-like T-cell lymphoma with a γ/δ phenotype*.[1]

Clinical Manifestations. Patients have disseminated ulceronecrotic nodules or tumors, particularly on the extremities, but other sites may be affected as well. Involvement of mucosal and other extra-nodal sites is frequent, but involvement of lymph nodes, spleen, or bone marrow is uncommon. A hemophagocytic syndrome may occur.

Histopathology. Histologically three major patterns of involvement can be present in the skin: epidermotropic, dermal, and subcutaneous. The neoplastic cells are generally medium to large with coarsely clumped chromatin. Large blastic cells with vesicular nuclei and prominent nucleoli are infrequent. Apoptosis and necrosis are common, often with vessel invasion. Immunohistologically the tumor cells have a $\beta F1^-$, $CD3^+$, $CD2^+$, $CD5^-$, $CD7^{+/-}$, $CD56^+$ phenotype with strong expression of cytotoxic proteins. Most cases lack both CD4 and CD8, although CD8 may be expressed in some cases. In frozen sections the cells are strongly positive for TCR δ (antibody testing is not available for paraffin sections). If only paraffin sections are available, the absence of $\beta F1$ may be used to conclude a γ/δ origin.

Treatment and Prognosis. Most patients have aggressive disease resistant to multiagent chemotherapy and/or radiation therapy. Median survival is 15 months.

Staging of Cutaneous T-Cell Lymphoma

Staging of CTCL includes examination of the entire skin, chest radiography, and ultrasonography of abdominal organs and peripheral lymph nodes (cervical, axillary, and inguinal). Blood investigations are complete blood cell count, lactate dehydrogenase level, sedimentation rate, and T-cell clonality. A biopsy specimen must be taken from representative skin lesions and from enlarged lymph nodes. Staging may be completed by computed tomographic scan and/or histologic and molecular (TCR rearrangement) investigations of suspicious lymph nodes and/or visceral organs. Staging examination should be repeated at relapse and every 12 months (chest radiography every 2 to 3 years).

The aforementioned investigations allow for classification according to the tumor, lymph node, metastases (TNM) system (Table 146-2). Although the prognostic value and applicability of TNM staging for different CTCLs is controversial, the TNM scheme directs the decision-making process toward an appropriate therapeutic regimen for most CTCLs.

TABLE 146-2
Staging System for Mycosis Fungoides and Sézary Syndrome

STAGE	T (TUMOR)	N (LYMPH NODE)	M (METASTASES)
IA	T1	N0	M0
IB	T2	N0	M0
IIA	T1 or T2	N1	M0
IIB	T3	N0 or N1	M0
III	T4	N0 or N1	M0
IVA	T1–T4	N2 or N3	M0
IVB	T1–T4	N0–N3	M1

T1: patch/plaque ≤ 10% of body surface; T2: patch/plaque ≥ 10% of body surface; T3: skin tumor(s); T4: erythroderma; N0: normal nodes; N1: palpable nodes without histologic evidence of lymphoma; N2: no palpable nodes, but histologic evidence of lymphoma; N3: palpable nodes with histologic evidence of lymphoma; M0: no visceral involvement; M1: histologically confirmed visceral involvement.

Principles of Treatment of Cutaneous T-Cell Lymphoma

Every successful strategy in managing CTCL begins with goals, tumor-burden assessments, questionnaires, and a timetable. The primary goals of therapy are to improve the quality of life, to prolong life, and to cure. With a chronic disease like CTCL, surrogate markers are a necessity, and tumor burden is still the best surrogate marker for survival. Tumor-burden measurements and measures of palliation are the markers most commonly used. Skin score systems and health assessment questionnaires that evaluate both discrete and global manifestations of the disease have also provided disease activity measurements. The first staging of CTCL was done on the basis of skin involvement in a multicenter project conducted by the Mycosis Fungoides Cooperative Group[32] (see Table 146-2). The T staging provided the only underpinning for linking tumor burden with survival in that the more skin involved, from limited patch to 100 percent involvement, the worse the prognosis. In addition to skin staging, there are other factors that contribute to the heterogeneity of CTCL. This heterogeneity has undermined the usefulness of the TNM staging system. Currently, skin scores provide a measure of objective responses to therapy, and questionnaires guide the assessment of subjective responses to therapy. It has not been shown that reducing disease in a patient from T3 to T1 is accompanied by any benefit in survival, yet it is also recognized that cure is unattainable unless the patient is first in remission with a skin score of 0 by whatever skin scoring system is used. Thus, remission is the first step toward achieving a cure.

A few principles help guide therapy strategies.[23] Excellent long-term results have been reported with the localized treatment of localized disease. More widespread disease requires total skin or systemic therapy. However, it is not known at what percentage of skin surface involvement it becomes imperative to treat the entire skin. Once remission is achieved, maintenance therapy has a role in preventing relapse. Because many patients will undergo treatments that span decades, it is also important to minimize exposure to therapies that have cumulative toxicities on keratinocytes (i.e., mutagens) or the bone marrow.

With these principles in mind, one can approach the treatment of a given patient based on the patient's clinical presentation. The clinical presentation of the patient can be matched up with a successful therapy modality for both the remission-induction phase of therapy and the maintenance phase. For patients with several types of lesions, priority is given to those further down in Table 146-2. For example, a patient with both patches and tumors would be approached as a patient with tumors until those lesions are cleared.

The therapies used to help a patient with CTCL can best be categorized into skin-directed therapies, biologic response modifiers (BRMs), cytotoxic therapies, and combination therapies. Within each category, the individual modalities have unique properties that are discussed in the following sections in the context of how these modalities are used.[23]

UNILESIONAL/OLIGOLESIONAL CUTANEOUS T-CELL LYMPHOMA: SKIN-DIRECTED THERAPY The modalities considered for inducing a remission of unilesional/oligolesional disease are spot x-ray therapy, topical chemotherapy with carmustine (BCNU), and topical retinoid therapy with bexarotene. Topical glucocorticoid therapy is discussed later in the sections Maintenance Therapy and Topical Steroid Therapy. Spot radiotherapy is the most reliable and rapid method of inducing a remission of localized CTCL. Radiotherapy is widely available, and most lesions, no matter where they occur on the body (e.g., eyelid, buttock crease, ear), can be treated with this modality. There are no compliance problems, with each treatment session conducted by a professional radiotherapist. The immediate toxicity is minimal, but the long-term toxic effects of radiation dermatitis and cutaneous malignancy encourage conservative use of this modality.

The limitations of topical BCNU therapy are the systemic toxicity from absorption of the chemotherapeutic agent and local irritation. As a result, topical BCNU is used primarily for a limited body surface area. The initial protocols for BCNU administration called for an alcohol-based solution kept in the refrigerator. However, ointment-based protocols are now more common. BCNU can be easily made up in 20-mg%, 30-mg%, or 40-mg% ointments with a petrolatum base. Patients typically apply BCNU ointment at night and wash it off in the morning. Locally, a dose-related irritation

and/or hyperpigmentation may appear over the 8 to 20 weeks needed to clear lesions. Monitoring includes performing complete blood cell counts every 2 weeks to check for marrow suppression. The cumulative toxicity of BCNU is primarily structural damage with skin thinning and telangiectasias. The patient must be reliable and adherent to the regimen for this therapy to succeed.[33]

The limitations of topical bexarotene gel are also due primarily to dose-related irritant effects. Hence, bexarotene gel is typically used for lesions on less than 15 percent of body surface area, as was the case in most of the patients in the pivotal trial that led to its approval.[34] The gel is commercially available in a 1-percent formulation, so that dose intensity is varied by changing the frequency of application. Patients typically initiate therapy with nightly lesional applications of bexarotene gel. After a week, the frequency is increased to twice daily, and the patient is cautioned about the possibility of an irritant dermatitis at the site of the lesions. Complete clearance of lesions will usually occur after 12 to 16 weeks of therapy. Irritant responses can be managed by decreasing the frequency of application.[35] Successful topical bexarotene therapy also requires a patient who adheres to the treatment regimen and is willing to put up with the irritant properties of this vitamin A derivative.

DISSEMINATED PATCH/PLAQUE DISEASE Cutaneous T-cells re-circulate through the vascular system and are capable of patrolling the entire skin. When CTCL lesions are scattered, the most successful treatment strategies are those that treat the entire skin so as to extend the antilymphoma effect to the entire reach of the cutaneous T cell. Re-circulating CTCL cells are detectable even in limited disease, and such re-circulating cells are capable of restarting the disease. These cells provide some of the rationale for the use of maintenance therapy after a complete response has been achieved in the management of patients with disseminated patch/plaque disease. The total skin treatment modalities most commonly used as first-line therapy against disseminated patch/plaque disease are phototherapies, topical chemotherapy, and total skin electron-beam radiotherapy.

Phototherapies. PUVA (see Chap. 239) can produce a definite clinical response and complete remissions of long duration in patients with patch/plaque CTCL. PUVA therapy requires regular treatments, initially three to four times a week, for up to 3 months or until remission occurs. The follow-up of a patient receiving PUVA for CTCL includes an assessment to be sure there is some mild degree of phototoxicity. Otherwise, dosing of either the psoralen or the ultraviolet A light may be insufficient. Risks of the treatment include possible induction of cutaneous epithelial neoplasms and cataract formation. Therefore, all patients should be observed closely and checked regularly for the development of skin cancer. In addition, patients are advised to protect their eyes for 24 hours after PUVA therapy and to have annual ophthalmologic examinations. These precautions should be enforced early, because PUVA is a therapy that may continue for years as a maintenance treatment. Even after poor responses to conventional therapy, patients have experienced complete clearing of the skin with PUVA.[36] Maintenance therapy may be needed, however, as shown by the prolongation of clinical remission with continued PUVA.[37] For this reason, a gradual taper of therapy from thrice weekly to one session every 2 to 4 weeks after the patient has achieved a stable remission is typical.

Ultraviolet B and narrow-band ultraviolet B light are both effective in treating CTCL. These phototherapies are more convenient for patients, although their efficacy, especially for plaque disease, may not be as great as that of PUVA. Patch CTCL can often be completely cleared with ultraviolet B or narrow-band ultraviolet B light. A complete response can typically be induced with three to five treatment sessions per week. After a complete response has occurred, phototherapy can be continued on a maintenance schedule, initially at one treatment per week. The immediate adverse effects are primarily phototoxicity; the long-term toxicity is an increased risk for cutaneous malignancy.

Total Skin Topical Chemotherapy. Total skin topical chemotherapy consists of nitrogen mustard (mechlorethamine hydrochloride) applied as either an ointment or a freshly prepared aqueous solution. As an initial dose, 10 mg of the drug is dissolved in approximately 50 mL of tap water. The entire amount is then applied to the whole body surface by the patient. The patient should wear protective plastic gloves while applying the solution. A delayed hypersensitivity reaction may complicate treatment, and it is possible to desensitize patients, although their confidence in the therapy may be compromised. Ointment-based mechlorethamine, typically 10-mg% strength, may be less sensitizing and is shelf stable for a long period. Other side effects from mechlorethamine hydrochloride therapy, besides hypersensitivity reactions and primary irritant reactions, include the development of second cutaneous malignancies and hypopigmentation and hyperpigmentation. This therapy is relatively easy for the patient to use at home, but daily whole body application is required for maintenance therapy once remission is induced.

Total Skin Radiation Therapy. The radiosensitivity of cutaneous lymphomas has been therapeutically exploited by the administration of total skin electron-beam radiation. Because electrons penetrate only to the upper dermis, electron-beam therapy may be used without systemic effect. The limited penetration of the electrons is advantageous because it spares the mucous membranes, bone marrow, gastrointestinal tract, and other vital internal organs. Only those portions of the skin that are directly exposed to the beam are irradiated. Therefore, the palms, soles, scalp, axillae, and perineum may need separate exposures to ensure total body treatment. The eyelids are routinely covered with lead eye shields to protect the cornea and lens from the effects of radiation. If the eyelids are involved, 5-mm–thick contact lenses are worn between the lid and cornea within the conjunctival sac. Nail shields may also be used to prevent anonychia.

Whole body electron-beam irradiation brings about complete remission in 80 percent to 95 percent of patients. The relapse rate is highest in the later stages of CTCL, that is, in those patients with tumors, lymphadenopathy, and visceral involvement. Patients with limited plaque disease were found to have the highest relapse-free rate (42 percent at 10 years). Most relapses occurred within the first year after completion of therapy, and relapses were very rare after 3 years. The median disease-free interval was longer than 3 years in the limited plaque group, approximately 1 year for patients with generalized plaque or erythrodermic disease, and less than 6 months for patients with cutaneous tumors. The total dose of radiation is important. A dose of 30 cGy (3000 rad) or more gives higher complete remission rates and disease-free survival than do

lower doses. The major disadvantages are that this type of therapy must be provided at a specialized center and up to 3 months are required for complete treatment.

Local side effects include alopecia, atrophy of sweat glands and skin generally, radiodermatitis, and edema. When the total dose is highly fractionated, these complications are minimized and often avoided. The question is, What is the maximum radiation tolerance of the skin? When the highly fractionated approach is used, patients can receive a second course of electron-beam therapy of 36 cGy (3600 rad) to reinduce a remission. As the total radiation dose increases, so does the risk of squamous cell carcinoma and radiodermatitis. Small-field or spot orthovoltage radiotherapy using soft x-rays (60 to 100 kV with half-value layers of 1 to 1.5 mm Al) fractionated to doses of 0.75 to 5 cGy (75 to 500 rad) and total doses of 8 to 15 cGy (800 to 1500 rad) will adequately eliminate most lesions.

In many patients, a second or even third complete course of total skin electron-beam radiation can be safely given. The strategy of administering electron-beam radiation for repeat courses requires the use of a highly fractionated dose of 1 Gy per dose.

Maintenance Therapy and Topical Steroid Therapy. The concept of treating normal skin evolved from the clinical experiences with skin-directed therapies. There are two components to this approach: the treatment of normal skin during remission-induction skin-directed therapy and the treatment of normal skin during the remission maintenance phase. Topical chemotherapy, PUVA, and total skin electron-beam radiation all involve the exposure of normal skin as an integral component of their success in achieving remission. This success reflects the ability of the therapy to interrupt the critical skin-based phase of the life cycle of a re-circulating CTCL cell. Once a remission has been achieved, normal skin can be maintained with lower doses and frequencies of the therapies used to clear it. Maintenance therapies have been described with PUVA, total skin application of nitrogen mustard, ECP, and IFN. The most commonly used maintenance therapy is PUVA (see Chap. 239) or ultraviolet B irradiation (see Chap. 238). As a maintenance therapy, PUVA is initially administered at once-weekly intervals until 1 year has passed. At this point, the schedule is changed to every other week for another year, to every third week for the following year, and finally to every fourth week for 2 years. At this point, the patient should have been in remission for 5 years. Consideration should be given to stopping therapy at this point. A cure is defined as freedom from disease for 8 years off all therapy. This definition arose from the experience with nitrogen mustard treatment and total skin electron-beam radiotherapy showing that after a patient achieves a remission off therapy of 5 to 8 years, late relapse is extremely rare. This would imply that malignant cutaneous T cells re-circulate without causing lesions for up to 5 years. With 5 years of intermittent PUVA, it is less likely that one of these cells will survive, but it is still possible. After therapy has been discontinued, patients should not be considered cured unless they remain clear of disease for 8 years.

The management of suspected relapse often includes the use of topical glucocorticoids and reflects the critical role this modality can play in the treatment of suspicious lesions. Early in the course of CTCL and in a recurrence of the disease in a patient in remission, the T-cell activation process can be blunted by the aggressive use of topical glucocorticoids. Indeed, most patients have a history of using these agents before a firm diagnosis is made. A regimen for treating early lesions of MF is twice-daily applications of a class I topical glucocorticoid for 8 weeks. This regimen is one of the first-line modalities for suspected relapse, and it can help identify which patients need to undergo a 4-week "wash-out" before repeat biopsies are performed.

ERYTHRODERMA The erythrodermas of CTCL represent florid immune dysfunctions that result in total skin redness, scaling, and discomfort. It is not surprising that immune-based therapies take the forefront in the management of these disorders. The three major BRMs used in the treatment of CTCL are oral retinoids, intravenous ECP, and subcutaneous injections of IFN-α. In the clinical trials of these agents, patients have undergone monotherapy for what has usually been heavily pre-treated refractory disease. In practice, these treatments are often used as first-line monotherapy in erythroderma, and other agents are incorporated for combination therapies if the response is incomplete. With these agents, partial responses are more common than complete responses. Thus, if the goal is remission, combination therapy is used more commonly than monotherapy. If the goal is palliation, monotherapy with a BRM is often sufficient. The BRMs differ in terms of their administration, side effects, interactions with other therapy modalities, and availability.

Retinoid Therapy. The first-generation retinoids such as isotretinoin have an effect on CTCL. The more CTCL-specific retinoid bexarotene selectively binds the retinoid X receptor, whereas the other available retinoids have less specific binding patterns. In the monotherapy trials, bexarotene was dosed at 300 mg/m^2 (average dose, 450 to 675 mg/day, taken as capsules with the evening meal). Responses were seen in patients with all phases of the disease: plaques, erythroderma, and tumors. Responses paralleled the secondary end points: decreases in overall body surface area involved and in overall tumor aggregate area, and improvement in pruritus. Erythrodermic patients may experience increased desquamation during the first few weeks of oral bexarotene therapy. Improvement typically occurs by week 12 of therapy.[38]

Although there appeared to be a dose-response relationship with respect to efficacy, the higher dosages were also associated with a higher rate of adverse events and dose-limited toxicities. The most common were hyperlipidemia/hypercholesterolemia and neutropenia. Elevations in lipid levels occurred rapidly, within 2 to 4 weeks, and were associated with serious, but reversible, pancreatitis. Monitoring of lipids and the use of lipid-lowering drugs were helpful in controlling the lipid levels.[39] Dosage reductions of bexarotene capsules were also required in some patients. Drug interactions of oral bexarotene with gemfibrozil and warfarin have been observed.

Patients started on bexarotene therapy develop central hypothyroidism with low levels of thyroid-stimulating hormone and free thyroxine within weeks of starting the medication. Symptoms of hypothyroidism may be subtle and include feeling fatigued and feeling cold, which may be attributed to the CTCL. Supplementation with levothyroxine while patients are taking bexarotene alleviates the symptoms and improves tolerance of treatment.[39] The condition is reversible within weeks of stopping therapy. There is no immunosuppression with bexarotene therapy.

Patients taking bexarotene typically have monthly monitoring visits to follow lipid, liver, and thyroid parameters.

Extracorporeal Photochemotherapy. (See Chap. 239) ECP involves the photoinactivation of a portion of a patient's lymphocyte compartment with 8-methoxypsoralen in the presence of ultraviolet A light, followed by reinfusion of these cells. The treatment is performed via an intravenous line that feeds into a photoinactivation device, and the procedure typically requires the patient to remain recumbent for 3 hours. Treatments are conducted on two consecutive days every 4 weeks. Erythrodermic CTCL can be managed with ECP monotherapy,[25] but treatment of other disease stages with monotherapy has not been rigorously studied. In a multicenter study involving erythrodermic CTCL patients, approximately one-fourth had a complete response, one-fourth had no response, and the remainder had partial responses. However, it is clear that even a partial response can improve the quality of life of these patients. Improvement sometimes began as early as 6 weeks into therapy, but some patients did not show complete lesion clearance until 12 months after starting therapy. There were occasional temporary responses immediately after a 2-day cycle of therapy. On average, after 4 to 6 months there was typically a gradual and permanent decrease in erythema, scaling, and pruritus. Patients often notice more subtle changes, such as the return of body hair, loss of rigors, and a return of the ability to sweat. Partial responses may also decrease the morbidity these patients experience in terms of infectious complications. More heavily involved and inflamed skin is more readily colonized, providing both a reservoir and access point for microbes to invade the host. Thus, cutaneous improvement can also minimize complications of CTCL.

The clinical experiences with ECP for CTCL suggest that the therapeutic response may well be based in the immune system.[18] One feature is that when less than 5 percent of the malignant lymphocyte pool is photoinactivated with 8-methoxypsoralen and ultraviolet A light, clinical responses can be seen, with more than 95 percent of the malignant lymphocytes disappearing over time. It also appears that most immunocompetent patients respond. Patients who were heavily pre-treated, with longer disease durations, showed less of a response. Also, patients with more normal $CD8^+$ lymphocyte levels were responsive to ECP. In one study, total skin electron-beam radiotherapy was combined with ECP in patients with T3 and T4 disease. Comparison of patients receiving skin-directed radiotherapy plus BRM with historic controls who underwent electron-beam radiotherapy at the same institution demonstrated the impact of ECP, because patients in the skin-directed therapy plus BRM group showed significantly longer survival.[40]

Interferon-α Therapy. The most-studied IFN has been IFN-α, but clinical trials have also been done with IFN-β and IFN-γ in the treatment of CTCL. The initial studies using IFN-α as monotherapy showed rates of complete responses that varied from 10 percent to 27 percent with treatment durations of less than 6 months.[41] Again, the heterogeneity of the disease and the pre-treatments patients undergo affect outcomes and make comparisons with other modalities impossible. IFN-α is typically started at 3 million units (MU) three times a week and can be increased to a maximally tolerated dose, typically in the range of 12 MU/day. As with the other BRMs, the response to IFN is gradual, and 3 to 6 months are needed to determine the maximal response. After patients achieve a maximal response, IFN dosage can be lowered to a maintenance level of 1 MU daily.[42]

All IFNs have similar toxicities. The initial week of IFN therapy is complicated by a flu-like illness that may be accompanied by fever, myalgia, fatigue, and listlessness. As this wears off, patients are often left with a slight feeling of chronic fatigue. The long-term toxicity that causes most concern is neurologic: depression, neuropathy, dementia, and myelopathy. There are autoimmune phenomena that may occur, such as proteinuria, thrombocytopenia, and anemia. Monitoring of IFN therapy includes blood counts and urinalysis along with questionnaires assessing the impact on the patient's quality of life.

The combined-modality therapies that use IFN in the management of erythrodermas combine IFN with ECP or retinoids. If IFN monotherapy of erythroderma produces a partial response, the addition of either of these other modalities can help produce the desired goal of either complete response or increased palliation.

PRIMARY CUTANEOUS B-CELL LYMPHOMAS

Primary CBCLs are B lymphocyte–derived malignancies that develop in the skin without internal involvement at the time of diagnosis. CBCLs comprise approximately 20 percent of all cutaneous lymphomas.

In comparison with the nodal B-cell lymphomas, the majority of the CBCLs are indolent lymphomas.

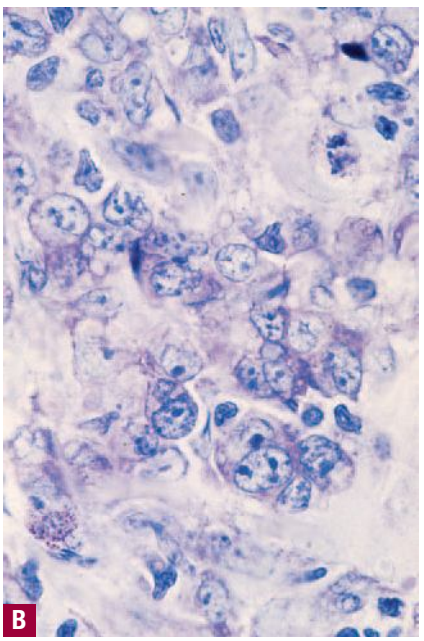
Primary Cutaneous Follicle Center Cell Lymphoma

DEFINITION PCFCL can be defined as a neoplasm of clonal centrocytes (small and large cleaved follicle center cells) and centroblasts (large follicle center cells with prominent nucleoli) with or without formation of follicular centers.[1,2]

CLINICAL MANIFESTATIONS Patients with PCFCL have lesions such as non-scaling solitary or grouped papules and thick plaques or tumors, and occasionally an annular erythema can be observed in the surrounding area (Fig. 146-22A). A typical finding is the occurrence of lesions in a circumscribed area of the head and neck region.

HISTOPATHOLOGY The typical histologic finding in PCFCL is nodular or diffuse infiltrates with almost constant sparing of epidermis. In the initial lesion a mixture of centrocytes, few centroblasts, and many reactive T cells is present. In parallel with progression of the tumor, the number and size of neoplastic B lymphocytes increases. In persisting lesions large follicle center cells (centrocytes and centroblasts) dominate (see Fig. 146-22B). A follicular growth pattern or remnants of follicles are observed. The abnormal follicles contain malignant $bcl\text{-}6^+$ follicle center cells and lack tingible body macrophages. The mantle zone is reduced or absent. The typical immunophenotype of the neoplastic cells is $CD19^+CD20^+CD22^+CD79A^+$. Clonal immunoglobulin rearrangements can be detected by molecular genetic analysis. Unlike in nodular follicular lymphomas, however, the t(14;18) translocation is not present and bcl-2 protein is expressed in only a minority of cases. A clonal rearrangement of the variable part of the immunoglobulin heavy chain gene is detected in 60 percent to 80 percent of cases.[43]

TREATMENT AND PROGNOSIS Radiotherapy is the preferred mode of treatment. Che-

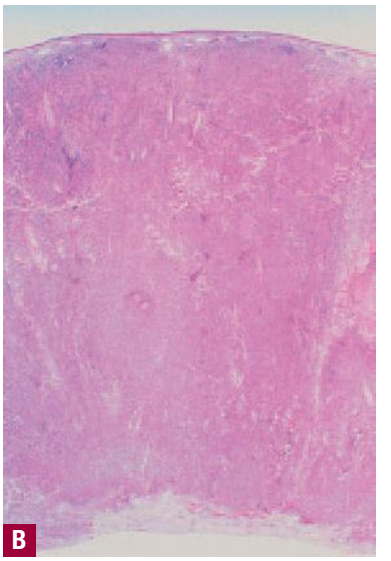


▲ **FIGURE 146-22** Primary cutaneous follicle center cell lymphoma. **A.** Tumor in the head area surrounded by erythema. **B.** The cellular infiltrate consists of a mixture of centrocytes, a number of centroblasts, and reactive T cells.

motherapy should be considered only in rare cases where more generalized skin lesions are present. Single lesions can be excised. Immune therapies such as administration of IFN-α or monoclonal antibodies against CD20 may be beneficial in cases with disseminated lesions.[10] With an estimated 5-year survival rate of 97 percent, the follicle center cell lymphoma is classified as an indolent type of primary CBCL. In untreated patients, the skin lesions increase in size over the years, but extracutaneous dissemination is uncommon.

Primary Cutaneous Marginal Zone Lymphoma

DEFINITION PCMZL is defined as a neoplastic proliferation of small lymphocytes, lymphoplasmacytoid cells, and plasma cells, which are initially localized in the marginal zone of a follicular center.[1,2]



▲ **FIGURE 146-23** Primary cutaneous large B-cell lymphoma of the leg. **A.** Nodules and tumors on the right leg 3 months after disease onset. The patient died 5 months later. **B.** Lesion from the same patient showing diffuse infiltrate of large B cells with centroblasts, large centrocytes, and numerous immunoblasts.

CLINICAL MANIFESTATIONS PCMZLs are seen most commonly on the upper extremities or the trunk and occur at a median age of 55 years; they predominate in females. Patients have small red to violaceous papules, plaques, or nodules that, in contrast to the lesions of PCFCL, frequently occur in multiple locations. PCMZL accounts for 25 percent of primary CBCLs.

HISTOPATHOLOGY Histologic analysis of well-developed lesions shows dense nodular or diffuse infiltrates with sparing of the epidermis. Hyperplastic germinal centers may be observed with or without a mantle zone. Outside the germinal centers (in the marginal zone) small lymphocytes with slight nuclear irregularity and moderate amounts of cytoplasm are present. Plasmacytic differentiation of the tumor cells may occur. Monotypic expression of immunoglobulin light chains can be observed in approximately 75 percent to 85 percent of cases. Importantly, the number of neoplastic cells within the infiltrate is variable and may be very low.

The typical immunophenotype is $CD20^{+}CD79a^{+}CD5^{-}CD10^{-}$ and bcl-6^{-}. An immunoglobulin light chain restriction can frequently be found. Monoclonal immunoglobulin gene rearrangement can be demonstrated by molecular genetic methods such as PCR or Southern blotting.[43]

TREATMENT AND PROGNOSIS Radiotherapy is the treatment of choice. Immune agents such as IFN-α or monoclonal antibodies against CD20 may be administered in cases with disseminated lesions. The disease has an indolent course with an excellent prognosis, and the 5-year survival rate is 100 percent. However, local recurrences are frequently observed. Extra-cutaneous involvement is extremely rare. PCMZLs are a part of the broad group of extranodal marginal B-cell lymphomas that involve mainly mucosal sites (mucosa-associated lymphoid tissue or MALT). Just as *Helicobacter pylori* has been implicated in the development of gastric MALT-type lymphomas, it has been suggested that *Borrelia burgdorferi* is involved in the development of MALT-type lymphomas in the skin, at least in Europe.[1,23]

Primary Cutaneous Large B-Cell Lymphoma of the Leg

DEFINITION PCLBCL leg type has been specifically identified as a distinct clinical entity because of its perceived poor outcome compared with other CBCLs (particularly PCFCL). This entity shows an intermediate clinical course and is defined by tumors composed of large B cells that present exclusively on the legs.[1,2]

CLINICAL MANIFESTATIONS PCLBCL leg type affects elderly patients (over 65 years), with a predominance in females. Typically patients have solitary or clustered bluish erythematous plaques and tumors located on one or, sometimes, both legs (Fig. 146-23A). Ulceration is common and sometimes leads to the misdiagnosis of chronic venous ulceration. It is important to note that, in rare

cases, PCLBCL leg type can also arise at cutaneous sites other than the legs.

HISTOPATHOLOGY The diffuse infiltrates spare the epidermis and often extend to the subcutaneous tissue. Monotonous populations or confluent sheets of centroblasts and immunoblasts with a high mitotic rate are admixed with only a few reactive T cells (see Fig. 146-23B). The neoplastic B lymphocytes express CD20, CD79a, multiple myeloma-1/interferon regulatory factor-4 (MUM-1/IRF4), and the bcl-2 molecule. Staining for bcl-6 gives positive results in most cases, whereas results for CD10 are generally negative. A clonal immunoglobulin rearrangement is detected in most cases.[43]

TREATMENT AND PROGNOSIS This tumor belongs to the intermediate aggressive group of CBCLs. Patients develop rapidly growing painless lesions, which initially disseminate along the lymph vessels. The tumor can involve the sentinel lymph node and progress to extra-cutaneous involvement. In cases of solitary or localized skin lesions, radiotherapy may be undertaken; in all other cases and when progression is observed, multiagent chemotherapy in combination with an immunotherapy agent (e.g., CHOP [*c*yclophosphamide, *h*ydroxydaunomycin, *O*ncovin (vincristine), *p*rednisone] plus anti-CD20 antibody treatment) should be administered. An unfavorable prognosis is reported, with a 5-year-survival rate of 55 percent.[23]

Provisional Entities of Primary Cutaneous B-Cell Lymphoma

In addition to the clearly defined primary CBCLs discussed in the preceding sections, provisional entities have been included in the WHO-EORTC classification.[1]

INTRAVASCULAR CUTANEOUS B-CELL LYMPHOMA Intravascular cutaneous B-cell lymphoma is characterized by clusters of large neoplastic B cells within dermal and subcutaneous blood vessels. Occasionally, slight extravascular infiltrates of atypical cells are observed. Clinically, red to bluish, indurated plaques can be observed on the legs or trunk. Sometimes a panniculitis-like pattern can be seen. Multiagent chemotherapy is the preferred mode of treatment.

Staging of Cutaneous B-Cell Lymphoma

Staging of cutaneous B-cell lymphoma includes examination of the entire integument, chest radiography, ultrasonography of abdominal organs and lymph nodes (cervical, axillary, and inguinal), and bone marrow biopsy. A complete blood cell count, lactate dehydrogenase level, sedimentation rate, serum and immune electrophoresis, *Borrelia* serologic testing, and B-cell clonality analysis are ordered for most patients. In the event of pathologic findings, staging is completed by computed tomographic scan and/or histologic investigation of suspect lymph nodes and/or visceral organs. Staging examination should be repeated at relapse and every 12 months (chest radiography every 2 to 3 years, bone marrow biopsy at relapse only).

Principles of Treatment of Cutaneous B-Cell Lymphoma

Treatment of primary CBCLs should be adapted to the favorable prognosis of these entities, in particular of PCFCL and PCMCL. Because no curative regimen has been defined so far, therapy depends on the entity and the dissemination of the cutaneous lesions. In the case of solitary lesions, complete excision of the tumor is the treatment of choice, and, in addition, local irradiation (single dose of 3 to 4 Gy; total dose of 20 to 40 Gy) by x-ray or electron beam can be considered. When this regimen is used, long-lasting remissions can be achieved. For local treatment, intralesional application of cisplatin has also been found to induce long-lasting, complete remissions in the case of solitary lesions.

For indolent CBCLs with disseminated lesions, immunotherapeutic regimens, including the application of IFN-α or anti-CD20 antibodies, are evaluated for their efficacy.

Systemic treatment regimens are recommended in cases of large B-cell lymphomas of the leg and in other CBCLs when multiple lesions or secondary extra-cutaneous manifestations are present. Polychemotherapy (six cycles of CHOP, COP [cyclophosphamide, Oncovin (vincristine), and prednisone], or MACOP [methotrexate-leucovorin, Adriamycin, cyclophosphamide, Oncovin, prednisone]) in combination with an anti-CD20 antibody is administered. After complete remission, maintenance therapy with IFN-α may be administered for a period of 1 year. Alternatively, use of a COP regimen with longer cycle intervals of 4 to 12 weeks is possible. For stage IV disease, combined myeloablative chemotherapy and irradiation with subsequent autologous bone marrow transplantation can be taken into consideration, although only a small number of cases have been treated using this regimen so far.

PRECURSOR HEMATOLOGIC NEOPLASM

CD4+/CD56+ Hematodermic Neoplasm

DEFINITION In the WHO-EORTC classification CD4+/CD56+ hematodermic neoplasm was included for the first time as a clinically aggressive neoplasm with a high incidence of cutaneous involvement and risk of leukemic dissemination.[1] The blastic cytologic appearance and CD56 expression initially suggested an NK precursor origin. More recent studies suggest derivation from a plasmacytoid dendritic cell precursor.[30]

CLINICAL MANIFESTATIONS CD4+/CD56+ hematodermic neoplasm commonly presents in the skin as solitary or multiple nodules or tumors with or without concurrent extra-cutaneous manifestations. Approximately 50 percent of patients have nodal or bone marrow involvement at presentation. Most patients who have only skin lesions when they first come for treatment rapidly develop involvement of bone marrow, peripheral blood, lymph nodes, and extra-nodal sites.

HISTOPATHOLOGY The typical histologic characteristics are diffuse monomorphous infiltrates of medium-sized cells separated by a grenz zone from the epidermis. Perivascular patchy infiltrates and an Indian file pattern are observed occasionally. Angiotropism is uncommon. The neoplastic cells express CD4, CD43, and CD56, as well as TCL1. Tests for markers of B-/T-cell (CD20/CD3) lineage, CD30, and markers of cytotoxic cells (TIA1, granzyme B) give negative results. The cells express CD123 and blood dendritic cell antigen 2, both of which support a relationship to plasmacytoid dendritic cells. TCR genes are in germline configuration. Tumor cells test negative for EBV.

TREATMENT AND PROGNOSIS CD4+/CD56+ hematodermic neoplasm is associated with a highly aggressive clinical course and thus a poor prognosis (median survival is 14 months). Although systemic chemotherapy is the first choice for treatment of this disease, the results are often disappointing. Studies suggest that patients can best be treated with regimens

used to treat acute myeloid leukemias, including bone marrow transplantation.[30]

CHAPTER 147

Inflammatory Diseases That Simulate Lymphomas: Cutaneous Pseudolymphomas

Gary S. Wood

Cutaneous pseudolymphoma is a term used to describe skin lesions that bear a clinical and/or histopathologic resemblance to lymphoma. Over the years, a wide variety of designations have been included in this category. Some of these represent outdated synonyms, some refer to variants of the same entity, and some are misnomers for diseases now recognized to be true lymphomas. The relevant entities that are discussed in this and other chapters can be organized into several distinct disorders based on their lymphoid subset composition, pattern of cutaneous infiltration, and associated clinical findings (Table 147-1).

CUTANEOUS LYMPHOID HYPERPLASIA

Epidemiology

Cutaneous lymphoid hyperplasia (CLH) has a world-wide distribution and affects all races and ethnic groups. It occurs in both adults and children. Females are more commonly affected than males.

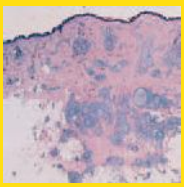
Etiology and Pathogenesis

CLH is characterized by a relatively dense lymphoid infiltrate, centered in the reticular dermis, that is usually B-cell rich and may resemble lymphoma clinically and/or histopathologically. Many terms are used to refer to this type of pseudolymphoma, including *Spiegler-Fendt sarcoid*, *lymphocytoma cutis*, *lymphadenosis benigna cutis*, and *cutaneous lymphoplasia*. *Cutaneous lymphoid hyperplasia* is the preferred term because it accurately describes the underlying pathophysiology of the lesion and is unlikely to be confused with terms used to describe various forms of cutaneous lymphoma.[1–5]

In most cases, CLH is idiopathic; however, some lesions are associated with exposure to foreign antigens from arthropods (bites, stings, infestations), infections (herpes zoster, *Borrelia burgdorferi*), tattoos, acupuncture, trauma, gold jewelry, vaccinations, hyposensitization injections, or medications (Figs. 147-1, 147-2, 147-3, and 147-4).[1–7] Medications that may induce CLH include phenytoin, carbamazepine, phenobarbital, β blockers, calcium channel blockers, angiotensin-converting enzyme inhibitors, allopurinol, D-penicillamine, penicillin, mexiletine chloride, cyclosporine, and agents that inhibit binding of histamine to H_1, H_2, or H_{1c} receptors. These drugs include conventional H_1 and H_2 antagonists, as well as tricyclic and nontricyclic antidepressants and phenothiazines.[8] It has been proposed that, rather than being the target of an

CUTANEOUS PSEUDO-LYMPHOMAS

AT A GLANCE



- A diverse group of skin disorders characterized by dense lymphoid infiltrates mimicking various types of cutaneous lymphomas.
- Two major immunologic categories: (1) mixed B and T cell (cutaneous lymphoid hyperplasia, Kimura disease, angiolymphoid hyperplasia with eosinophilia, Castleman disease) and (2) T cell (pseudo–mycosis fungoides, lymphomatoid contact dermatitis, Jessner's lymphocytic infiltration of the skin).
- Most are idiopathic but some are reactions to foreign antigens introduced locally or systemically.
- Usually present as violaceous, solitary, or localized papules, plaques, or nodules.
- Some cases harbor occult dominant lymphoid clones; occasional cases progress to overt cutaneous lymphomas.

immune response themselves, these latter agents may alter lymphocyte reactivity in a way that promotes a CLH response to other antigens in some individuals.[9,10]

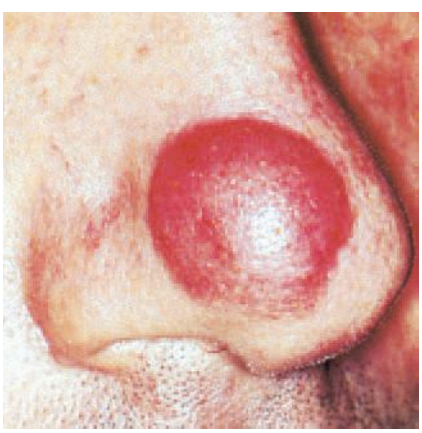
Clinical Findings

APPROACH TO THE PATIENT Although the details of the workup for individual patients will vary with the specific type of pseudolymphoma being considered, certain data are generally important for establishing the correct diagnosis, identifying potential causative factors, and ruling out an underlying lymphoma. The clinical history taking should elicit information about the duration and symptomatology of lesions; the nature and pace of clinical progression; past treatment; local or systemic exposure to foreign antigens, including medications; and personal or family history of other lymphoproliferative disorders. It should also include a review of systems focusing on so-called *lymphoma B symptoms*, such as fever of unknown origin, unexplained weight loss, night sweats, fatigue, and malaise. A general physical examination is important, with special attention to the type and distribution of skin lesions and to the status of peripheral lymph nodes, liver, and spleen. A complete blood count with differential review, general chemistry panel, and a chest radiograph are screening tests that help to exclude extra-cutaneous involvement. Lesional skin biopsy is an essential part of the diagnostic evaluation. The use of topical and systemic glucocorticoids should be discontinued approximately 4 weeks before biopsy if possible, because these agents can attenuate lymphoid infiltrates and thereby confound their interpretation. Skin specimens should be large enough and deep enough to ensure representative sampling and to provide adequate tissue for routine histopathologic, immunohistologic, and molecular biologic studies. As with squamoproliferative skin lesions, the most diagnostic areas within cutaneous lymphoid infiltrates are often their deepest portions (Fig. 147-5). For cost effectiveness, one can often perform these biopsy studies in a sequential fashion, proceeding to the next test only if a firm diagnosis cannot be made based on the results of preceding analyses. However, rigorous characterization of a pseudolymphomatous infiltrate requires the full complement of these assays. If there is only a solitary lesion, it is generally best to obtain all biopsy material at one time, because inflammatory changes induced by the initial biopsy may interfere with the interpretation of subsequent specimens from the same locale.

TABLE 147-1
Classification of Cutaneous Pseudolymphomas

Clinicopathologic Sub-Type	Predominant Lymphoid Subset(s)	Predominant Localization	Major Associated Findings
Cutaneous lymphoid hyperplasia	B and T cell	Reticular dermis	—
Kimura disease	B and T cell	Subcutis	Lymphadenopathy
Angiolymphoid hyperplasia with eosinophilia	B and T cell	Reticular dermis	Eosinophilia
Castleman disease	B and T cell	Subcutis	Lymphadenopathy, POEMS syndrome
Pseudo–mycosis fungoides	T cell	Papillary dermis and epidermis	—
Lymphomatoid contact dermatitis	T cell	Papillary dermis and epidermis	Contact allergen
Lymphocytic infiltration of the skin (Jessner's)	T cell	Perivascular and periadnexal dermis	—

POEMS = polyneuropathy, organomegaly, endocrinopathy, M protein, and skin changes.



▲ **FIGURE 147-1** Cutaneous lymphoid hyperplasia. Solitary infiltrated nodule with a smooth surface in a classic location. (Lymphocytoma cutis in Lyme borreliosis.)

▲ **FIGURE 147-2** Cutaneous lymphoid hyperplasia. Involvement of the breast in a patient with elevated titers of antibodies against *Borrelia burgdorferi* spirochetes.

▲ **FIGURE 147-3** Cutaneous lymphoid hyperplasia. Multiple lesions of nodular scabies involving the genitalia.

▲ **FIGURE 147-4** Cutaneous lymphoid hyperplasia. Lymphomatoid drug reaction manifest as a generalized papulonodular eruption in a patient who was taking various neuroleptics.

In the event that there is still uncertainty as to whether the lymphoid infiltrate represents a pseudolymphoma or a lymphoma, additional workup can be helpful. This includes computed tomographic scans of the chest, abdomen, and pelvis, as well as bone marrow aspiration and biopsy. Biopsy can be performed on abnormally enlarged lymph nodes identified by physical examination or radiography and the specimens evaluated as described in the preceding paragraph for skin lesions. It is possible for patients with atypical cutaneous B-cell infiltrates manifesting as only one or a few skin lesions to have an otherwise unremarkable workup until radiographic scans of deep lymph nodes or bone marrow sampling demonstrates advanced-stage B-cell lymphoma with minor skin involvement.

HISTORY There may be a history of contact with an etiologically relevant foreign antigen; however, the majority of CLH cases are idiopathic. Lesions may be pruritic or asymptomatic. Occasionally, they may be slightly tender.[11]

CUTANEOUS LESIONS CLH presents most commonly as a solitary nodule, but it can also appear as a localized array of nodules, plaques, or papules. Generalized forms occur rarely. The head, neck, extremities, breasts, and genitalia are common sites (see Figs. 147-1, 147-2, 147-3, and 147-4). Lesions have a doughy to firm consistency and range from red-brown to violaceous in color. Lesions secondary to arthropod bites can be pruritic, ulcerated, or crusted. Occasionally, reactive lymphadenopathy may be present in the area of regional lymphatic drainage.[11,12]

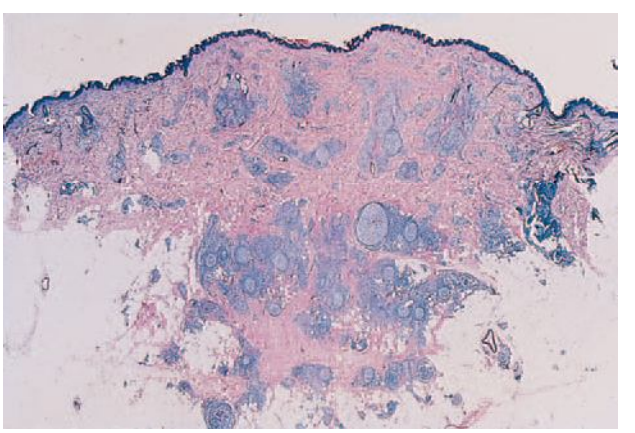
Hydantoin-associated pseudolymphoma syndrome is caused by anticonvulsant drugs such as phenytoin. This syndrome is characterized by fever, lymphadenopathy, hepatosplenomegaly, arthralgia, eosinophilia, and generalized cutaneous macules and papules or, rarely, nodules.[2,3] Nodules may contain aggregates of large lymphoid cells that raise concern for lymphoma; however, both B and T cells are polyclonal. Subcutaneous lymph nodes may exhibit reactive follicular hyperplasia or atypical features suggestive of lymphoma. The macular and papular lesions of this syndrome share histopathologic features with those of hypersensitivity reactions to other drugs.

Acral pseudolymphomatous angiokeratoma of children presents as a unilateral eruption of angiomatous papules on the extremities.[13] There is a dense lymphoid infiltrate associated with histiocytes, plasma cells, and prominent, thickened capillaries.[14] This disorder is probably a variant of CLH secondary to arthropod bites.

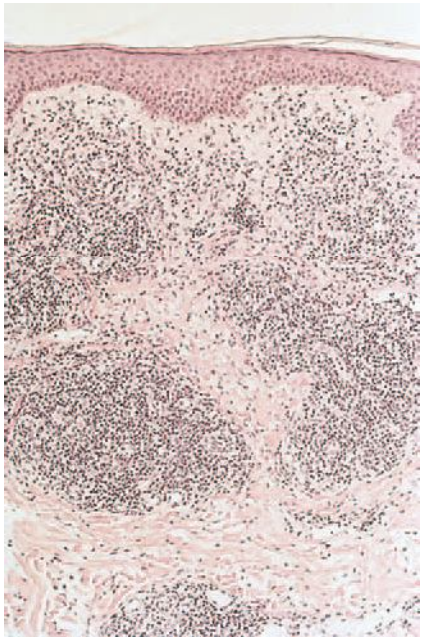
Large cell lymphocytoma, originally reported as a cutaneous pseudolymphoma, most likely represents a mixed cell or large cell form of primary cutaneous B-cell lymphoma (CBCL).[1]

Laboratory Tests

HISTOPATHOLOGY Histopathologic examination of CLH lesions reveals a dense, nodular or diffuse lymphoid infiltrate that is concentrated in the reticular dermis (see Figs. 147-5, 147-6). It tends to be top heavy and to taper out in the lower dermis, although more widespread dermal infiltration with extension into the subcutis can sometimes be seen. In most cases, the epidermis is normal and separated from the underlying infiltrate by a narrow grenz zone of uninvolved papillary dermis. Occasionally, the epidermis may exhibit variable degrees of hyperkeratosis, parakeratosis, acanthosis, dyskeratosis, spongiosis, and basal vacuolar degeneration. Arthropod-induced reactions may show prominent epidermal hyperplasia or ulceration. Rarely, retained mouth parts may be seen associated with foreign-body granulomatous

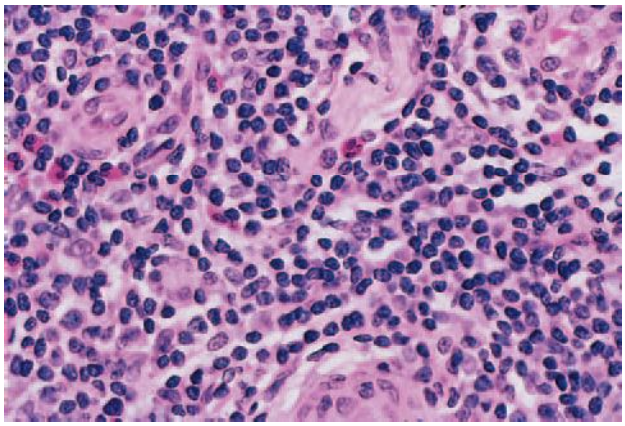


▲ **FIGURE 147-5** Cutaneous lymphoid hyperplasia. Infiltrate is wedge shaped and tapers out in its deeper portions. Note reactive lymphoid follicles containing pale germinal centers.



▲ **FIGURE 147-6** Cutaneous lymphoid hyperplasia. Nodular scabies. Patchy dense infiltrate composed of small lymphocytes, histiocytes, eosinophils, and plasma cells.

reactions. The dermal infiltrate is composed primarily of small mature lymphocytes, with a minor component of large lymphoid cells containing large, pale vesicular nuclei with small nucleoli (Fig. 147-7). Fewer than half of cases exhibit well-defined reactive lymphoid follicles discernible in routinely stained sections (see Figs. 147-5 and 147-8). These B-cell follicles may be either primary or secondary. The former are composed of homogeneous small lymphocytes, whereas the latter are compartmentalized into a peripheral mantle zone of small lymphocytes surrounding a germinal center composed of a heterogeneous mixture of small and large lymphoid cells with cleaved and noncleaved nuclei known as *centrocytes* and *centroblasts*. Also present in germinal centers are tingible-body macrophages, so named because they contain phagocytized debris from apoptotic lymphoid cells. Mitotic figures may be numerous within germinal centers but are usually uncommon elsewhere in the infiltrate. Various types of histiocytes, including macrophages, dermal dendritic cells, and Langerhans cells, are scattered throughout the infiltrate in variable proportions. Capillary hyperplasia and endothelial swelling are often present. Other cells are sometimes admixed, including plasma cells, eosinophils, mast cells, neutrophils, and histiocytic giant cells. The first two are particularly common in arthropod-induced reactions such as nodular scabies (see Fig. 147-6).[11,12]

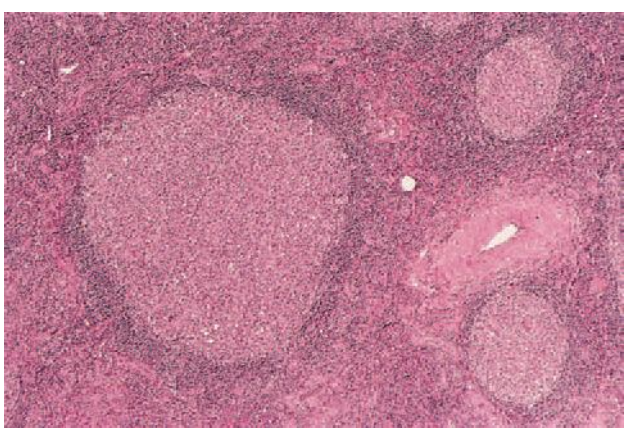


▲ **FIGURE 147-7** Cutaneous lymphoid hyperplasia. Infiltrate consists predominantly of small lymphocytes with an admixture of large lymphoid cells, histiocytes, and eosinophils.

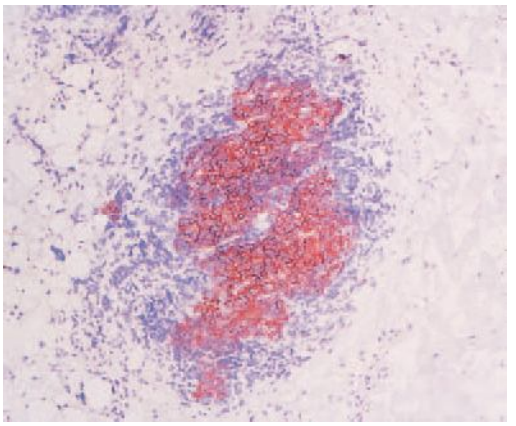
In the less common T-cell CLH, there are only rare B cells.[1–3,15–17] Lesions may be idiopathic or secondary to drugs or arthropod bites. Sparse to moderate epidermotropism by atypical lymphoid cells may be seen. The dermal infiltrate has a nodular or diffuse pattern and may contain cerebriform cells, immunoblasts, and histiocytes mixed with a preponderance of small mature lymphocytes. The histiocytes are sometimes numerous enough to impart a vaguely granulomatous appearance.[17] The author has seen one such case presenting as multiple nodules on the trunk and extremities that was associated with rheumatoid arthritis and eventuated in T-cell lymphoma.

SPECIAL TESTS CLH is just one special case of extra-nodal lymphoid hyperplasia that may occur in a variety of organ systems. In their most well-developed form, these extra-nodal reactions re-create the immunoarchitectural features of reactive follicular lymphoid hyperplasia occurring in lymphoid tissues. CLH is generally a mixed B-cell/T-cell disorder. B cells may be organized into primary or secondary lymphoid follicles, simple clusters devoid of the follicular dendritic cell network seen in B-cell follicles, or may be randomly scattered throughout the infiltrate (Fig. 147-9).[5] A defining immunophenotypic feature of CLH is that the small, non–germinal center B cells and plasma cells are polytypic; that is, instead of restriction to only one type of immunoglobulin light chain, there is a mixture of κ-positive and λ-positive cells.[18–20] The follicular dendritic cell networks in lymphoid follicles co-express both immunoglobulin light chains because of the polytypic nature of the immunoglobulins bound to these networks (Fig. 147-10). The larger germinal center B cells are also polytypic but generally have very low levels of immunoglobulin expression, which is obscured by the more intense staining of the follicular dendritic cell networks in which they are enmeshed.[21] Consistent with their role as a site of antigen selection and apoptosis, reactive germinal centers test negative for the bcl-2 oncoprotein.[1]

Some researchers classify CLH into follicular and diffuse variants based on



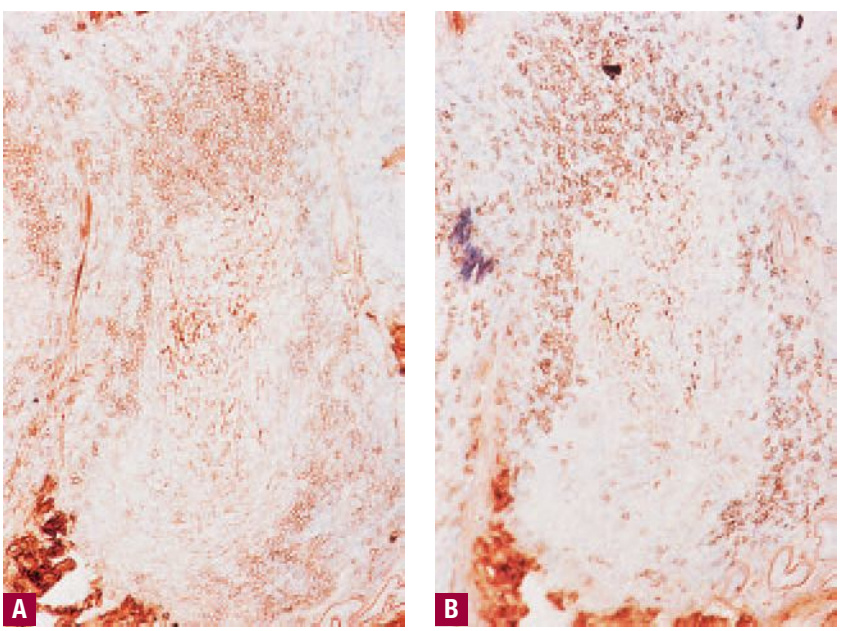
▲ **FIGURE 147-8** Cutaneous lymphoid hyperplasia. Lymphoid follicles in the dermis contain pale germinal centers surrounded by darker mantle zones.



◀ **FIGURE 147-9** Cutaneous lymphoid hyperplasia. Reactive lymphoid follicle contains B cells (*blue*) enmeshed in a network of follicular dendritic cells (*red*). Frozen section immunoperoxidase-stained using the anti–dendritic reticulum cell monoclonal antibody.

the identification of lymphoid follicles in routinely stained sections. This distinction is probably not relevant biologically, because most of the apparently diffuse cases also exhibit B-cell follicles when examined immunohistologically. T cells are also present in all cases of CLH. They are found in small numbers within lymphoid follicles but are concentrated mainly between follicles, constituting an interfollicular T-cell domain. This imparts an overall compartmentalization of B and T cells in CLH lesions. The $CD4^+$ T-cell subset predominates over the $CD8^+$ subset. There is a normal pattern of T-cell antigen expression except that CD7 may be moderately deficient at times, being expressed by only 20 percent to 40 percent of T cells. Germinal center B cells, mantle zone B cells, interfollicular B cells, and plasma cells also express the same complement of cell surface differentiation antigens expressed by their counterparts in reactive lymphoid tissues.

Unlike in most nodal follicular B-cell lymphomas (Chap. 146), the t(14;18) translocation, which results in inappropriate expression of the bcl-2 oncoprotein, is absent in CLH.[1,22–24] Molecular biologic studies show that 5 percent to 33 percent of CLH cases defined by clinicopathologic and immunohistologic criteria contain occult dominant immunoglobulin gene rearrangements, which indicate the presence of a dominant B-cell clone.[1,25–29] These cases, known as *clonal CLH*, have progressed in some cases to overt B-cell lymphoma exhibiting the same dominant B-cell clone. These findings support the view that CLH, clonal CLH, and primary CBCL exist as points along a continuum of cutaneous B-cell lymphoproliferative disorders. Progression across this spectrum of disease clearly occurs in some cases, most likely as the result of serial mutations within the dominant B-cell clone. This implies that patients with persistent CLH require regular monitoring for the development of lymphoma.[19] Clonal T-cell receptor gene rearrangements have also been detected in up to one-third of CLH cases.[29,30] This may represent an expanded reactive T-cell clone within the CLH infiltrate. Evidence for this has been observed in CLH related to human immunodeficiency virus infection.[31] Other less likely possibilities include an abortive T-cell lymphoma or an evolving B-cell lymphoma bearing T-cell receptor gene rearrangements.



▲ **FIGURE 147-10** Cutaneous lymphoid hyperplasia. Reactive lymphoid follicle contains a germinal center surrounded by a mantle zone composed of a mixture of B cells that express either κ-immunoglobulin light chain (**A**) or λ-immunoglobulin light chain (**B**). Note that the central follicular dendritic cell network stains positive for both light chains because polytypic immunoglobulins are bound to its surface.

Differential Diagnosis

The differential diagnosis of CLH includes all of the conditions listed in Box 147-1. Many of these entities, such as granuloma faciale, Merkel cell tumor, histiocytomas, granulomas, and metastatic carcinoma, are readily distinguished from CLH by their histopathologic features.

A principal challenge in the differential diagnosis of CLH is its distinction from CBCL of either the diffuse or follicular types (see Chap. 146).[1–3,22,32] The most common variant of CBCL is diffuse large cell lymphoma, which is readily distinguished from follicular CLH on the basis of its diffuse architec-

Box 147-1

Differential Diagnosis of Cutaneous Lymphoid Hyperplasia

Most Likely

- Chronic cutaneous lupus erythematosus
- Jessner's lymphocytic infiltration of the skin
- Granuloma faciale

Consider

- Polymorphous light eruption
- Drug eruption
- Angiolymphoid hyperplasia with eosinophilia
- Deep figurate erythemas
- Metastatic carcinoma
- Merkel cell carcinoma
- Secondary syphilis
- Histiocytomas
- Infectious and inflammatory granulomas

Always Rule Out

- Cutaneous B-cell lymphoma
- Leukemia cutis

ture and monomorphous large cell composition. Differentiating follicular CLH from follicular CBCL can be difficult. Follicular CBCL tends to be more bottom heavy with adnexal infiltration and lymphoid follicles lacking the cellular heterogeneity, zonation, and macrophages typical of reactive follicles. Immunophenotyping shows that neoplastic B-cell follicles are either monotypic or immunoglobulin negative.[15–17] Cases involving cutaneous lymphoid infiltrates that are hard to classify or that contain a dominant lymphoid clone often benefit from a staging workup as described in the section Approach to the Patient. In those instances representing lymphoma, workup will sometimes reveal extracutaneous involvement, and biopsy specimens from these lesions may be easier to diagnose as lymphoma. Staging also provides useful prognostic data and is essential for appropriate management of patients with overt lymphoma.

CLH must also be distinguished from other disorders with lymphocytic infiltrates such as chronic lymphocytic leukemia, deep figurate erythemas, polymorphous light eruption, discoid lupus erythematosus, and Jessner's lymphocytic infiltration of the skin. All of these disorders tend to produce perivascular, and sometimes periadnexal, infiltrates whose density is far lower than that of the nodular or diffuse infiltrates typical of CLH. With the exception of chronic lymphocytic leukemia, these are all T-cell disorders. Chronic lymphocytic leukemia is a B-cell disorder that exhibits monotypic immunoglobulin and CD5 expression and involves the blood and bone marrow. CLH lesions rich in plasma cells must be distinguished from the lesions of secondary syphilis, plasmacytoma, myeloma, and immunocytoma. The infiltrate in secondary syphilis is generally richer in plasma cells or histiocytes than in small lymphocytes and is associated with epidermal hyperplasia, an interface inflammatory component, and positive results on serologic tests. The plasma cells in plasmacytoma and myeloma are monotypic and tend to exhibit mitotic figures, atypia, immaturity, and multinucleated forms. Monotypic immunoglobulin is also present in the tumor cells of primary cutaneous immunocytoma. This B-cell neoplasm is also known as *marginal zone lymphoma, mucosa-associated lymphoid tissue (MALT)–type lymphoma,* and *low-grade skin-associated lymphoid tissue (SALT) B-cell lymphoma*.[1,22,33] It is composed of varying proportions of small lymphocytes, plasmacytoid lymphocytes, plasma cells, and marginal zone–like B cells. The latter have monocytoid features with a halo of cytoplasm visible around their nuclei. These cells often surround clusters of small lymphocytes, imparting a "reverse reactive follicle" appearance with smaller cells centrally and the larger monocytoid cells peripherally.

It should be noted that typical reactive lymphoid follicles with germinal centers are not specific for CLH. They can be seen in some lymphomas (e.g., marginal zone lymphoma), Kimura disease, angiolymphoid hyperplasia with eosinophilia, Castleman disease, inflammatory pseudotumor of the skin, and morphea and as part of the host response to tumors such as basal cell carcinoma. The broad histopathologic differential diagnosis of CLH also includes histiocytoses, especially Rosai-Dorfman disease (sinus histiocytosis with massive lymphadenopathy; see Chap. 149), as well as so-called *small round cell tumors* such as Merkel cell carcinoma (see Chap. 120), oat cell carcinoma, neuroblastoma, and Ewing sarcoma.

Differentiation between T-cell CLH and T-cell lymphomas relies on the fact that most cases of mycosis fungoides exhibit marked epidermotropism, and most non–mycosis fungoides cutaneous T-cell lymphomas are either diffuse large cell or mixed cell types, although a pleomorphic small cell type occurs rarely. Many T-cell lymphomas show loss of one or more T-cell antigens, and most have monoclonal T-cell receptor gene rearrangements. Progression to T-cell lymphoma has been reported in occasional patients with T-cell CLH.[15,16]

Complications

One of the most challenging issues concerning cutaneous pseudolymphomas has been the nature of their relationship to true lymphomas. Many patients with CBCL have a history of prior diagnosis of biopsy specimens as CLH or atypical CLH. Patients with disorders such as lymphomatoid papulosis, lymphomatoid granulomatosis, and angioimmunoblastic lymphadenopathy with dysproteinemia have an increased risk of developing various forms of overt lymphoma.[1,2,22,33] The advent of molecular biologic methods for determining B-cell or T-cell clonality by analyzing immunoglobulin or T-cell receptor gene rearrangements, respectively, has provided important insights into the relationship between pseudolymphomas and lymphomas.[1,2,22] It appears that many forms of cutaneous pseudolymphoma represent the benign end of a lymphoproliferative continuum eventuating in true lymphoma at its malignant extreme. In between lies a spectrum of intermediate disorders that are often difficult to classify unless one conceptualizes the disorders along such a continuum. In some cases, such as the CLH-CBCL spectrum, lesions range from polyclonal CLH at the benign extreme, through an intermediate form known as clonal CLH, to overt CBCL at the malignant extreme. In other instances, such as the lymphomatoid papulosis–CD30$^+$ lymphoma spectrum, dominant clonality is already present in most cases at the clinically benign end of the spectrum. The most compelling evidence for the validity of this concept of a continuum is that case studies verify that the same dominant lymphoid clone is involved in the clonal pseudolymphomatous precursor and the subsequent overt lymphoma when they arise in the same individual. This relationship between overt neoplasia and clonal precursor lesions is not unique to cutaneous pseudolymphomas. It is also seen in the connection between other forms of extra-nodal lymphoid hyperplasia and overt lymphoma and in the relationship between monoclonal gammopathy of uncertain significance (formerly termed *benign monoclonal gammopathy*) and subsequent B-cell malignancies.

The concept of a spectrum for cutaneous pseudolymphomas and associated lymphomas has several important implications for the diagnosis, management, and pathogenesis of these disorders. First, because some cases will exhibit lesions at an intermediate point along the lymphoproliferative continuum, they may be difficult to classify neatly into a specific disease entity. It is probably more important to recognize that they belong to a particular disease spectrum, because it is the spectrum that is often the most relevant factor for determining optimal therapy as well as the magnitude and nature of the subsequent lymphoma risk. Second, because many patients with cutaneous pseudolymphomas are at increased risk for a clonally related lymphoma, they should have regular clinical follow-up, and all reasonable attempts should be made to eradicate or suppress their disease. Third, patients with pseudolymphomas probably have underlying abnormalities in the regulation of lymphoid proliferation and/or clearance (e.g., via apoptosis). Clonal evolution and concomitant clinical disease progression are likely to occur through a sequence of somatic mutations that act through these mechanisms to confer progressively increasing autonomy to the

dominant lymphoid clone. Elucidating these pathogenetic mechanisms will be important not only for developing novel therapies for cutaneous pseudolymphomas but also for improving the treatment of analogous lymphoproliferative disorders occurring in other organ systems.

Prognosis and Clinical Course

CLH lesions may resolve spontaneously or persist indefinitely. Nodular scabies (see Figs. 147-3 and 147-6) is a well-recognized form of persistent CLH. Solitary lesions sometimes regress after biopsy or may be eradicated by excision. Those lesions that are secondary to drug use usually regress when the offending agent is withdrawn.

Treatment

CLH related to infection with *B. burgdorferi* (lymphocytoma cutis; see Chap. 187) responds to antibiotic therapy with cephalosporins, as do some cases of idiopathic CLH. Glucocorticoids (topical, intralesional, systemic), cryotherapy, antimalarials, minocycline, and radiation therapy have all been used with variable success (Box 147-2). The latter is particularly effective but is usually regarded as a treatment of last resort. Laser therapy and photodynamic therapy have also been beneficial in some cases.[35,36] Local or distant recurrence can arise after any of these treatments. Cases of atypical CLH that cannot be distinguished from lymphoma are usually treated as localized lymphoma after staging rules out extra-cutaneous disease. Treatment typically involves local radiation therapy, which may be preceded by excision of the lesion.

Box 147-2

Treatment of Cutaneous Lymphoid Hyperplasia

FIRST LINE

- Excision
- Topical corticosteroids (mid to high potency twice daily)
- Intralesional corticosteroids (5–40 mg/mL, 1 mL monthly)
- Systemic antibiotics (e.g., minocycline 50–100 mg PO twice daily; cephalexin 500 mg PO twice daily)
- Topical tacrolimus[34]

SECOND LINE

- Cryotherapy
- δ-Aminolevulinic acid photodynamic therapy
- Laser therapy (e.g., pulsed dye laser)
- Hydroxychloroquine (200 mg PO twice daily)
- Systemic corticosteroids (60/40/20 mg PO taper, 5 days each)
- Local radiation therapy

Prevention

The principal preventive strategy is to avoid contact with, or ingestion of, agents known to induce CLH in those patients with a relevant clinical history. Examples include anticonvulsant medications, arthropods, gold jewelry, and hair dyes.[37–41]

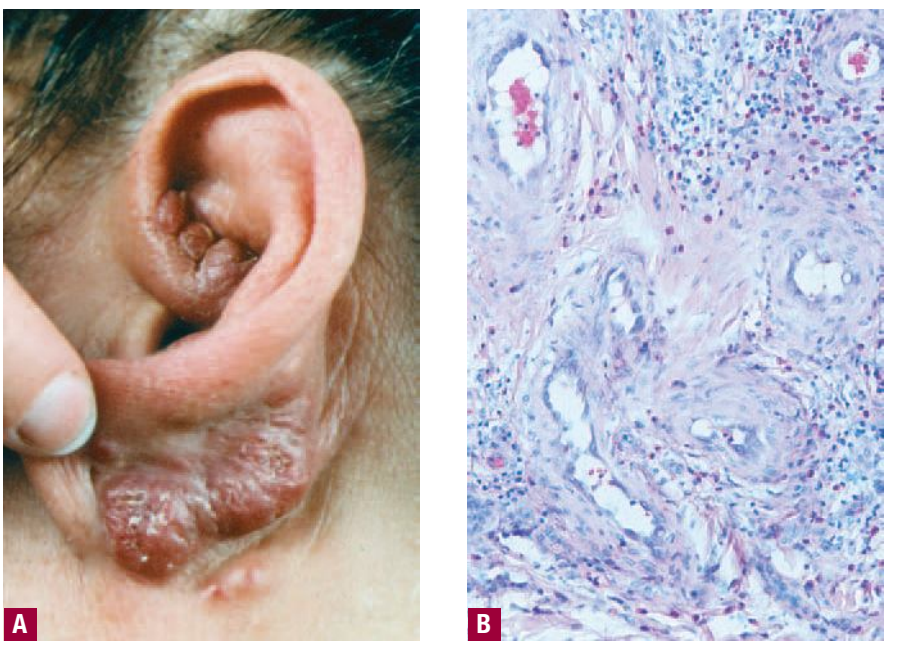
KIMURA DISEASE AND ANGIOLYMPHOID HYPERPLASIA WITH EOSINOPHILIA

Epidemiology

The skin lesions of Kimura disease and angiolymphoid hyperplasia with eosinophilia (AHLE) most commonly affect young to middle-aged adults. Kimura disease is more common in Asian men, whereas AHLE is more common in women.[42,43]

Etiology and Pathogenesis

It is possible that Kimura disease represents a florid, subcutaneously deep-seated form of the same basic pathogenetic process that gives rise to classic dermal CLH. There is controversy regarding whether Kimura disease and ALHE are variants of the same disorder, although most favor the concept that they are distinct clinicopathologic entities despite some clinicopathologic overlap.[44–46] The terms *epithelioid hemangioma* and *pseudopyogenic granuloma* have been used as synonyms for ALHE. Some regard ALHE essentially as a malformation of blood vessels caused by an underlying arteriovenous shunt. They consider the CLH-like aspects of the lesional infiltrate to be a secondary feature. Those who believe that ALHE should be classified as a separate disorder argue that, compared with the lesions of Kimura disease, ALHE lesions tend to be smaller (Fig. 147-11) and more superficial (centered in the dermis rather than the subcutis) and exhibit a more prominent vascular hyperplasia, characterized by small blood vessels lined by plump endothelial cells with abundant cytoplasm and sometimes atypical nuclei (see Fig. 147-11). In addition, there is often evidence of arteriovenous anastomoses, the lymphoid infiltrate is less extensive, secondary lymphoid follicles are present in only a minority of cases, and lymphadenopathy is usually absent. Patients with both AHLE and Kimura disease have been shown to harbor dominant clonal T-cell populations in some cases.



▲ **FIGURE 147-11** Angiolymphoid hyperplasia with eosinophilia. **A.** Clinically there are soft, confluent papular lesions typically located in the auricular region. **B.** Histologically blood vessels are lined by plump endothelial cells protruding into the lumen; there is vascular hyperplasia with thickened vascular walls, lymphocytic infiltrates, and prominent eosinophilia.

Clinical Findings

Kimura disease presents as solitary or multiple nodules up to 10 cm in diameter centered in the subcutis, most commonly involving the head and neck.[44–46] Peripheral eosinophilia and regional lymphadenopathy are characteristic. AHLE tends to present with multiple smaller, more superficial intradermal papulonodules that are typically unilateral. Salivary glands, lymph nodes, and other cutaneous sites can also be affected in either disorder, although such locations are more typical of Kimura disease.

Histopathologically, the dermis and/or subcutis exhibit hyperplasia of small blood vessels lined by plump endothelial cells similar to those present in the high endothelial venules of lymphoid tissues. These venules are a major point of lymphocyte trafficking between the blood and the paracortical T-cell domain of lymph nodes. Surrounding these hyperplastic vessels is a dense infiltrate composed of small lymphocytes, plasma cells, histiocytes, and eosinophils. The latter are typically prominent but may be absent in some cases. There are usually multiple secondary lymphoid follicles with prominent germinal centers, particularly in the subcutaneous lesions. In general, lesions are more superficial and the vascular features are more prominent in AHLE, whereas lesions are deeper and the lymphoid features are more prominent in Kimura disease.[42,43,47]

Differential Diagnosis

Kimura disease, which generally forms deeper, larger lesions, needs to be distinguished from CBCL, sinus histiocytosis with massive lymphadenopathy, soft tissue tumors, and subcutaneous deposits of metastatic carcinoma (Box 147-3). AHLE, which has smaller, more superficial lesions, should be differentiated from CLH, CBCL, hemangioma, angiosarcoma, pyogenic granuloma, nodular Kaposi sarcoma, bacillary angiomatosis, and bartonellosis. Many of these entities have distinctive histopathologic features. The distinguishing features of CLH and CBCL have been discussed earlier (see Differential Diagnosis under Cutaneous Lymphoid Hyperplasia).

Complications

Kimura disease has been associated with lichen amyloidosis and renal disorders such as nephrotic syndrome.[48]

Box 147-3

Differential Diagnosis of Kimura Disease and Angiolymphoid Hyperplasia (AHLE)

Most Likely

- Cutaneous lymphoid hyperplasia (both)
- Sinus histiocytosis with massive lymphadenopathy (both)
- Pyogenic granuloma (AHLE)
- Hemangioma (AHLE)

Consider

- Soft tissue tumors (both)
- Angiosarcoma (AHLE)
- Kaposi sarcoma (AHLE)
- Bacillary angiomatosis (AHLE)
- Bartonellosis (AHLE)

Always Rule Out

- Cutaneous B-cell lymphoma and other lymphomas (both)
- Metastatic carcinoma (both)

Prognosis and Clinical Course

Some cases, such as those associated with dominant T-cell clonality, have exhibited a chronic clinical course marked by multiple recurrences and resistance to treatment.

Treatment

The treatment of Kimura disease and AHLE is not well established because of the rarity of the disorders. Many approaches have been tried in only a limited number of cases. The most common and distinctive therapies are listed in Box 147-4. Topical treatments are used mainly for AHLE. Local radiation therapy has been reported to be superior to surgery and corticosteroids for treatment of Kimura disease.[43,48–50]

Box 147-4

Treatment of Kimura Disease and Angiolymphoid Hyperplasia (AHLE)

FIRST LINE

- Excision
- Topical corticosteroids (high potency twice daily)
- Intralesional corticosteroids (5–40 mg/mL, 1 mL monthly)

SECOND LINE

- Topical tacrolimus ointment (twice daily)
- Systemic corticosteroids (60/40/20 mg PO taper, 5 days each)
- Cyclosporine [microemulsion (Neoral) 2.5–4 mg/kg/day total dose divided into twice daily PO doses; use the minimum]
- Local radiation therapy
- Vinblastine (15 mg/wk IV; one report of extensive AHLE lesions treated successfully)

CASTLEMAN DISEASE

Epidemiology

Castleman disease is also known as *angiofollicular lymphoid hyperplasia* or *giant lymph node hyperplasia*.[51–54] The hyaline vascular variant is more common in younger patients, whereas the plasma cell variant tends to occur in older individuals.

Etiology and Pathogenesis

Castleman disease is a polyclonal lymphoproliferative disorder of undetermined etiology. Studies of multicentric Castleman disease demonstrate increased levels of lesional and circulating interleukins 1β and 6, which suggests that cytokine abnormalities may mediate the systemic manifestations of POEMS syndrome (*p*olyneuropathy, *o*rganomegaly, *e*ndocrinopathy, *M* protein, and *s*kin changes).[55,56] Castleman disease occurring in the setting of human immunodeficiency virus infection is associated with human herpesvirus type 8,[57,58] which has also been detected in Kaposi sarcoma (see Chap. 128) and primary effusion lymphomas.

Clinical Findings

CUTANEOUS LESIONS Castleman disease most often presents as an isolated mediastinal mass, although a multicentric form of the disease also exists. Lesions can be nodal and/or extra-nodal. Rarely, it may present as solitary or multiple, subcutaneous or cutaneous tumors in various locations.

RELATED PHYSICAL FINDINGS The plasma cell variant can be associated with polyneuropathy, organomegaly, endocrinopathy, the presence of M protein, hyperpigmentation, and hypertrichosis (POEMS syndrome).[55,59]

Laboratory Tests

Three histopathologic variants of Castleman disease exist. The more common hyaline vascular variant exhibits small, concentrically whorled, lymphoid follicles surrounded by small lymphocytes arranged in a concentric, onion-skin pattern. An extensive proliferation of capillaries is present between folli-

cles. The rarer plasma cell variant exhibits large, hyperplastic secondary lymphoid follicles associated with a highly vascular interfollicular zone rich in plasma cells. An intermediate form has also been reported.

Differential Diagnosis

The differential diagnosis of cutaneous and subcutaneous Castleman disease includes eosinophil-poor ALHE, Kimura disease, plasmacytoma, myeloma, sinus histiocytosis with massive lymphadenopathy, CLH, angioimmunoblastic T-cell lymphoma, and follicular types of CBCL (Box 147-5). All of these diseases lack the characteristic features of the lymphoid follicles seen in the two histopathologic variants of Castleman disease. These disorders also lack prominent vascular hyperplasia except for ALHE and Kimura disease, whose characteristic endothelial cells aid in their recognition, and angioimmunoblastic T-cell lymphoma, which contains large clonal atypical T cells. Plasmacytoma and myeloma contain dense sheets of atypical plasma cells and differ in their associated clinical findings. CLH is usually centered in the dermis rather than the subcutis. Most cutaneous lymphomas have a diffuse, monomorphous appearance. The rare follicular types of CBCL have distinctive features, as summarized earlier in Differential Diagnosis under Cutaneous Lymphoid Hyperplasia. Sinus histiocytosis with massive lymphadenopathy is rich in S100$^+$ histiocytes that exhibit emperipolesis (intact lymphocytes within their cytoplasm).

Complications

Castleman disease has been associated with paraneoplastic pemphigus, plane xanthomas, vasculitis, and peliosis hepatis.[60,61] Lymphomas and follicular dendritic cell sarcomas can develop in the setting of Castleman disease.

Prognosis and Clinical Course

The clinical course is usually favorable for patients with localized and extranodal lesions.

Treatment

Surgical excision is effective therapy for localized Castleman disease. Radiation and chemotherapy have been used to treat multicentric variants (Box 147-6).[62,63]

Box 147-5

Differential Diagnosis of Castleman Disease

Most Likely
- Cutaneous lymphoid hyperplasia

Consider
- Angiolymphoid hyperplasia with eosinophilia
- Kimura disease
- Plasmacytoma
- Sinus histiocytosis with massive lymphadenopathy

Always Rule Out
- Cutaneous B-cell lymphoma
- Myeloma
- Non–mycosis fungoides cutaneous T-cell lymphoma

Box 147-6

Treatment of Castleman Disease

FIRST LINE
- Excision

SECOND LINE
- Radiation therapy
- Chemotherapy

PSEUDO–MYCOSIS FUNGOIDES

Epidemiology

Eruptions mimicking mycosis fungoides occur typically in adults. Both genders can be affected.

Etiology and Pathogenesis

Pseudo–T-cell lymphomas with a band-like or mycosis fungoides–like histopathologic pattern may arise spontaneously or may occur as a T-cell infiltrate co-existing with B-cell chronic lymphocytic leukemia, as a rare variant of the eruption of lymphocyte recovery (which occurs in the setting of leukocyte reconstitution after iatrogenic marrow aplasia), or in association with ingestion of various drugs, including hydantoins, carbamazepine, propylvalerate, imatinib mesylate, and dexchlorpheniramine maleate and other antihistamines.[1–3,9,44,64,65]

Clinical Findings

HISTORY There may be a history of an associated disease or medication. Lesions may be pruritic or asymptomatic.

CUTANEOUS LESIONS The lesions present clinically as one or a few plaques on the trunk or extremities. Occasionally, several plaques or a Sézary-like syndrome develops.

Laboratory Tests

Histopathologically, there is a papillary dermal, band-like infiltrate containing mostly small and medium-sized atypical lymphocytes with clefted and cerebriform nuclei. Moderate numbers of histiocytes are admixed, but eosinophils and plasma cells are rare. The dermal-epidermal junction is obscured, and there is no grenz zone. The overlying epidermis may be hyperplastic and/or may contain a sparse to moderate atypical lymphoid infiltrate; however, compared with mycosis fungoides, epidermotropism is typically far less prominent and Pautrier's microabscess–like cell aggregates are rare. Most cases contain polyclonal T cells, although occasional cases exhibit dominant T-cell clonality.[64,66]

Differential Diagnosis

The differentiation of these pseudolymphomas from mycosis fungoides is aided by their tendency toward minimal epidermotropism in many cases, the small number of lesions, their tendency to be polyclonal, and their resolution after discontinuation of an inducing drug and/or local therapy.

Lichenoid drug eruptions caused by agents such as gold, thiazides, and antimalarials may also bear a histopathologic resemblance to atrophic forms of large plaque parapsoriasis and overt mycosis fungoides when they result in a band-like dermal lymphoid infiltrate that involves an atrophic epidermis. As in mycosis fungoides, eosinophils and plasma cells may also be present. However, these lesions lack lymphoid atypia, exhibit the clinical features of typical lichenoid drug rashes, and regress eventually after discontinuation of the causative agent. Poikilodermatous skin lesions of collagen vascular diseases and genodermatoses are distinguished from mycosis fungoides by their associated clinical and laboratory findings; by sparser infiltrates lacking atypia; and, for collagen vascular diseases, by dermal mucin, thickened epidermal basement membranes, and characteristic epidermal alterations. Chronic radiodermatitis may resemble poikilodermatous mycosis fungoides clinically but is distinguished by clinical history, sparse infiltrate, keratinocyte atypia, dermal fibrosis, and loss of adnexa.

Some cases of secondary syphilis may also mimic mycosis fungoides, showing a dense, band-like, upper dermal infiltrate that obscures the dermal-epidermal junction and invades a nonspongiotic epidermis. However, the infiltrate contains more plasma cells and fewer lymphocytes than expected in mycosis fungoides; there is no lymphoid atypia; there may be neutrophils in the epidermis; and there is a deep perivascular extension of the infiltrate that is unusual in mycosis fungoides except in the tumor phase. Furthermore, the patient's history, the clinical appearance of the lesions, serologic testing, and response to antibiotic therapy will facilitate the correct diagnosis (Box 147-7).

Three other disorders that may mimic mycosis fungoides/Sézary syndrome clinically and/or pathologically are follicular mucinosis, lymphomatoid contact dermatitis, and actinic reticuloid. Because of their distinctive features, each is discussed separately in this text.

Complications

Severe pseudo–mycosis fungoides eruptions such as erythrodermas may be associated with serious complications common to other forms of generalized exfoliative dermatitis, including local skin infection, sepsis, disrupted barrier function, and cardiovascular imbalance.

Box 147-7

Differential Diagnosis of Pseudo–Mycosis Fungoides

Most Likely
- Lichenoid drug eruption
- Psoriasis
- Tinea corporis

Consider
- Dermatomyositis
- Subacute cutaneous lupus erythematosus
- Pityriasis rubra pilaris
- Secondary syphilis
- Chronic radiodermatitis
- Genodermatoses with poikiloderma
- Alopecia mucinosa
- Actinic reticuloid
- Non–cutaneous T-cell lymphoma erythrodermas

Always Rule Out
- Mycosis fungoides
- Large plaque parapsoriasis
- Associated drug ingestion
- Associated iatrogenic marrow aplasia
- Associated B-cell chronic lymphocytic leukemia

Box 147-8

Treatment of Pseudo–Mycosis Fungoides

FIRST LINE
- Drug discontinuation (when drug induced)
- Treatment of underlying disorder (when associated with a specific disease)
- Topical corticosteroids
- Ultraviolet B and narrowband ultraviolet B phototherapy
- Psoralen plus ultraviolet A phototherapy

SECOND LINE
- Systemic corticosteroids (60/40/20 mg PO taper, 5 days each)

Prognosis and Clinical Course

Prognosis depends heavily on the clinical context and the ability to remedy the underlying cause of the pseudo–mycosis fungoides lesions. If this can be accomplished, then the lesions generally regress, although lichenoid infiltrates may require many months to resolve.

Treatment

When the disorder is drug induced, identification and withdrawal of the offending agent is the principal therapy (Box 147-8). Corticosteroids (topical or systemic) and various forms of phototherapy may also be beneficial in hastening the resolution of skin lesions. Excision can be effective for isolated or sparse lesions. When pseudo–mycosis fungoides is associated with a specific disease, treatment should be directed at that underlying disorder.

Prevention

Strategies for prevention are similar to those described for treatment.

LYMPHOMATOID CONTACT DERMATITIS

Epidemiology

Lymphomatoid contact dermatitis has been observed in adults of both genders.

Etiology and Pathogenesis

Lymphomatoid contact dermatitis was described originally in four patients with persistent allergic contact dermatitis proven by patch testing.[67] Responsible allergens include gold, nickel, and para-phenylenediamine.[68–72] The clinical and histopathologic changes in the lesions are said to resemble those of mycosis fungoides.

Clinical Findings

HISTORY Skin lesions are generally pruritic. Patients may be aware of the offending contact allergen.

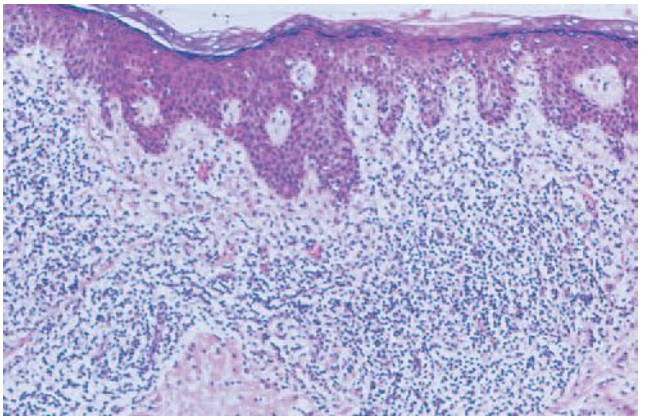
CUTANEOUS LESIONS Clinically, lymphomatoid contact dermatitis is characterized by generalized red, scaly papules and plaques that may become confluent (Fig. 147-12) with resultant exfoliative erythroderma.

Laboratory Tests

Results of patch tests for a variety of common allergens, such as ethylenediamine dihydrochloride, may be positive.

Histopathologically, lymphomatoid contact dermatitis exhibits a superficial lymphocytic dermatitis that contains foci of spongiosis simulating the appearance of cutaneous T-cell lymphomas. It must be differentiated from mycosis fungoides (Fig. 147-13), usually on the basis of changes within the epidermis;

▲ **FIGURE 147-12** Lymphomatoid contact dermatitis. Erythematous papules and plaques on the forehead. Patch test with local anesthetics gave positive results.



▲ **FIGURE 147-13** Lymphomatoid contact dermatitis. Dense band-like infiltrate in the upper part of the dermis and spongiotic foci in the epidermis ("spongiotic simulator" of mycosis fungoides).

specifically, in mycosis fungoides more atypical lymphocytes have a tendency to form Pautrier's microabscesses. Frequently there is edema in the papillary dermis in lymphomatoid contact dermatitis, a finding that is usually absent in mycosis fungoides. Immunohistopathologic investigations indicate that lymphomatoid contact dermatitis represents a T-cell pseudolymphoma. Examination of the cells in the infiltrate by electron microscopy reveals many atypical lymphocytes with cerebriform nuclei like those in mycosis fungoides.

Differential Diagnosis

Concern for mycosis fungoides is based mainly on the histopathologic features of the lesions. Recognition of the contact allergen is central to the correct diagnosis, aided by the microscopic distinctions noted in the preceding section. Other causes of spongiotic dermatitis and, in severe cases, erythroderma should also be considered (Box 147-9).

Box 147-9

Differential Diagnosis of Lymphomatoid Contact Dermatitis

Most Likely
- Conventional allergic contact dermatitis
- Irritant contact dermatitis

Consider
- Drug eruption
- Psoriasis
- Tinea corporis
- Non–cutaneous T-cell lymphoma erythrodermas (when extensive)

Always Rule Out
- Mycosis fungoides and Sézary syndrome
- Large plaque parapsoriasis

Complications

Although in rare cases lymphomatoid contact dermatitis has been reported to evolve into lymphoma, it is more likely that those patients had lymphoma from the outset.

Prognosis and Clinical Course

Avoidance of the responsible allergens leads to eventual resolution of the condition.

Treatment

A thorough search for the offending antigen by way of patch testing is necessary if the process of lymphomatoid contact dermatitis is to be interrupted. Topical application of glucocorticoids is beneficial (Box 147-10).

Prevention

The only relevant preventive measure for lymphomatoid contact dermatitis is avoidance of known causes.[67,73–77]

LYMPHOCYTIC INFILTRATION OF THE SKIN

Epidemiology

The vast majority of cases of lymphocytic infiltration of the skin (LIS) occur in middle-aged adults, with a roughly equal gender ratio. Children have been affected rarely. There is also a rare familial variant.[78]

Etiology and Pathogenesis

The etiology of LIS is unknown. Some regard it as a distinct disease, whereas others consider it to be a variant of lupus erythematosus or, less commonly, polymorphous light eruption, CLH, or lymphocytic lymphoma. Photo-exacerbation occurs in a minority of patients according to some observers. Immunologic investigations have shown decreased natural killer cell function as well as elevation in circulating immune complexes, the levels of which were reported to parallel disease activity.[79] Skin lesions known as *arcuate dermal erythema* may arise in female carriers of chronic granulomatous disease. These lesions resemble LIS clinically and microscopically.

Box 147-10

Treatment of Lymphomatoid Contact Dermatitis

FIRST LINE
- Elimination of responsible allergen
- Topical corticosteroids

SECOND LINE
- Topical tacrolimus or pimecrolimus

Clinical Findings

HISTORY Skin lesions are typically asymptomatic.

CUTANEOUS LESIONS LIS, which was first described by Jessner and Kanof,[80] presents as one or more erythematous plaques or nodules, generally localized to only one or a few sites on the face, neck, upper trunk, or arms.[81,82] Pustules, pruritus, and epidermal alterations are absent. In contrast to discoid lupus lesions, LIS lesions show no epidermal atrophy or follicular plugging.

Laboratory Tests

Histopathologic examination reveals a superficial and deep, perivascular and variably periadnexal infiltrate of small mature lymphocytes, often with a minor admixture of histiocytes, plasmacytoid monocytes, and plasma cells. Lymphoid follicles and eosinophils are absent. The epidermis is unremarkable. Results of direct immunofluorescence studies are negative or non-specific. Immunohistologic studies have demonstrated a predominantly HLA–DR$^-$ Leu-8$^+$ T-cell infiltrate with some B cells and histiocytes admixed. In contrast, most of the T cells in discoid lupus are HLA-DR$^+$ Leu-8$^-$.[83–85] Immunopathologic studies have shown a predominance of CD8$^+$ T cells within lesional infiltrates.

Box 147-11

Differential Diagnosis of Lymphocytic Infiltration of the Skin

Most Likely

- Chronic cutaneous lupus erythematosus
- Cutaneous lymphoid hyperplasia
- Polymorphous light eruption

Consider

- Granuloma faciale
- Infectious and inflammatory granulomas
- Erythema chronicum migrans
- Other deep figurate erythemas
- Reticular erythematous mucinosis

Always Rule Out

- Cutaneous B-cell lymphoma
- Leukemia cutis (especially B-cell chronic lymphocytic leukemia)

Box 147-12

Treatment of Lymphocytic Infiltration of the Skin

FIRST LINE

- Topical corticosteroids
- Topical tacrolimus and pimecrolimus
- Photoprotection (if historically relevant)
- Intralesional corticosteroids (5–40 mg/mL, 1 mL monthly)

SECOND LINE

- Hydroxychloroquine (100–200 mg PO twice daily)
- Systemic corticosteroids (60/40/20 mg PO daily taper, 5 days each; if effective, then as needed)
- Auranofin (3 mg PO twice daily)
- Acitretin (25–50 mg PO daily)
- Thalidomide (100 mg PO daily)

Initial studies indicate that the infiltrate lacks dominant clonality.[1,86,87]

Differential Diagnosis

The differential diagnosis of LIS includes chronic cutaneous lupus erythematosus, polymorphous light eruption, CLH, lymphocytic lymphoma and leukemia, deep figurate erythemas such as erythema chronicum migrans, granuloma faciale, and reticular erythematous mucinosis (Box 147-11). Discoid lupus generally exhibits epidermal changes, an interface inflammatory component, and a lupus band on direct immunofluorescence. The tumid variant of discoid lupus is typified by abundant dermal mucin and subtle alterations at the dermal-epidermal interface. These changes are not seen in LIS. Antinuclear antibody panel results and erythrocyte sedimentation rate are also normal. Polymorphous light eruption exhibits papillary dermal edema, which is absent in LIS. CLH contains nodular or diffuse, dermal lymphoid infiltrates that are much denser than the predominantly perivascular infiltrate of LIS. Furthermore, LIS lacks reactive B-cell follicles. Well-differentiated or small lymphocytic lymphoma/leukemia is usually a monoclonal B-cell process, and there is a peripheral lymphocytosis in the leukemic form of the disease. These findings are absent in LIS. In erythema chronicum migrans and some cases of CLH there is serologic evidence of active infection with *B. burgdorferi*, whereas this is rarely seen in LIS. Granuloma faciale is rich in neutrophils and eosinophils that are not features of LIS. Reticulated erythematous mucinosis has a reticulated clinical appearance, favors the trunk rather than the head and neck, and shows bipolar fibroblasts. These are not features of LIS.

Complications

Post-inflammatory pigmentary alterations and corticosteroid-associated skin atrophy may complicate the clinical course of LIS, especially in cosmetically sensitive locations.

Prognosis and Clinical Course

LIS has a chronic course and may show periods of spontaneous remission and eventual resolution. Lesions may recur at their original sites or elsewhere.

Treatment

LIS may respond favorably to topical or intralesional glucocorticoids, calcineurin inhibitors, antimalarials, or thalidomide; however, a persistent, indurated variant has been described that may require systemic glucocorticoid therapy to achieve remission[88] (Box 147-12).

Prevention

Photoprotection may be helpful in those cases with a history of photoexacerbation.

CHAPTER 148

Langerhans Cell Histiocytosis

Ruggero Caputo
Carlo Gelmetti

EPIDEMIOLOGY

The prevalence of Langerhans cell histiocytosis (LCH) is internationally estimated to be from 4.0 to 5.4 per million population; however, because internal and skin lesions may not be diagnosed as LCH, this may be an underestimation. In children, the annual incidence is estimated at 0.5 per 100,000 children in the United States and at 0.5 per million worldwide. The male-female ratio is 2:1. The disease can occur in individuals of any age and can also be congenital but is more common in children aged 1 to 3 years.[1]

ETIOLOGY AND PATHOGENESIS

The pathogenesis of LCH remains a mystery despite numerous investigative efforts. In addition to genetic factors, infectious agents (especially viruses), and cellular and immune system dysfunction, including abnormalities of lymphocytes and cytokines (interleukin 1α, interleukin 10), cellular adhesion molecules, and a combination of these, have been implicated.[2] The role of genetics is not well defined. Although LCH has been reported in both monozygotic and dizygotic twins, the relative rarity of the familial occurrence does not favor a significant hereditary influence.[3]

The reactive versus neoplastic nature of LCH cells is also debated.[4] Although clonality has been demonstrated in all forms of LCH, this does not mean that the process is histologically and biologically malignant. The following features substantiate the reactive hypothesis: (1) LCH cells are highly differentiated, (2) histologically the granulomatous lesions resemble those seen in infections or foreign-body reactions, and (3) lesions may spontaneously regress. These pathogenic steps have been suggested: (1) viruses induce activation of histiocytes, (2) immunologic mechanisms produce the pathologic Langerhans cell phenotype, and (3) a cytokine-mediated storm results in LCH lesions. Many viruses (human herpesvirus 6, cytomegalovirus, adenovirus, and parvovirus) are suspected to play an etiologic role, but none has been proved to be responsible for the disease.

In contrast, the following observations support a clonal neoplastic origin of LCH: (1) bone marrow derivation and clonality of LCH cells, (2) the existence of familial cases of LCH, (3) findings of chromosomal instability with an abnormality on chromosome 7 and of p53 protein in LCH, and (4) co-occurence of LCH and a myelodysplastic marrow. Two possible explanations have been proposed for the association between LCH and myelodysplasia. The first is that the marrow dysplastic features are secondary to the infiltration of the marrow by LCH cells induced by cytokines and do not represent elements of a true myelodysplastic syndrome. A second possibility is that the abnormal marrow cells are related to the clonal LCH cells and are part of the disease process; that is, myelodysplastic cells could be arising from the same clonal cell [an anomalous pluripotent dendritic (stem) cell line]. This possibility raises the issue of whether LCH could be considered a "myeloid dendritic stem cell disorder."[5] These findings also suggest a genetic predisposition in LCH and stimulate the search for potential candidate genes in LCH. Fig. 148-1 illustrates the histiocyte developmental pathway according to Weitzman and Jaffe.[6]

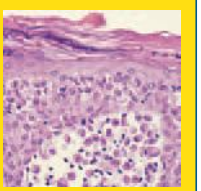
CLINICAL FINDINGS

Classification

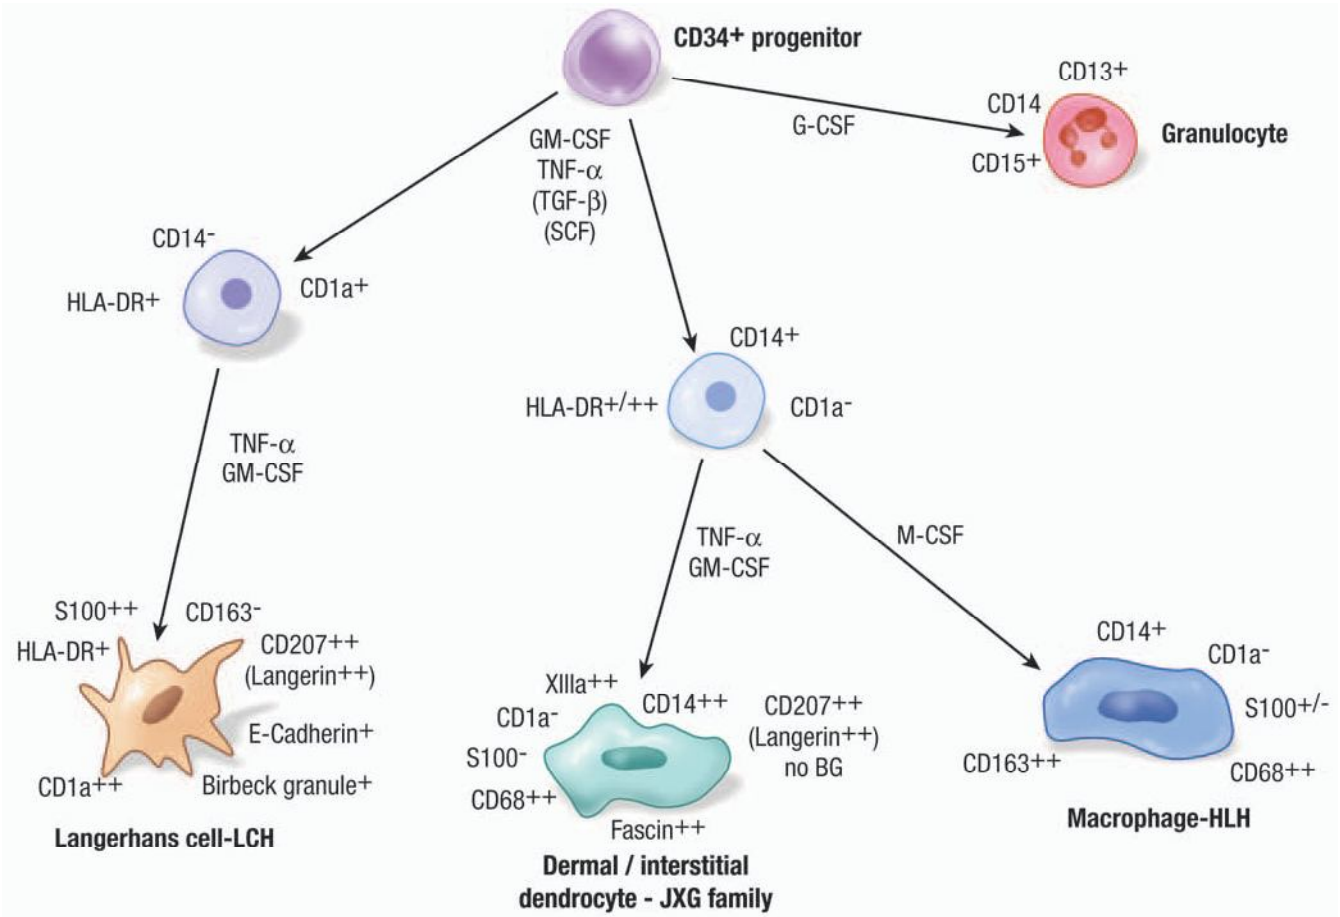
LCH is a disorder with a broad spectrum of forms: it can be local, asymptomatic with an indolent course, limited to an isolated bone lesion, or systemic and aggressive involving multiple organs and producing significant symptoms. Thus, the clinical manifestations depend on the site of the lesions and the systems involved.[7] Historically, LCH has been described under various names: Letterer-Siwe disease (LSD) is the prototype of the acute, disseminated, multisystemic form that usually appears in infants or newborns. Its course, if the disease is untreated, is fatal; Hand-Schüller-Christian disease (HSC) is the chronic, progressive, multifocal form, commonly beginning in childhood; eosinophilic granuloma (EG) is the localized, benign form; and Hashimoto-Pritzker disease (HPD) represents the benign, self-healing variant of LCH, usually present at birth or during the first few days of life. The classification system for histiocytosis defined by the Histiocyte Society is shown in Table 148-1. At present it seems realistic to describe LCH as a continuum as in Fig. 148-2, because every patient is unique with regard to the type, number, and location of lesions.

Although the historical terminology can be maintained for didactic purposes, it is more important to distinguish the forms with systemic involvement that require systemic management (multisystemic diseases or extensive LCH) from those with localized lesions that can be treated with a topical medication or observational approach (single-sys-

LANGERHANS CELL HISTIOCYTOSIS AT A GLANCE



- A group of rare disorders that are considered reactive but have a broad spectrum of severity.
- The reactive versus neoplastic nature of the disease is debated. A clonal origin for the cells of Langerhans cell histiocytosis (LCH) in genetically predisposed patients is the most probable hypothesis.
- Histopathologic features consist of a dense infiltrate of histiocytes with a strong epidermotropism. The unifying element is the typical "LCH cell"—a histiocyte with an irregular vesiculated, often reniform nucleus and an abundant, slightly eosinophilic cytoplasm. These cells test positive for S100 protein, CD1a, and CD207 and contain cytoplasmic Langerhans granules.
- Cutaneous lesions vary from papules to vesicles, pustules, nodules, and ulcers. The course is also variable, with disease ranging from localized self-healing forms to generalized and fatal cases. The most common sites of involvement are the head, trunk, and skinfolds. Mucosal lesions are usually ulcerated nodules involving mainly gingival and genital regions.
- Associated manifestations include diabetes insipidus and exophthalmos. Systemic lesions may affect bones, lungs, bone marrow, liver, spleen, and lymph nodes. Aggressive forms may be treated successfully with vinblastine and other drugs.



▲ **FIGURE 148-1** Schematic representation of histiocyte developmental pathway. BG = Birbeck granule; G-CSF = granulocyte colony-stimulating factor; GM-CSF = granulocyte-macrophage colony-stimulating factor; HLA = human leukocyte antigen; HLH = haemophagocytic lymphohistiocytosis; JXG = juvenile xanthogranuloma; LCH = Langerhans cell histiocytosis; M-CSF = macrophage colony-stimulating factor; SCF = stem cell factor; TGF-β = transforming growth factor-β; TNF-α = tumor necrosis factor-α. (Modified from Weitzman S, Jaffe R: Uncommon histiocytic disorders: The non–Langerhans cell histiocytoses. *Pediatr Blood Cancer* **45**:256, 2005.)

tem diseases or restricted LCH) or that are self-healing (Fig. 148-3).

History

The Writing Group of the Histiocyte Society proposed a guideline identifying confidence levels for the diagnosis of class I histiocytosis (LCH). These criteria were as follows: (1) presumptive diagnosis—light morphologic characteristics; (2) designated diagnosis—light morphologic features plus two or more supplemental positive results to stains for adenosine triphosphatase, S100 protein, α-D-mannosidase, and peanut lectin; (3) definitive diagnosis—light morphologic characteristics plus Birbeck granules in the lesional cell visible with electron microscopy and/or positive results on staining for CD1a antigen on the lesional cell[8] (Table 148-2).

Current immunostaining techniques allow the definitive diagnosis of LCH from just paraffin-embedded tissue, which avoids the need for sophisticated and expensive methods such as electron microscopy (see Table 148-2). Because the location and diffusion of the lesions have a significant influence on the course of the disease and its prognosis, various classification schemes assign scores for each organ and system involved. The former classification of LCH into three disease categories (i.e., EG, HSC, LSD) is no longer used. The present system attempts to evaluate the extent of involvement and its relationship to prognosis (Table 148-3).

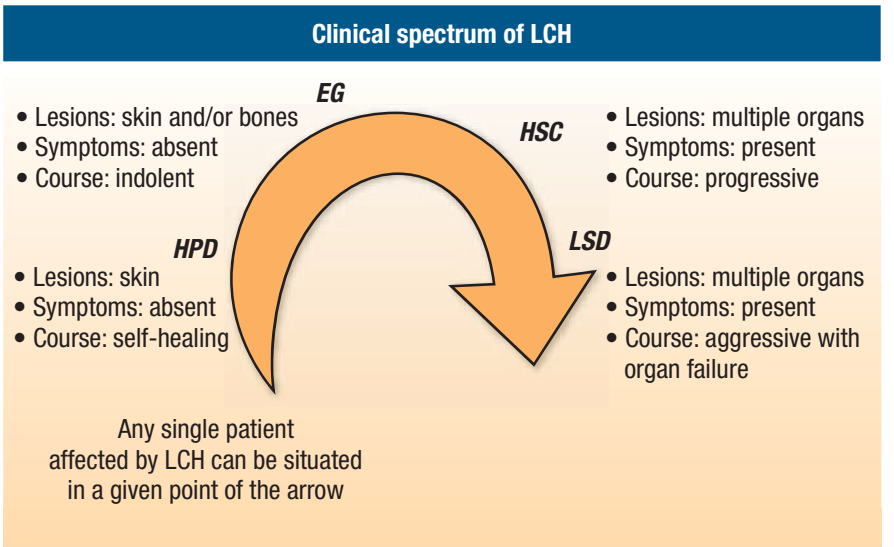
TABLE 148-1
Classification System for Histiocytosis Developed by the Histiocyte Society (1987 and 2004)

Class I: Langerhans cell histiocytosis
Class II: Histiocytosis of the mononuclear phagocyte system or non–Langerhans cell histiocytosis (see Chap. 149)
- IIa: Histiocytosis involving dermal CD68+ and factor XIII+ dendrocytes (histiocytosis involving cells of dermal dendrocyte lineage)
- IIb: Histiocytosis involving cells other than Langerhans cells and cells of the dermal dendrocyte lineage

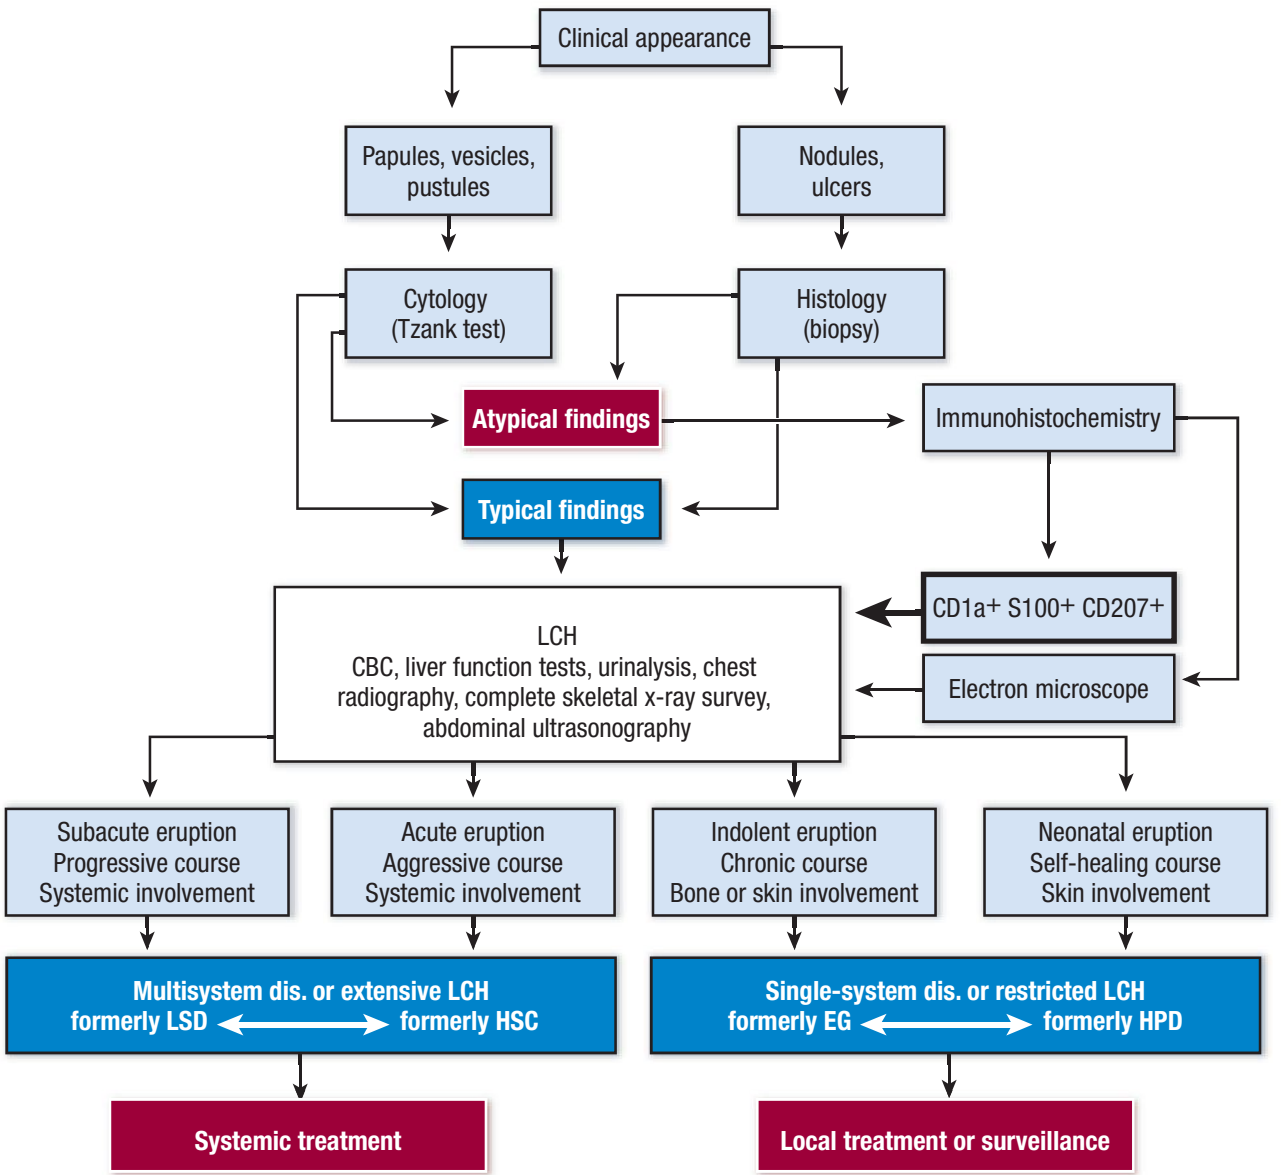
Class III: Malignant histiocytosis

Cutaneous Lesions

Cutaneous manifestations are very common in LCH and may represent the earliest sign of the disease.[9] The typical lesion is a small translucent papule, 1 to 2 mm in diameter, slightly raised, rose-yellow (Fig. 148-4A and B), and usually located on the trunk (see Fig. 148-4A and B) and scalp. The lesions frequently show scaling (see Fig. 148-4A) and may become crusted and ulcerate (see Fig. 148-4B and C). Vesicles and pustules may occur, simulating eczema, miliaria, scabies, and varicella. This is an especially common presentation during the neonatal period (first month of life). The presence of purpura is a poor prognostic sign. Although in LSD and HSC early le-



◀ **FIGURE 148-2** Clinical spectrum of Langerhans cell histiocytosis (LCH). All patients with LCH fit along this continuum. EG = eosinophilic granuloma; HPD = Hashimoto-Pritzker disease; HSC = Hand-Schüller-Christian disease; LSD = Letterer-Siwe disease.



▲ **FIGURE 148-3** Approach to the patient with Langerhans cell histiocytosis (LCH). CBC = complete blood cell count; dis. = disease; EG = eosinophilic granuloma; HPD = Hashimoto-Pritzker disease; HSC = Hand-Schüller-Christian disease; LSD = Letterer-Siwe disease.

sions are similar, HPD has traditionally been characterized by the eruption of multiple or solitary elevated, firm, red-brown nodules (Fig. 148-5A) or flesh-red lesions similar to infantile angiomas; late papulonodular lesions may show elevated borders and ulcerate easily. These lesions can grow in size and number in the first few weeks of life, and some may become quite large. They then form brown crusts, which are shed and occasionally leave whitish atrophic scars after spontaneous resolution. Since the original description of the papulonodular lesions of HPD, it is clear that small reddish brown crusted papules that may resemble chickenpox are a common manifestation of "self-healing Langerhans cell histocytosis," with spontaneous clearance by 2 to 3 months of age (see Fig. 148-5B).[10]

Cutaneous lesions appear more (LSD) or less (HSC) rapidly in successive crops. The lesions tend to merge on the scalp, mimicking seborrheic dermatitis or folliculitis, and leading to alopecia, and on the folds (retroauricular, axillary, and genital), mimicking intertrigo. Occasionally, the lesions merge into plaques on the medial aspect of the chest (Fig. 148-6), the mid-back, and temporoparietal regions, and may become xanthomatous.

Mucous membrane lesions are commonly noduloulcerative and mainly involve the perioral area and gingiva (Fig. 148-7) and, especially in EG, the perigenital or perianal regions (Fig. 148-8). Although the absence of mucous membrane lesions is a key feature of HPD, oral manifestations may be the first sign of LCH: non-specific pain, aphthae, gingival bleeding, candidiasis, ulceration with loosening of the teeth, and premature eruption of the teeth can be observed.

Nail changes include fragile lamina, paronychia, subungual pustules, nail fold destruction, onycholysis, subungual hyperkeratosis, longitudinal grooving, and pigmented and purpuric striae of the nail bed (Fig. 148-9). These features are considered to be unfavorable prognostic signs. Cutaneous manifestations in elderly patients (Fig. 148-10) are similar to those seen in children.

TABLE 148-3
Classification of Langerhans Cell Histiocytosis (LCH) According to Extent of Disease

- Single-system disease or restricted LCH
  - Skin lesions without any other site of involvement
  - Monostotic lesion with or without diabetes insipidus, adjacent lymph node involvement, or rash
  - Polyostotic lesions involving several bones or more than two lesions in one bone, with or without diabetes insipidus, adjacent lymph node involvement, or rash
- Multisystem disease or extensive LCH
  - Visceral organ involvement with or without bone lesions, diabetes insipidus, adjacent lymph node involvement, and/or rash but without signs of organ dysfunction of the lungs, liver, or hematopoietic system
  - Visceral organ involvement with or without bone lesions, diabetes insipidus, adjacent lymph node involvement, and/or rash but with signs of organ dysfunction of the lungs, liver, or hematopoietic system

Related Physical Findings

Malaise, weight loss, failure to thrive, nausea, myalgia, arthralgia, and fever are frequently present in aggressive forms.

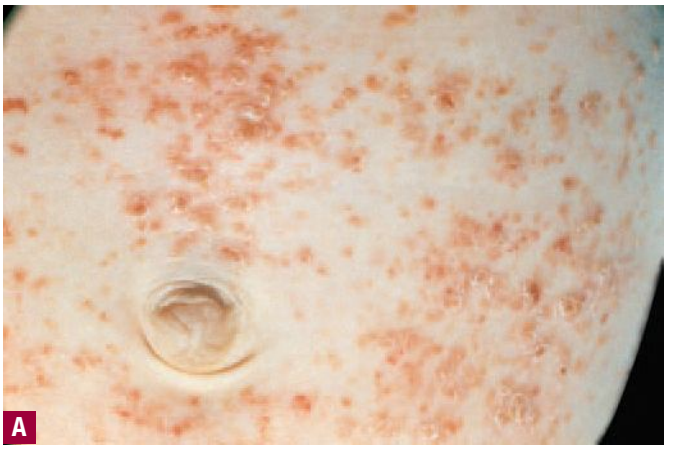
Bone lesions are the most frequent manifestations of LCH (80 percent of cases), and bone involvement alone is seen in 50 percent to 60 percent of cases.[11] The lesions preferentially involve the skull, especially in the temporoparietal region, where the infiltrates lead to limited osteolytic foci that merge to form typical "map" lesions (Fig. 148-11). Because osteolysis of the lower maxillary bones is also frequent, on x-ray images the teeth appear to be floating in the mouth. Mastoid involvement is common and often symptomatic. Bone involvement can be shown by computed tomography (CT) or gadolinium-enhanced magnetic resonance imaging (MRI) and can lead to organ dysfunction such as diabetes insipidus and growth retardation. Retro-ocular bone involvement is responsible for exophthalmos. In addition, flat bones, vertebral bones, and long bones can be involved. Osteolytic lesions, either asymptomatic or accompanied by pain and functional impairment, are generally multiple and appear gradually. At times, lesions may cause a significant periosteal reaction. Extension to the adjacent tissues (e.g., muscles) can produce symptoms, which may be unrelated to the bone involvement. The onset can be insidious, and the osseous lesion can be single and may go undetected until spontaneous fracture or destruction of an organ occurs. When the lesions become symptomatic, there is localized pain, tenderness, soft tissue swelling, deformation, fracture or medullar compression (vertebra plana), or premature tooth loss.

Bone marrow involvement, which is rare and generally occurs late in aggressive forms of LCH, is characterized by the presence of numerous histiocytic cells. When thrombocytopenia, leukopenia, and anemia occur, death is almost certain.

Conventional radiography and MRI can both be used in the diagnosis of bone LCH lesions, but MRI has an advantage in the detection of muscle involvement. In addition, isotopic bone scanning can be used for multiple lesions, and scintigraphy and fluorodeoxyglucose positron emission tomography can identify active osseous lesions. Isolated bone lesions, typically with bevelled margins and without sclerosis, have the best prognosis, whereas bone lesions with multisystem involvement predict a more problematic course.

Pulmonary involvement can be more easily detected in elderly patients and is quite frequent (12 percent to 23 percent of patients).[12] Pulmonary lesions may be asymptomatic but can also cause death. Functional signs consist of dyspnea, tachypnea with rib retraction, cough, cyanosis, and thoracic pain. Other signs include mediastinal compression and pneumothorax caused by bulla formation. In chest radiographs, the lungs may show a classic "honeycomb" appearance (Fig. 148-12) or a micronodular pattern. Pulmonary function tests may reveal restrictive lung disease with decreased pulmonary volume. The diagnosis of LCH can be made if more than 5 percent of the cells in specimens obtained by bronchoalveolar lavage are Langerhans cells as indicated by immunostaining or electron microscopic examination.

Involvement of the liver and spleen is quite frequent (15 percent to 50 percent of patients). Hepatic lesions may evolve to severe fibrosis, biliary cirrhosis, and liver failure. Hepatosplenomegaly, often due to portal infiltration by Langerhans cells or Kupffer cell hyperplasia, is never the initial sign of the disease but



▲ **FIGURE 148-4** Extensive Langerhans cell histiocytosis. **A.** Abdominal area of infant with multiple yellowish erythematous papules covered by scale or crust. **B.** Infant with multiple ulcerated skin lesions on the trunk. **C.** Severe disease with confluent erosive and crusted lesions forming ulcers; distension of the abdomen reflects hepatosplenomegaly.

▲ **FIGURE 148-6** Extensive Langerhans cell histiocytosis. The papuloscaling and papulocrusted lesions show a typical distribution on the trunk and the scalp. The involvement of the face in this patient is unusual.

is a frequent complication and is a prognostically unfavorable sign, particularly when accompanied by jaundice and ascites. Splenomegaly may increase the severity of thrombocytopenia.

Lymphadenopathy is rarely prominent but has been noted in 25 percent to 75 percent of fatal cases. Cervical lymph nodes are the most often affected. The nodes are only rarely symptomatic, but if massive, they may damage the surrounding structures. For example, enlargement of the nodes surrounding the respiratory tract may provoke cough, dyspnea, or cyanosis. Suppuration and chronic drainage can also occur.

Diabetes insipidus is present in more than 50 percent of cases and occurs more often in patients with involvement of the skull and the orbits. It should be evaluated by water deprivation testing and measurement of urinary levels of arginine vasopressin. Diabetes insipidus is easily controlled by vasopressin therapy.[13] Although diabetes insipidus is an obvious marker of skull invasion, it is not considered a prognostically unfavorable symptom. Growth retardation in children can be due to anterior pituitary involvement leading to growth hormone deficiency; however, it is more commonly caused by chemotherapy, systemic steroids, malabsorption, and general malaise. Other endocrine organs, such as the pancreas, thymus, and gonads can also be affected.[14]

Exophthalmos is present in only 10 percent to 30 percent of cases. It may be unilateral or bilateral and is due to retroocular bone infiltration by Langerhans cells. Mastoid involvement mimics an infectious mastoiditis and leads to chronic otitis media, otorrhea, and also deafness caused by the extension of the disease to the middle ear.

Gastrointestinal symptoms are nonspecific and are due to mucosal infiltration. Abdominal pain, diarrhea, vomiting, bloody stools, duodenal ulcers, and malabsorption have been described. Although conventional radiographs may show either dilated or stenotic segments, the specific diagnosis can be made by only endoscopic biopsy.[15]

Brain involvement by LCH is uncommon. Besides growth retardation, signs may include cranial nerve deficit, blurred vision, tremors, dysarthria, ataxia, spastic paraplegia or tetraplegia, and progressive intellectual deficit. Other signs, such as seizures and those related to increased intracranial pressure, are rare and depend on the site and size of the lesion. Cerebellar manifestations may appear as a first sign, followed by signs of involvement of the paraventricular cerebral white matter. CT or MRI may reveal tumor lesions as a sign of primary invasion or secondary atrophic or demyelinizing lesions.

▲ **FIGURE 148-7** Extensive Langerhans cell histiocytosis. Infiltrating lesions of the gingival tissue, which frequently leads to loss of teeth.

▲ **FIGURE 148-8** Restricted Langerhans cell histiocytosis. Noduloulcerative lesions in the vulva and on the perianal area. These lesions, although rare, are as unique as the bone lesions.

LABORATORY TESTS

The recommended laboratory evaluations for a patient with LCH are shown in Table 148-4. Other investigations that should be carried out in LCH are listed in Table 148-5.

Imaging Studies

Diagnostic imaging, from plain films to axial high-resolution CT and gadolinium-enhanced MRI, plays a major role in the diagnosis and management of LCH. As already noted, bone involvement can be investigated using isotopic bone scans to reveal multiple lesions and fluorodeoxyglucose positron emission tomography to identify active osseous lesions. These techniques may allow the precise visualization of lesions in potentially dangerous bony locations such as the skull and the spine. In the thorax, reticulonodular shadowing and honeycombing of the lung with preserved lung volume is typically revealed.[16]

Histopathologic, Immunohistochemical, and Ultrastructural Evaluation

The pathologic features of LCH provide the unifying aspect for the entire con-

▲ **FIGURE 148-9** Extensive Langerhans cell histiocytosis. All nails, save one, show purpuric striae of the nail bed. Nail changes are considered an unfavorable prognostic sign.

tinuum of LCH disorders. The common histologic element of the different lesions is the typical "LCH cell," a cell easily identified and differentiated from the non-specific elements of the infiltrate by its size and configuration. This cell is approximately four to five times larger than small lymphocytes, has an irregular and vesiculated nucleus, is often reniform (kidney shaped), and has abundant, slightly eosinophilic cytoplasm (Figs. 148-13, 148-14, and 148-15). The histologic patterns observed in LCH are of three types: proliferative, granulomatous, and xanthomatous. A proliferative reaction is seen in early papules. It consists of an extensive epidermotropic, lichenoid infiltration of LCH cells in the upper dermis. The epidermis soon becomes compressed, thinned, invaded, and even destroyed (see Fig. 148-13). In the upper dermis, LCH cells are typically separated by edema, whereas in the lower dermis their cell membranes coalesce. In the deep dermis, the infiltrate is often localized around vessels and may invade the hypodermis. A few mitotic figures are occasionally found. Cytologic examination of LCH cells is easily accomplished by scraping early papules. The granulomatous reaction (see Fig. 148-14) consists of an aggregation of LCH cells with some multinucleated histiocytes and a varying number of eosinophils, generally in clusters. Neutrophils, lymphocytes, and plasma cells may also be present in the infiltrate. This type of reaction is seen in the chronic stages of the disease. The xanthomatous reaction is encountered mainly in HSC and consists of numerous foam cells intermingled with LCH cells and eosinophils (see Fig. 148-15). Multinucleated giant cells are frequently seen. They are mainly of the foreign-body type but occasionally may have the appearance of Touton giant cells. Lipid accumulation is considered to be a late secondary phenomenon. These different types of histologic reactions may be found simultaneously in the same patient, and the visceral lesions present in LCH show the same three types of reactions observed in the skin.

In HPD, the infiltrate appears to consist mostly of large multinucleated giant cells intermingled with typical LCH cells. In HPD, LCH cells are fewer (10 percent to 25 percent of tumor cells) and may contain dense and regularly laminated bodies. The cytoplasm of the giant cells is either acidophilic or has a "ground glass" appearance. It is usually localized in the mid and deep dermis; occasionally, the epidermis may be infiltrated and ulcerated. The LCH cells show the immunophenotype of normal Langerhans cells, expressing high levels of major histocompatibility complex class II molecules, CD1a complex, CD4, CD207 molecules, and S100 protein. Electron microscopic studies show that approximately 50 percent of the histiocytes of LCH contain

▲ **FIGURE 148-10** Extensive Langerhans cell histiocytosis in an 81-year-old woman. The diffuse papuloscaling and papulocrusted lesions on the trunk are similar to those seen in early childhood. Systemic involvement consists of hepatosplenomegaly and pulmonary lesions. DIFFERENTIAL DIAGNOSIS

The differential diagnosis for LCH is summarized in Boxes 148-1 and 148-2.

COMPLICATIONS

Intercurrent infections, mainly candidiasis and sometimes dermatophytosis,[18] are frequently observed in LCH, especially in LSD. The development of severe pyogenic abscesses has been reported in elderly patients. The results of the progressive destruction of the surrounding tissue by invading histiocytes can therefore be highly variable and multifocal. The association of LCH with malignant neoplasms, particularly solid tumors (lung tumors, celiomesenteric neuroblastoma), malignant lymphomas, or acute leukemia is not unusual. In some of these cases, LCH may be considered as a reactive process associated with malignancy. Neoplasms may also be related to chemotherapy or radiotherapy for LCH. The synchronous occurrence of LCH with leukemias may be interpreted as additional clinical evidence in favor of a common origin of monocytes and Langerhans cells.

PROGNOSIS AND CLINICAL COURSE

Although the presence of numerous lesions, either in the skin or in other tissues, generally indicates an unfavorable course, the evolution of LCH is unpredictable. The prognosis is based on clinical features and is related to the age at onset, the rate of disease progression, and the number of organ systems involved.[19] It is not related to the histopathologic features. In short, an early onset (under the age of 2 years), extensive disease, and the presence of organ failure are the three main negative prognostic indicators.

Restricted LCH or single-system disease is usually associated with a good prognosis, whereas extensive LCH or multisystem disease may be fatal.[20] However, some patients with multiple lesions have been reported to recover spontaneously. The appearance of xanthomatous lesions in the course of LCH is considered by some authors to be an expression of a shift from a disseminated aggressive form into a progressive chronic form; others believe that these lesions may represent a distinct clinical entity independent of the primary disease. Organ dysfunction (liver, bone mar-

TABLE 148-5
Procedural Investigations for Langerhans Cell Histiocytosis

SPECIFIC INVESTIGATION	INDICATION
Skin biopsy or cytology	Mandatory to determine diagnosis
Weight and height	To determine general health
Chest radiography[a]	To determine respiratory system involvement
Abdominal ultrasonography[a]	To determine gastrointestinal involvement
Endoscopy and biopsy	To investigate malabsorption
Bone marrow biopsy	To evaluate cause of anemia, leukopenia, thrombocytopenia
Liver biopsy	To determine specific infiltration and involvement
Pulmonary function tests	To investigate tachypnea; to assess before chemotherapy
Bronchoalveolar lavage	To determine specific infiltration
Lung biopsy	To exclude opportunistic infection
Brain magnetic resonance imaging	To evaluate neurologic, visual, endocrine anomalies
Endocrine evaluation	
Growth hormone level	To determine cause of short stature, hypothalamic syndrome
Thyroid-stimulating hormone level	To investigate galactorrhea, precocious puberty
Otorhinolaryngologic evaluation, audiogram	To evaluate auricular discharge, deafness
Bone scans, skeletal survey, or fluorodeoxyglucose positron emission tomography	To assess bone involvement
Urine osmolality after water deprivation	To investigate diabetes insipidus

row, and lung), which occurs in approximately 15 percent of patients with LCH, is the most important predictor of poor outcome; however, diabetes insipidus is not a poor prognostic indicator.[21] In infants with organ dysfunction, the mortality rate may be as high as 50 percent to 65 percent. The most frequent causes of death are pulmonary and bone marrow dysfunction and intercurrent infections.

ure, and nail involvement are considered unfavorable prognostic indicators. A favorable prognosis is associated with a small number of lesions, nodular lesions (as in HPD), prompt resolution of lesions, and the involvement of only one organ system (skin or bones). Multisystem LCH carries a better prognosis in adults than in children.

Liver dysfunction is considered present if there is hypoproteinemia not due to protein-losing enteropathy (less than 5.5 mg/dL total protein and/or less than 2.5 g/dL of albumin), edema, ascites, and/or hyperbilirubinemia (total serum bilirubin of more than 1.5 mg/dL). Lung dysfunction is considered present if there is cough, dyspnea or tachypnea, cyanosis, radiologically evident interstitial disease, restrictive lung disease, pneumothorax, or pleural effusion attributable to the disease rather than to infection.[22] The presence of dense areas on radiography alone is not interpreted as evidence of dysfunction. Hematopoietic dysfunction is considered present if there is anemia (less than 10 g/dL hemoglobin) not due to infection or iron deficiency, leukopenia (white blood count of fewer than 4000/μL), or thrombocytopenia (fewer than 100,000 platelets/μL). The presence of excessive numbers of histiocytes in the marrow aspirate per se is not considered as evidence of dysfunction. Hypercalcemia is also associated with a poor prognosis and is sometimes caused by bone resorption or excess prostaglandin production.[23] Finally, the rapidity and intensity of the clinical response to initial treatment is a good indicator of prognosis.

TREATMENT

Treatment strategies for LCH are chosen on the basis of the age of the patient, the extent of disease, and the location of lesions (see Fig. 148-3 and the treatment algorithm in Fig. 148-16).[24]

In single-system disease involving skin or bone, management is nonaggressive. In children with skin involvement only, observation is the best option.[25] If the lesions are persistent, topical nitrogen mustard may be an effective treatment. Therapy consists of application of this substance diluted in water to a concentration of 20 mg/dL and applied daily for 5 days. Systemic glucocorticoids or antimitotic drugs are indicated in resistant cases. In adults with skin involvement only, topical treatment with nitrogen mustard may be an effective treatment strategy. Significant improvement has been obtained with conventional psoralen plus ultraviolet A light treatment in a considerable number of cases. CO_2 laser therapy has been suggested to treat periorificial eosinophilic granuloma. The use of thalidomide at a dosage of 100 mg/day for 1 month and then 50 mg/day for 1 or 2 months may induce a remission of skin lesions. Usually the disease recurs after treatment is stopped. The effect of thalidomide seems to be a result of its immunomodulatory and anti-inflammatory properties.[26] In one case, a complete remission of skin lesions was obtained after oral isotretinoin therapy. The patient was treated with 1.5 mg/kg daily for 8 months and remained free of recurrence and visceral involvement for 5 years.

For patients with bone involvement only, surgery (excision or curettage) is the treatment of choice if the lesions are accessible (see eFig. 148-16.1 in on-line edition). In children, glucocorticoid injections into selected sites may prevent surgical trauma to developing teeth or the growth plate of long bones.[27] In adults, radiotherapy is indicated for involvement of vertebrae, the sella turcica, and weight-bearing bones with risk of spontaneous fracture. In children, radiotherapy must be reserved for cases that fail to respond to other measures to avoid the risk of long-term effects. In the case of multiple bone lesions, monochemotherapy is suggested as with multiorgan involvement.

The management of patients with multisystem disease is controversial. Currently, monochemotherapy with vinblastine or etoposide with or without glucocorticoids is probably the most suitable treatment.[28] Vinblastine is given intravenously at doses of 0.1 to 0.2 mg/kg (6.5 mg/m^2) once weekly for 1 to 3 months. Re-administration of the alkaloid should be instituted only when new lesions appear. Etoposide is administered at a dose of 200 mg/m^2 orally or

intravenously for 3 consecutive days every 3 to 4 weeks for at least three to four courses. Both vinblastine and etoposide are well tolerated and cause only a few toxic effects; however, cumulative doses of etoposide exceeding 4000 mg/m^2 carry a significant risk of causing acute myeloid leukemia. Therefore, this drug is not the first choice in children and should be reserved for the treatment of LCH that is severe and resistant to other therapies. In the event of relapse, retreatment with the same type of monochemotherapy results in complete clearing in 60 percent of cases. Finally, methylprednisolone (30 mg/kg intravenously on 3 consecutive days) may be the initial therapeutic approach.

Only patients for whom monochemotherapy is not effective should be given multiagent regimens including vincristine, cyclophosphamide, doxorubicin, and chlorambucil. In refractory and advanced cases of LCH, cyclosporine and interferon-α2, and 2-chlorodeoxyadenosine have been used. Allogenic bone marrow transplantation or autotransplantation with CD1a-depleted bone marrow has been successful in some patients.

CHAPTER 149

Non–Langerhans Cell Histiocytosis

Carlo Gelmetti
Ruggero Caputo

Non–Langerhans cell histiocytosis (NLCH), or class II histiocytosis, represents a broad group of different disorders characterized by the proliferation of histiocytes other than Langerhans cells[1] (Table 149-1).

Most of these cells share the same immunophenotypes, but the resulting disorders differ in clinical presentation and course. Although all NLCH disorders are considered reactive with no clinical evidence of malignancy, some forms, as with class I histiocytosis (Langerhans cell histiocytosis, or LCH), can be invasive and therefore are not necessarily biologically benign. Patients have been described who have developed both LCH and an NLCH, particularly juvenile xanthogranuloma (JXG) or benign cephalic histiocytosis (BCH),[2–4] and overlap between JXGs and BCH has also been described.[5]

Several attempts have been made to classify NLCH,[6] but none has been universally accepted.[7,8]

It is not possible to perfectly correlate the histologic features and the immunophenotype with either the clinical presentation or the course of a single disease. As a practical guide one could suggest that infantile forms with individual papulonodular lesions tend to be almost all purely cutaneous and self-healing [e.g., JXG, generalized eruptive histiocytosis (GEH), BCH], whereas the adult forms with coalescing plaque-like lesions tend often to be systemic and progressive/aggressive [e.g., Erdheim-Chester disease (ECD); necrobiotic xanthogranuloma (NXG); sinus histiocytosis with massive lymphadenopathy (SHML)]. An approach to the patient with NLCH is outlined in Fig. 149-1.

This chapter discusses only disorders of significance to the general dermatologist. Forms that are very rare (e.g., indeterminate cell histiocytosis) or that have been described in a single patient (e.g., fat-storing hamartoma of dermal dendrocytes) are not considered.

TABLE 149-1
Disorders Categorized as Non–Langerhans Cell Histiocytosis (with Abbreviations)

Juvenile xanthogranuloma	JXG

Generalized eruptive histiocytosis	GEH
• Benign cephalic histiocytosis	BCH
Xanthoma disseminatum	XD
• Erdheim-Chester disease	ECD
Multicentric reticulohistiocytosis	MRH
• Solitary cutaneous reticulohistiocytosis	SRH
• Diffuse cutaneous reticulohistiocytosis	DRH
Progressive nodular histiocytosis	PNH
Necrobiotic xanthogranuloma	NXG
Sinus histiocytosis with massive lymphadenopathy	SHML

Note: Major disorders are in bold. The other forms are considered variants of these diseases.

EPIDEMIOLOGY

JXG accounts for 80 percent to 90 percent of cases of NLCH. All of the other NLCHs are rare. The authors have encountered almost 300 cases in the past 35 years. There is no sexual or racial predilection. JXG appears within the first year of life in approximately 80 percent of cases; in 20 to 35 percent of cases, it is congenital.[9,10] Approximately 30 adult cases are reported in the literature. There is a slight male predominance among in-

NON–LANGERHANS CELL HISTIOCYTOSIS

AT A GLANCE

- A broad enigmatic group of different and only partially related disorders characterized by the proliferation of histiocytes involving cells other than Langerhans cells.
- The disorders classified as non–Langerhans cell histiocytosis (NLCH), as a whole, are not rare and can be observed everywhere without sexual or racial predilection. Most cases are seen in infants and run a benign, self-healing course lasting a few years.
- The primary histopathologic feature is a dense, diffuse infiltrate that is less epidermotropic than in Langerhans cell histiocytosis and composed of occasionally foamy macrophages intermingled with lymphocytes, plasma cells, eosinophils, and sometimes Touton giant cells. In typical cases, histiocytes are $CD68^+$ but $CD1a^-$ and $CD207^-$.
- Cutaneous lesions range from papules to nodules. The number as well as the size of lesions is variable from one single small lesion to numerous nodules and plaques. Lesions become more or less xanthomatous in the absence of metabolic disorders.
- The most common sites of involvement are the head, trunk, and skinfolds. Mucosal lesions are rare and can be confused with trivial problems.
- Systemic manifestations such as ocular involvement, diabetes insipidus, and joint and visceral impairment are rare in juvenile xanthogranuloma, by far the most common NLCH, but are common in the rarer forms of NLCH.

dividuals with solitary JXG lesions and a strong male predominance among those with multiple cutaneous lesions.[9] Papular xanthoma (PX), considered a variant of JXG, is a rare disorder; fewer than 20 cases have been described. The onset of PX in children is usually during the first year of life. The disease seems to be more frequent in males. GEH is rare, with approximately 40 cases described, of which 10 were in children. It may start at any age, with reports of onset ranging from 3 months to 58 years. BCH is also rare. Over the past 3 decades, approximately 30 cases have been described, with the same incidence in boys and girls. The age of onset is 5 to 34 months (mean, 13.5 months). Progressive nodular histiocytosis (PNH) is an exceptional form described in a few children and adults. Xanthoma disseminatum (XD) is rare (approximately 100 published cases) and affects males more frequently than females. The random nature of the disorder does not permit an exact evaluation of either familial involvement or morbidity. In approximately 60 percent of patients, onset is before age 25 years. ECD is also rare, and only about 60 cases have been described in 70 years. Multicentric reticulohistiocytosis (MRH) is an uncommon disorder but has been observed in more than 100 individuals reported up to 1990, with the purely cutaneous forms seen in more than 50 patients. Caucasians are affected in more than 85 percent of cases, and women are more frequently affected than men (female-male ratio of 3:1). In general MRH affects adults 40 years of age, but the disease may appear during adolescence and rarely in childhood (pure cutaneous forms).

NXG has been described in approximately 60 cases. The age of onset of NXG ranges from 17 to 85 years, and the disease shows no gender predilection. SHML is also a relatively rare disease; approximately 365 cases have been studied. The disease has a worldwide distribution with increased incidence in blacks from Africa and the West Indies. There is no gender predilection. Any age group may be affected, but 80 percent of cases occur in the first or second decade of life.

ETIOLOGY AND PATHOGENESIS

The pathogenesis of NLCH is unknown. MRH may represent an abnormal histiocytic reaction to different stimuli. In forms with solitary lesions, local trauma may play a role, whereas in diffuse forms, the association with internal malignancies and autoimmune diseases suggests an immunologic basis for the initiation of the reaction.

PNH is a progressive disease with no tendency to involute spontaneously. It is thought to entail proliferation of mature spindle-shaped cells and may represent an evolution of another form of NLCH. According to some authors, MRH may evolve from a less developed form of NLCH such as GEH or adult JXG. It has also been suggested that urokinase released by the activated histiocytes may play a role in the extracellular matrix degradation leading to erosion of cartilage and adjacent bone. The origin and function of the pleomorphic cytoplasmic inclusions that are frequently present in the histiocytes forming the infiltrate in this disease are still debated. They may result from a peculiar kind of endocytosis or from the expression of an exocytosis phenomenon. These unique granules have already been described in several cases of reticulohistiocytosis, and if their presence is confirmed by subsequent observations, they could represent the ultrastructural marker.

The cause of NXG and its link to paraproteinemia are uncertain. It has been suggested that serum immunoglobulins complexed with lipid become deposited in the skin, eliciting a giant cell foreign-body reaction. Another hypothesis is that the paraproteinemia is the primary phenomenon, and a secondary proliferation of macrophages with receptors for the Fc portion of immunoglobulin G occurs. It has also been proposed that the paraprotein in NXG has functional features of a lipoprotein that may bind to lipoprotein receptors of histiocytes and induce granuloma formation. The cause of SHML remains obscure. Two main etiologies have been proposed: a disturbance of cell-mediated immunity and a primary infection (Epstein-Barr virus, *Klebsiella*).

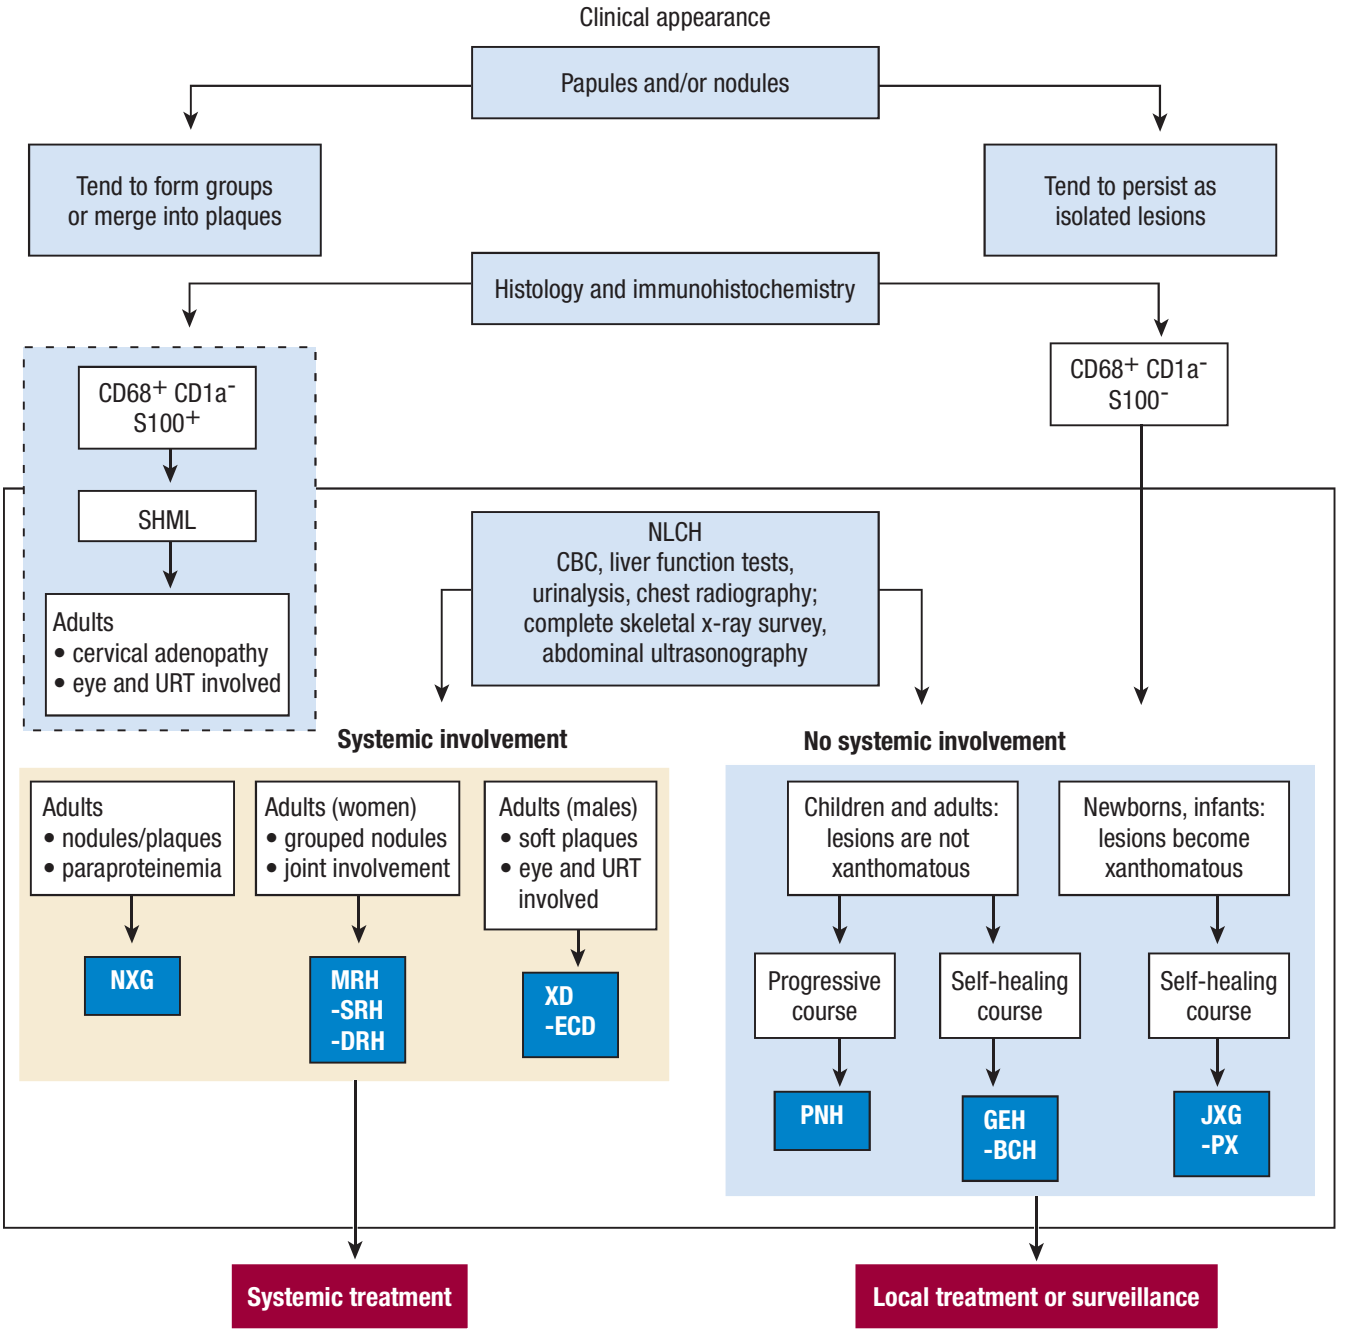
HISTORY

JUVENILE XANTHOGRANULOMA

Clinical Findings

CUTANEOUS LESIONS JXG is a benign, self-healing disorder that is characterized by asymptomatic yellowish papulonodular lesions of the skin and other organs in the absence of a metabolic disorder. Lesions consist of an infiltrate of histiocytes with a progressively greater degree of lipidation.

In JXG two main clinical forms can be distinguished, a papular and a nodular form. In both the lesions are initially orange-red or red-brown but quickly turn yellowish. The papular form (Fig. 149-2) is characterized by numerous (up to



▲ **FIGURE 149-1** Approach to the patient with non–Langerhans cell histiocytosis (NLCH). BCH = benign cephalic histiocytosis; CBC = complete blood count; DRH = diffuse cutaneous reticulohistiocytosis; ECD = Erdheim-Chester disease; GEH = generalized eruptive histiocytosis; JXG = juvenile xanthogranuloma; MRH = multicentric reticulohistiocytosis; NXG = necrobiotic xanthogranuloma; PNH = progressive nodular histiocytosis; PX = papular xanthoma; SRH = solitary cutaneous reticulohistiocytosis; SHML = sinus histiocytosis with massive lymphadenopathy; URT = upper respiratory tract; XD = xanthoma disseminatum.

100) firm hemispheric lesions 2 to 5 mm in diameter. These lesions are irregularly scattered throughout the skin but are located mainly on the upper part of the body. PX is considered to be a form of JXG in which the lesions rapidly become xanthomatous. PX lesions range from 2 to 12 mm and show a generalized distribution with no tendency to merge into plaques. The nodular form (Fig. 149-3) is less frequent and occurs as one or a few lesions. Such nodules are generally round, 10 to 20 mm in diameter, and translucent, and might show telangiectases on their surface. The term *giant juvenile xanthogranuloma* is applied to lesions larger than 2 cm. Unusual clinical variants have been also reported. The mixed form is characterized by the simultaneous presence of both small and large nodules. The term *juvenile xanthogranuloma en plaque* defines a group of JXG lesions with a tendency to coalesce into a plaque as the only expression of the disease. In one study, 67 percent of 174 cases involved solitary papular lesions, and an additional 16 percent showed solitary nodular lesions.[9] Multiple cutaneous lesions were noted in 7 percent of affected individuals, a solitary extra-cutaneous lesion in 5 percent, and multiple cutaneous and visceral-systemic lesions in an additional 5 percent.

RELATED PHYSICAL FINDINGS Ocular involvement is the most typical extracutaneous manifestation. It may precede or follow the cutaneous lesions. Ocular JXGs are usually unilateral and

▲ **FIGURE 149-2** Juvenile xanthogranuloma. Papular form.

may lead to hemorrhage and glaucoma.[11,12] An extremely rare extra-cutaneous manifestation of the papular variant is central nervous system (CNS) involvement. The nodular form of JXG may occasionally be related to systemic lesions of the lungs, bones, kidneys, pericardium, colon, ovaries, and testes. Juvenile chronic myelogenous leukemia has been observed in association with this variant of JXG. Café-au-lait macules and JXGs occur together in 20 percent of individuals with papular JXGs and can be considered an excellent marker of neurofibromatosis type 1 (NF-1) (see Chap. 142) during the first years of life, even in the absence at that age of other reliable markers of NF-1.[13] Although the presence of JXGs in children has been said to be a marker of chronic myelogenous leukemia with and without concurrent NF-1,[14] few children with café-au-lait macules and JXGs show evidence of leukemia.[15]

Laboratory Tests

No abnormalities in laboratory test results are usually found in JXG except in the very rare cases in which juvenile chronic myeloid leukemia is associated with JXG.

Histopathologic and Ultramicroscopic Findings

Biopsy sections of JXG lesions show a feature that is common to many NLCHs, that is, a nonepidermotropic histiocytic infiltrate lacking Langerhans granules. Early lesions of JXG are characterized by a monomorphous, non–lipid-containing histiocytic infiltrate that occupies at least the upper half, and sometimes the entire thickness, of the dermis. Mature lesions (Fig. 149-4) contain foam cells, foreign-body giant cells, and Touton giant cells, mainly distributed in the superficial dermis and on the border of the infiltrate. Lymphocytes, eosinophils, and neutrophils are variably associated. Older lesions may show fibrosis. In mature lesions, fat stains yield positive results. The majority of JXG lesional biopsy sections stain positive for CD68/Ki-M1P and factor XIIIa but negative for CD1a and S100 protein.[10]

Under the electron microscope, the histiocytes that characterize the early stage of the disease exhibit pleomorphic nuclei, are rich in pseudopods, and contain many elongated and irregular dense bodies. Clusters of comma-shaped bodies can occasionally be observed. In older lesions, there is a predominance of foam cells, the cytoplasm of which is completely filled with lipid vacuoles, cholesterol clefts, and myeloid bodies. Touton giant cells are extremely large and sometimes contain more than 10 nuclei. Lipid material fills the periphery, whereas mitochondria and lysosomes predominate at the center.

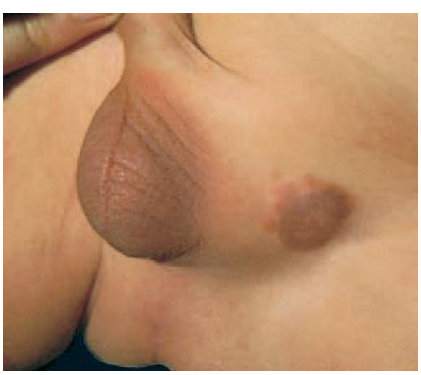
The lesions of PX are composed almost entirely of foam cells and Touton giant cells. There is no evidence of a primitive histiocytic phase, and inflammatory cells are scarce or absent. Ultrastructurally, the cytoplasm is completely filled with lipid vacuoles without a limiting membrane, myeloid bodies, and lysosomal inclusions. Comma-shaped bodies are not found in these histiocytes.

Differential Diagnosis

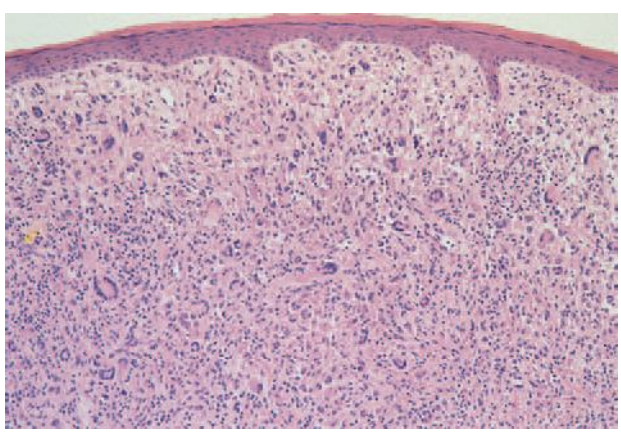
The differential diagnosis of JXG is summarized in Box 149-1.

Complications

Eye involvement of a JXG lesion can cause a major visual problem leading to



▲ **FIGURE 149-3** Juvenile xanthogranuloma. Nodular form.



▲ **FIGURE 149-4** Juvenile xanthogranuloma. Histopathologic features. A mature lesion containing foam cells, foreign-body giant cells, and Touton giant cells.

- Molluscum contagiosum
- Leukemia

NODULAR

Most Likely

- Hashimoto-Pritzker disease
- Nodular mastocytoma
- Spitz nevus

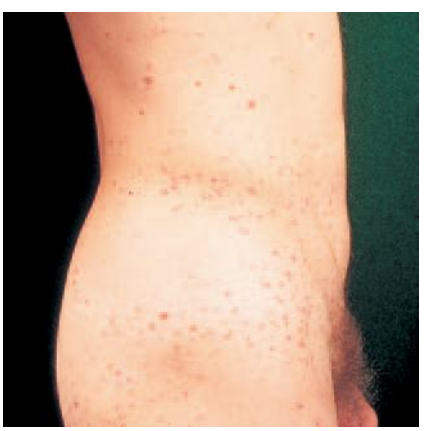
Consider

- Dermatofibroma
- Solitary cutaneous reticulohistiocytosis
- Giant molluscum contagiosum

severe secondary glaucoma. Lesions compatible with JXG have been described in many other organs as well, including lungs, spleen, liver, testes, pericardium, gut, kidney, and even the CNS, and in rare cares can lead to death. Patients may respond to multiagent chemotherapeutic regimens used to treat LCH.

Prognosis and Clinical Course

The cutaneous lesions of JXG tend to flatten with time. Each lesion evolves separately; thus, lesions at different stages of development may be seen in the same patient. Both cutaneous and visceral lesions disappear spontaneously, usually within 3 to 6 years. The patient's general health is not impaired, and physical and mental development is normal. Metabolic disturbances have not been identified. In the absence of associated conditions, prognosis is good.



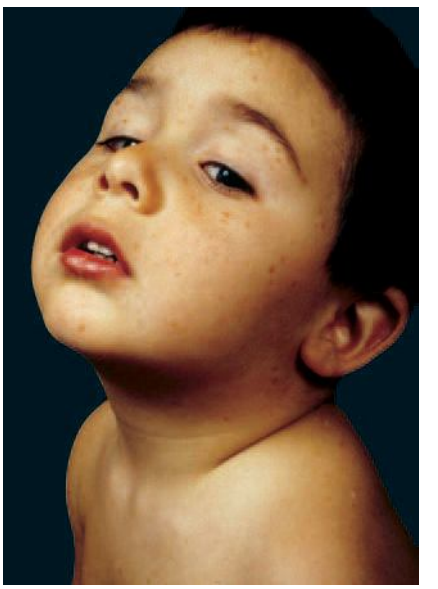
▲ **FIGURE 149-5** Generalized eruptive histiocytosis in an adult.

GENERALIZED ERUPTIVE HISTIOCYTOSIS

Clinical Findings

The skin lesions of GEH consist of an asymptomatic eruption of round or oval papules that are firm, pink or dark red, and range in size from 3 to 10 mm[16] (Fig. 149-5). These lesions appear in successive crops and are usually numerous (in the hundreds). In adults, the lesions are symmetrically distributed and may involve the mucous membranes, whereas in children the lesions are irregularly scattered over the entire body and the mucous membranes are spared.

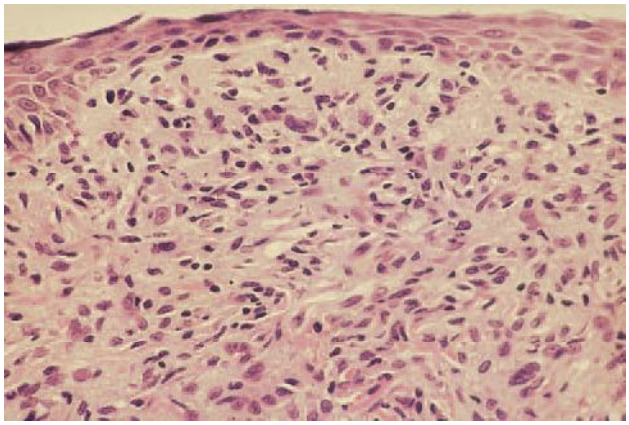
BCH may evolve into GEH and therefore is now considered a limited form of the latter. BCH manifests as asymptomatic, slightly raised, round or oval, orange-red or red-brown lesions, 2 to 8 mm in diameter, that are initially localized on the upper part of the face, mainly around the eyelids, forehead, and cheeks[17] (Fig. 149-6; see eFig. 149-6.1 in on-line edition). Other lesions subsequently appear over the entire head, the auricles (particularly on the posterior side), the occipital region, and the neck. A few lesions may appear on the shoulders and arms. The number of early lesions varies considerably, from 2 to more than 100, and new ones continue to appear for many months. GEH and BCH do not, in general, show other features, lead to abnormalities in laboratory test results, or have known complications. However, diabetes insipidus has been reported in association with BCH from infiltration of the pituitary stalk,[18] as has been described more commonly in LCH (see Chap. 148) and XD (see the section Xanthoma Disseminatum later).



▲ **FIGURE 149-6** Benign cephalic histiocytosis. Note the distribution on the face.

Histopathologic and Ultramicroscopic Findings

The lesions of GEH (Fig. 149-7) show a dense, monomorphous, non-xanthomatous histiocytic infiltrate in the papillary and midportion of the dermis, with a few lymphocytes. The histiocytes contain a nucleus with scanty chromatin and an abundant light, poorly limited cytoplasm. These cells are often arranged in nests around vessels. Older lesions in children may contain rare foam cells and few multinucleated giant cells with peripheral nuclei. By conventional microscopy, lesions of BCH cannot be distinguished from GEH lesions. In GEH, electron microscopy shows the tumor cells to contain a large number of dense and regularly laminated bodies, often clustered together. Occasionally, worm-like bodies are found. In BCH, many coated vesicles with a diameter ranging from 500 to 1500 nm are seen in all the histiocytes. Clusters of comma-



▲ **FIGURE 149-7** Generalized eruptive histiocytosis. Histopathologic features. Dense monomorphous histiocytic infiltrate in the papillary and mid-dermis, intermingled with a few lymphocytes.

shaped bodies are present in nearly one-fourth of the histiocytes. The comma-shaped bodies are formed by two electron-dense membranes of approximately 6 nm, separated by a light space of approximately 8 nm. Where the infiltrate is more dense, desmosome-like junctions may be observed among the histiocytes.

Differential Diagnosis

The disorders from which GEH should be differentiated are listed in Box 149-2.

Prognosis and Clinical Course

In GEH, new crops of lesions may continue to appear for years. Slowly the disease subsides spontaneously without a trace or leaving anetoderma-like macules. Spontaneous regression of lesions occurs months to years after the onset of BCH. Regression of lesions starts characteristically where papules first appeared. The papules begin to flatten, and then, after a short period of hyperpigmentation, the lesions disappear without leaving scars.

[a]Children.

PROGRESSIVE NODULAR HISTIOCYTOSIS

Clinical Findings

PNH is a histiocytic disorder of skin and mucous membranes with a progressively deforming course. Cutaneous lesions consist of the eruption of hundreds of lesions of two different types: superficial papules and deep nodules. The most common lesions are yellow to orange papules, 2 to 10 mm in diameter, that are randomly scattered over the body without localization in the flexural areas. These lesions may be present in the oral, laryngeal, and conjunctival mucosae. The deep lesions are dermal nodules ranging from 1 to 5 cm, with overlying telangiectasia, mainly located on the trunk. Café-au-lait spots, arthritis, and diabetes insipidus are absent. PNH has been described in a child with a hypothalamic tumor, probably histiocytic.[19] Another patient with PNH had hepatosplenomegaly, hypothyroidism, hypocholesterolemia, hyperuricemia, and chronic myeloid leukemia, but the relationship between these features and the PNH was not established.[20]

Histopathologic and Ultramicroscopic Findings

The histopathologic features of PNH are those of a xanthogranuloma with a predominance of storiform, spindle-shaped histiocytes that are positive for macrophage/dendritic cell line markers (CD68), and negative for CD1a and S100. Electron microscopic examination reveals histiocytes with a large indented nucleus.

Differential Diagnosis

The differential diagnosis for PNH is summarized in Box 149-3.

Box 149-3

Differential Diagnosis of Progressive Nodular Histiocytosis

Most Likely

- Multicentric reticulohistiocytosis
- Papular xanthoma
- Xanthoma disseminatum
- Generalized eruptive histiocytosis
- Sarcoidosis
- Lepromatous leprosy

Consider

- Nodular mastocytoma

Prognosis and Clinical Course

In PNH new lesions continue to develop during successive years with no sign of spontaneous involution. Despite the progressive nature of the lesions, patients remain in good health.

XANTHOMA DISSEMINATUM

Clinical Findings

CUTANEOUS LESIONS XD is a rare, benign, normolipemic form of NLCH affecting the skin and mucous membranes. It is frequently associated with diabetes insipidus. The cutaneous manifestations consist of hundreds of papules that are red-brown at first and then become yellowish. They symmetrically involve the eyelids, trunk, face, and proximal extremities and, in flexures and folds, tend quickly to merge, forming soft plaques (Fig. 149-8). ECD is considered a variant of XD that has visceral manifestations and is progressive.

▲ **FIGURE 149-8** Xanthoma disseminatum.

RELATED PHYSICAL FINDINGS In approximately 50 percent of cases of XD, xanthomatous lesions may also be observed on the mouth, pharynx, larynx, conjunctiva, and cornea. Symptoms of dyspnea and dysphagia are not uncommon. Vasopressin-sensitive transitory diabetes insipidus may be present, but polyuria and polydipsia are generally mild. Osteolytic lesions have been reported in only a few patients. XD may be associated with multiple myeloma, Waldenström macroglobulinemia, and monoclonal gammopathy. In ECD the most common sign is chronic bone pain, usually mild and localized in the lower limbs. Extraosseous involvement can affect almost every organ, including the lungs, liver, kidney, heart and CNS.[21,22]

Laboratory Tests

A normal lipid profile is present in this disease, but slightly elevated levels of serum cholesterol or triglycerides have been found in a few cases. In some cases, multiple myeloma, Waldenström macroglobulinemia, and monoclonal gammopathy have been detected. When lesions affect the CNS, magnetic resonance imaging may show foci of abnormally high signal intensity. In ECD, radiographs show symmetric sclerosis typically affecting the long bones of the lower limbs with involvement of the diaphyseal and metaphyseal regions.

Histopathologic and Ultramicroscopic Findings

In the early stage of XD, biopsy specimens show a mixture of histiocytes, foam cells, and inflammatory cells; later, foam cells predominate and Touton giant cells are frequently present (Fig. 149-9). Siderosis is often observed. The proliferating cells resemble those of JXG ultrastructurally, but the plasma membranes of foam cells show many microvilli. Lesional skin sections in ECD show an infiltrate of lipid-laden histiocytes intermingled with Touton giant cells and eosinophils, surrounded by fibrosis.

Differential Diagnosis

The disorders from which XD should be differentiated are listed in Box 149-4.

Complications

In XD organ involvement may lead to a variety of complications, particularly conjunctival inflammation and respiratory obstruction. Seizures, diabetes insipidus, and growth retardation have also been described. Chronic bone pain is the hallmark of ECD.

Prognosis and Clinical Course

Based on the evolution and prognosis of reported cases, three clinical variants of XD have been distinguished: a self-healing form, a persistent form, and a progressive form (ECD).[23] The persistent form is the most frequent one. Prognosis is usually good, but respiratory tract involvement may lead to dyspnea and dysphagia. Tracheotomy has been required in a few cases. In ECD the prognosis is poor because of the high risk of visceral involvement, particularly pulmonary fibrosis.[24]

MULTICENTRIC RETICULOHISTIOCYTOSIS

Clinical Findings

CUTANEOUS LESIONS MRH is characterized by the association of a cutaneous and mucosal eruption with severe arthropathy and other visceral symptoms. The papulonodular lesions range in diameter from a few millimeters to 2 cm and are round, translucent, and yellow-rose or yellow-brown (Figs. 149-10, 149-11). Grouping of lesions into plaques can give a cobblestone appearance, but lesions are generally scattered and isolated (see eFig. 149-11.1 in on-line edition). They do not tend to ulcerate and are pruritic in about one-third of cases. These lesions preferentially affect the fingers (see Fig. 149-10), the palms and backs of the hands, the juxta-articular regions of the limbs, and the head (see Fig. 149-11). Small scattered lesions may be found on the trunk. Periungual papules (see Fig. 149-10), arranged around the nail folds, resemble "coral beads"[25] and have been noted in approximately 40 percent of cases. Severe involvement of the face may lead to a leonine facies. Xanthomatous lesions are found in 30 percent of cases. Periarticular nodules, resembling rheumatoid nodules, may occasionally be seen. Erythematous, photodistributed macules and papules have been observed in approximately 15 percent of cases and may be confused with dermatomyositis. Nail changes, including brittleness, longitudinal ridging, and atrophy, may occur. Almost 50 percent of affected patients have specific nodular lesions of the oral, nasal, and pharyngeal mucosae.

Two different sub-types without joint or visceral manifestations have been described: solitary cutaneous reticulohistiocytosis (or reticulohistiocytoma cutis) and diffuse cutaneous reticulohistiocytosis. Solitary cutaneous reticulohistiocytosis is characterized by a single firm, rapidly growing nodule varying in color from yellow-brown to dark red (Fig. 149-12). Its most common location is the head, but it may be found in almost any cutaneous site. It occurs without evidence of systemic involvement, and its onset may be preceded by trauma.

Box 149-4

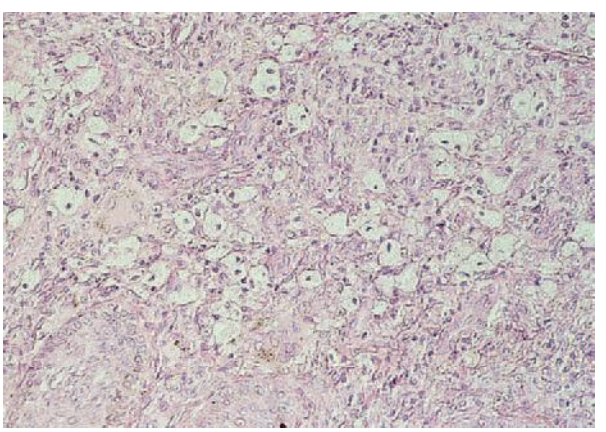
Differential Diagnosis of Xanthoma Disseminatum

Most Likely

- Chronic disseminated Langerhans cell histiocytosis
- Tuberous xanthoma (hyperlipemic)
- Papular xanthoma

Consider

- Juvenile xanthogranuloma
- Generalized eruptive histiocytosis
- Multicentric cutaneous reticulohistiocytosis
- Progressive nodular histiocytosis



▲ **FIGURE 149-9** Xanthoma disseminatum. Histopathologic features. The lesions are characterized by a mixture of histiocytes, inflammatory cells, and foam cells. Touton giant cells are present.

▲ **FIGURE 149-10** Hands of a patient with active skin lesions of multicentric reticulohistiocytosis. Note the periungual array of some of the nodules, resembling "coral beads."

Diffuse cutaneous reticulohistiocytosis is a purely cutaneous form characterized by the eruption of firm, smooth, asymptomatic papulonodular lesions, 3 to 10 mm in diameter, scattered diffusely over the skin. The color of early lesions is pinkish yellow, whereas older lesions show a red-brown color.

RELATED PHYSICAL FINDINGS In MRH, severe chronic diffuse polyarthritis with arthralgias is the initial sign of the disease in up to two-thirds of cases.[26] The lesions symmetrically involve the hands (80 percent of cases), knees (70 percent), wrists (65 percent), and less frequently the shoulders, ankles, elbows, hips, feet, and spine. The osteoarticular lesions show a progressive destructive course for 6 to 8 years and then become stable.[27] Involvement of the muscles (myositis, myotonia, and myoatrophy), cardiopulmonary system (pericarditis, cardiac insufficiency, pleuritis, pulmonary infiltration), eyes (exophthalmos, conjunctival infiltration), gastrointestinal system (gastric ulcer), thyroid gland (thyroid nodules), and submandibular salivary glands have occasionally been reported, but histologic documentation of involvement at these sites is rare. Fever, weight loss, and weakness can be present. The term *familial histiocytic dermatoarthritis* is used to indicate a particular form of MRH characterized by familial occurrence and typical ocular involvement (glaucoma, uveitis, and cataracts). Internal malignancy may be associated in 15 percent to 27 percent of cases. Solid tumors such as bronchial, breast, gastric, and cervical carcinomas are most common. Lymphomas and myelodysplastic syndromes have been found less frequently, and malignant melanoma has been reported in three cases. Whether MRH can be interpreted as a true paraneoplastic disease is not clear. Whatever the nature of the association, the incidence of internal neoplasia is such that patients who come for treatment of MRH should be investigated for concomitant internal neoplasm. MRH has been described in association with autoimmune diseases, systemic vasculitis, tuberous sclerosis, sclerosing lesions of the leg, and tuberculosis.

▲ **FIGURE 149-11** Mucocutaneous nodular infiltrate on the perioral and perinasal areas, as well as the oral and nasal mucosae in a patient with multicentric reticulohistiocytosis.

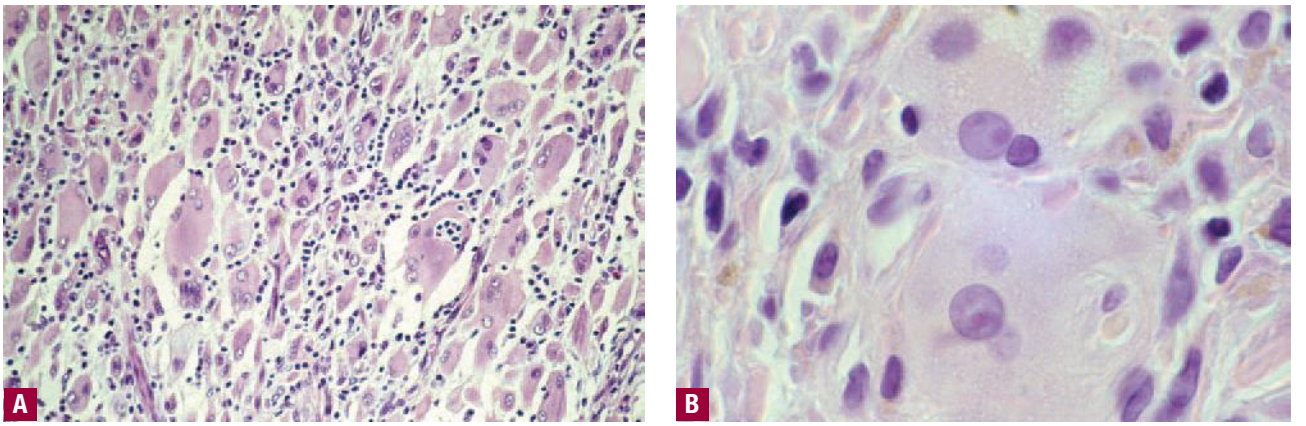
▲ **FIGURE 149-12** Solitary cutaneous reticulohistiocytosis.

Laboratory Tests

In MRH, elevated erythrocyte sedimentation rate and anemia have been observed in about half of patients and hypercholesterolemia in one-third of cases. An increase in immunoglobulin G and the presence of cryoglobulinemia and cold agglutinins have occasionally been reported. Rheumatoid factor is usually not detected. Radiographically, the joint lesions of MRH are characterized by bilateral, symmetrical, sharply circumscribed, and rapidly progressive erosions that spread from the margins to the joint surfaces, often with concomitant separation of the bone ends but without subchondral sclerosis.

Histopathology and Ultramicroscopic Findings

The histologic findings in MRH and its sub-types are identical. Histologically, the early lesions may be composed of histiocytes and lymphocytes, and therefore may be confused with other cutaneous histiocytoses. Older lesions show the presence of numerous large, mononucleated or multinucleated histiocytes with an abundance of eosinophilic, homogeneous cytoplasm containing fine granules that has a ground-glass appearance (Fig. 149-13). The number of giant cells may vary, and the diameter of these cells may reach 100 nm. The nuclei of the multinucleated cells may be arranged haphazardly or they may align along the periphery or cluster in the center. Plasma cells and eosinophils are sometimes present. Fragmentation and clumping of collagen and elastic fibers have been reported. At times, connective tissue and cell phagocytosis may be seen. Histochemically, the granular material in histiocytes and giant cells stains with periodic acid-Schiff after diastase digestion, Sudan black, and scarlet red, which indi-



▲ **FIGURE 149-13** Photomicrographs of a lesion of multicentric reticulohistiocytosis. Note the histiocytic infiltrate (**A**) and multinucleated giant cells with aggregated nuclei and ground-glass cytoplasm (**B**).

cates the presence of glycolipids and/or glycoproteins and neutral fat.[28]

Differential Diagnosis

The differential diagnosis for MRH is summarized in Box 149-5.

Complications

Complications occurring in MRH are mainly due to visceral involvement of the disease. Lesions in the upper airway may lead to dysphonia and/or dysphagia. Cardiopulmonary manifestations are more frequently reported and may also be fatal. In addition, bones and all the visceral organs may be affected, which leads to weight loss and pyrexia that complicate the potentially mutilating inflammatory polyarthritis.

Prognosis and Clinical Course

The purely cutaneous forms of reticulohistiocytosis may involute spontaneously. It is possible that the diffuse, purely cutaneous form is an early stage of MRH before the appearance of joint and visceral lesions. In MRH, the mucocutaneous course does not parallel the articular course. The mucocutaneous lesions have an unpredictable course and may remit spontaneously. In half of the patients, the osteoarticular manifestations become stable, whereas in the other half, they cause progressive destruction. The prognosis is favorable for cutaneous forms. The prognosis for MRH is related to the severity of the osteoarticular manifestations, the presence of visceral involvement, and underlying neoplasms if present.

NECROBIOTIC XANTHOGRANULOMA

Clinical Findings

CUTANEOUS LESIONS In NXG, early cutaneous lesions consist of indurated papulonodules varying in color from red-orange to violaceous or yellow and involving the dermis and subcutaneous tissue. These lesions slowly enlarge into plaques with well-demarcated edges, ranging in diameter from a few to 25 cm. There is central atrophy with telangiectasias or areas of ulceration (Fig. 149-14). Most cases are asymptomatic, but pain or a burning sensation may be noted. The lesions are usually multiple and involve, in order of frequency, the face, trunk, and extremities. The periorbital area is the site of predilection and is involved in 85 percent of cases. The oral mucosa is occasionally involved. Hepatosplenomegaly has been observed in approximately 20 percent of patients.

RELATED PHYSICAL FINDINGS NXG may be associated with myeloma, arthropathy, hypertension, neuropathy, neoplastic syndrome, primary biliary cirrhosis, and Graves disease.

Laboratory Tests

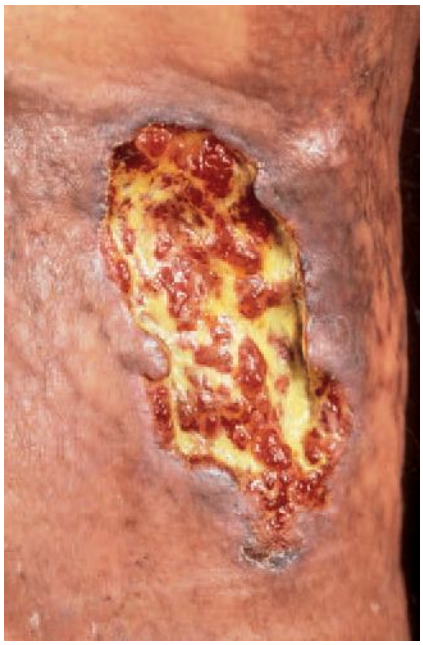
Ninety percent of patients with NXG have paraproteinemia (immunoglobulin G κ or λ light chains), especially in cases with associated myeloma. Cryoglobulinemia has been found in approximately 40 percent of cases. Other abnormal laboratory test results may include an elevated sedimentation rate, neutropenia, leukopenia, anemia, and decreased levels of CH50.

Histopathologic and Ultramicroscopic Findings

The histopathologic picture of NXG is characteristic and consists of a granulomatous infiltrate involving the whole dermis and subcutis composed of a mixture of lymphocytes, epithelioid cells, foam cells, and Touton giant cells. Areas of severe, clearly defined necrosis are sharply delineated from the surrounding granuloma. Typically, cholesterol crystals are located within the necrobiotic areas. Numerous, atypical, very large, bizarrely angulated, multinucleated giant cells may be seen adjacent to the areas of necrosis. Dense, well-defined lymphoid nodules, occasionally containing a germinal center, may be present in the dermis or subcutis. Touton cell panniculitis may involve the entire fat lobules. Occasionally, a granulomatous infiltrate may surround some vessels. Ultrastructurally, cells are rich in lipid droplets, cholesterol clefts, and myeloid bodies and are similar to those observed in JXG.

Differential Diagnosis

The disorders from which NXG should be differentiated are listed in Box 149-6.



▲ **FIGURE 149-14** Necrobiotic xanthogranuloma on the calf. Note "granulomatous" periphery of the lesion, with central ulceration and necrotic material at the base.

Complications

In NXG the periorbital involvement may lead to ocular complications such as lagophthalmos, conjunctivitis, keratitis, scleritis, uveitis, corneal ulceration, and even loss of ocular function. Nausea, vomiting, epistaxis, back pain and Raynaud phenomenon have also been recorded.

Prognosis and Clinical Course

NXG has a chronic, often progressive course that is characterized by the appearance of new lesions and ulcerations. The prognosis in given cases is difficult to predict and depends on extra-cutaneous involvement and the presence of visceral tumors such as multiple myeloma.

Box 149-6

Differential Diagnosis of Necrobiotic Xanthogranuloma

Most Likely

- Granuloma annulare
- Necrobiosis lipoidica
- Xanthoma disseminatum
- Multicentric reticulohistiocytosis

Consider

- Juvenile xanthogranuloma
- Hyperlipemic xanthoma

SINUS HISTIOCYTOSIS WITH MASSIVE LYMPHADENOPATHY (ROSAI-DORFMAN DISEASE)

Clinical Findings

CUTANEOUS LESIONS SHML is a benign, generally self-limited disease confined mainly to cervical lymph nodes. Cutaneous manifestations are observed in approximately 10 percent of patients and are polymorphic (Fig. 149-15). They may occur as yellowish macules and patches, reddish-brown papules, and plaques and nodules that may become eroded or ulcerated. In one patient, firm purple nodules and tumors as large as 10 cm in diameter were noted, but in most instances the lesions are much smaller, multiple, widespread, and asymptomatic. Periocular involvement of SHML can result in lobulated induration of the eyelids. Cutaneous lesions may be the initial manifestation and sole presenting feature of the disease. Massive bilateral cervical lymphadenopathy, usually painless, is the hallmark of the condition.[29] Less commonly, axillary, mediastinal, inguinal, and preauricular lymph nodes may be affected.

RELATED PHYSICAL FINDINGS SHML is usually accompanied by fever. Extra-nodal disease occurs in approximately 25 percent of patients and may be the initial manifestation of the disorder. The extra-nodal non-cutaneous sites most commonly affected are the eye, upper respiratory tract, liver, spleen, testes, skeleton, and nervous system. Involvement of the gastrointestinal tract is rare. An elderly woman with hematochezia was found to have SMLH of the rectum presenting as a rectal mass.[30]

Laboratory Tests

SHML is usually accompanied by an elevated erythrocyte sedimentation rate, leukocytosis with neutrophilia, and polyclonal hypergammaglobulinemia. Less frequent findings include moderate anemia (60 percent), lymphopenia, elevated titers of Epstein-Barr virus, and, in one case,[31] elevated *Klebsiella* antibody titers. Axial post-contrast computed tomography can highlight the lymphadenopathy.

Histopathologic and Ultramicroscopic Findings

Histopathologically, the skin lesions of SHML are characterized by a diffuse dermal infiltrate composed predominantly of histiocytes with large vesicular nuclei and abundant pale cytoplasm. Some histiocytes are foamy, multinucleated, or both.

▲ **FIGURE 149-15** Sinus histiocytosis with massive lymphadenopathy.

Histiocytes are sometimes aggregated in clusters resembling lymph node sinuses. Lymphocytes, plasma cells, and polymorphonuclear leukocytes, typically eosinophils, may be intermixed in the infiltrate. Emperipolesis (phagocytosis of leukocytes, especially lymphocytes) is a constant feature. In electron microscopic views most of the histiocytes are rich in phagosomes and may contain clusters of comma-shaped bodies.

Differential Diagnosis

The differential diagnosis for SHML is summarized in Box 149-7.

Complications

Extra-nodal SHML lesions have led to bilateral anterior granulomatous uveitis and may mimic neurofibromatosis, meningioma, pachymeningitis, and chronic ankle arthritis.[32,33]

Prognosis and Clinical Course

In most patients, SHML has a benign course with spontaneous regression over a period of months to years. Usually the extra-nodal lesions regress first,

Box 149-7

Differential Diagnosis of Sinus Histiocytosis with Massive Lymphadenopathy

Most Likely

- Abscesses
- Hodgkin disease
- Tuberculosis

Consider

- Sarcoidosis
- Leukemia
- Acquired immunodeficiency syndrome

whereas adenopathy may persist for years. A worse prognosis results mainly from the associated immunologic abnormalities.

TREATMENT

Most forms of NLCH, such as JXG, do not require treatment because the disease is asymptomatic and self-healing. When treatment is necessary, as in XD, ECD, MRH, NXG, or SHML, therapy options are few and treatment is often unsuccessful.

Treatment of XD is usually not helpful. Vasopressin is necessary for the associated diabetes insipidus. Radiotherapy, cryotherapy, corticosteroids, and antiblastic chemotherapy have been attempted with palliative results in the more disfiguring forms.

Therapy for MRH has frequently been disappointing. Anti-inflammatory agents such as aspirin, indomethacin, and pyrazolones have shown little effect. Systemic corticosteroids may be effective on articular lesions, but only for a short period of time. Dexamethasone pulse therapy led to a dramatic response in one case.[34] Azathioprine is of no benefit alone but in association with prednisolone may have a beneficial effect on both skin and joint lesions. Antimitotic agents (mainly cyclophosphamide and chlorambucil) have been reported to induce regression of lesions in only a few patients. Oral methotrexate seems to be the most effective. Etanercept has been used successfully to treat both cutaneous and articular symptoms. Generally, solitary cutaneous lesions are surgically excised.

In NXG, intermittent glucocorticoid treatment can induce a partial response. Low dosages of alkylating agents, such as chlorambucil or melphalan, may lead to remission of the paraproteinemia and skin lesions but do not prevent the evolution to multiple myeloma. Temporary remission of skin lesions has been obtained with radiation therapy and with plasmapheresis.[35]

As a rule, because the vast majority of lesions of SHML heal spontaneously, no treatment is necessary.[36] In rare instances, a space-occupying lesion will interfere with the function of an organ, and then treatment with systemic glucocorticoids or with various chemotherapeutic regimens might be useful.[37]

PREVENTION

At present, because the causes of all of the forms of NCLH are unknown, the possibility of preventing such diseases does not exist. As in LCH, future directions include complete genome hybridization and derivation of a gene expression profile.

CHAPTER 150

Biology of Mast Cells and the Mastocytosis Syndromes

Melody C. Carter
Dean D. Metcalfe

BIOLOGY OF MAST CELLS

Mast cells are the primary effector cells in immunoglobulin E (IgE) mediated inflammatory reactions. They are implicated in both acquired and innate immune responses, wound healing, fibrosis, angiogenesis, and autoimmune diseases.

Mast Cell Distribution and Identity

Mast cells are widely distributed, long-lived cells found predominately in connective and mucosal tissues and often in proximity to blood vessels, nerves, and lymphatic tissues.[1] Mast cells are abundant in the skin, respiratory tract, gastrointestinal tract, and genitourinary tract. The cytoplasmic granule content, cell size, and susceptibility to pharmacologic agents vary with specific location. All human mast cells contain tryptase, histamine, and proteoglycans, including heparin and chondroitin sulfate E. Mast cells are classically identified in tissue by toluidine blue or Giemsa dye that stains the cytoplasmic granules, and more recently, by immunohistochemistry using an antibody that recognizes mast cell tryptase. Human mast cells are classically divided into two types. Mast cells that contain tryptase and chymase are referred to as *TC mast cells* (MC_{TC}). Such cells tend to be located in submucosal tissues. Increased numbers of these cells are found in fibrotic diseases.[2] Mast cells that contain tryptase but not chymase are referred to as *T mast cells* (MC_T) and are increased in allergic and parasitic diseases. MC_T cells are decreased in the gastrointestinal mucosa in patients infected with human immunodeficiency virus.[3] A third mast cell phenotype has been described. These mast cells are located in the skin, lymph nodes, and intestinal submucosa and contain only chymase.[4,5]

MAST CELLS AT A GLANCE

- Mast cells are derived from pluripotent stem cells.
- Stem cell factor is required for proliferation and survival.
- Mast cells release both pre-formed and generated mediators when activated.
- Activation occurs both in innate and acquired immune responses.

Development and Differentiation

Mast cells arise from a $CD34^+$, KIT^+ pluripotent progenitor stem cell. Cross-

linking KIT by stem cell factor (SCF) is essential for these precursor cells to differentiate into mast cells. Mature mast cells require SCF for survival. Other cytokines that regulate SCF-dependent mast cell differentiation and proliferation include interleukin 13 (IL-13), IL-4, IL-5, and interferon-γ (IFN-γ). IL-3 shares a number of signal transduction pathways with SCF but has minimal direct effects on human mast cell proliferation except in early cultures. IL-4 enhances mast cell function when added to mature cultures. For example, IL-4 increases FcεRI expression on mast cells and subsequently potentiates spontaneous and antigen-stimulated degranulation release. In contrast, when IL-4 is added during SCF-dependent mast cell differentiation, it inhibits cell division and decreases final mast cell numbers. In developing mast cells, IFN-γ inhibits mast cell proliferation and influences mast cell phenotype and function. Although mature mast cells express the IFN-γ receptor, IFN-γ has a minimal effect on mature mast cell activation.[6]

Mast Cell Activation and Mediators

Antigen-dependent aggregation of FcεRI-bound IgE on the surface of mast cells is a primary mechanism of activation of mast cells and subsequent release of preformed pro-inflammatory mediators, as well as of newly synthesized mediators (Table 150-1). Non–IgE-driven signals that activate mast cells include Toll-like receptor ligands such as lipopolysaccharide and nucleic acids, the anaphylatoxins C3a and C5a, and certain chemokines and cytokines.[7]

PRE-FORMED SECRETORY MEDIATORS Preformed secretory granular mediators are released in response to aggregation of the high-affinity IgE receptor, activation through complement receptors, or activation by cytokines. Mast cell tryptase is released upon activation of mast cells, along with histamine, heparin, chymase, and carboxypeptidase A.

Tryptase is the most abundant human mast cell protein and exists in two forms that show 90 percent homology, α and β tryptases. Proforms of tryptase are believed to be secreted from mast cells and account for background serum tryptase levels. The biologic function of tryptase has not been completely defined, but it appears to activate protein cascade systems, enhance vasopermeability, and alter airway smooth muscle reactivity. Tryptase has the capability to cleave fibronectin, vasoactive intestinal peptide, and kininogens. It is also a growth factor for epithelial cells and fibroblasts. The total tryptase level in blood is used as an indirect parameter of mast cell burden and mast cell activation. Baseline tryptase levels are generally elevated in patients with systemic mastocytosis (SM). Increased serum tryptase levels are also observed within 15 minutes of onset of anaphylaxis with a peak level seen at 1 to 2 hours, although this is not consistent.[8]

The mast cell protease, chymase, converts angiotensin I to angiotensin II.[9] The vasoactive properties produced by angiotensin II may contribute to transient hypertension in some individuals during mast cell activation reactions. Carboxypeptidase A similarly converts angiotensin I to angiotensin II.[10]

Histamine is stored in all mast cells, as well as basophils, and released with cell activation. The biologic effects of histamine are mediated through activation of H_1, H_2, H_3, and H_4 receptors. H_1 receptors are located on epithelial cells as well as vascular and perivascular cells and mediate vascular permeability and instability, bronchial and intestinal smooth muscle contraction, edema, pruritus, and flushing. H_2 receptors are present on epithelial cells in the gastrointestinal tract and are associated with gastric hypersecretion. H_3 receptors are found in the brain and gastrointestinal tract and may be associated with certain neurologic effects such as headache. H_4 receptors are expressed predominately on bone marrow cells and are present on eosinophils and mast cells.[11–17] H_4 receptor function in humans is not well understood. Although the expression of H_4 receptors is low in most tissues, its expression on mast cells, eosinophils, and T cells implies it has a role in inflammatory and immune responses.

TABLE 150-1
Selected Mast Cell Mediators

Mediators	Biologic Effects	Possible Consequences
Pre-formed		
Histamine	Vasodilation, increased vascular permeability, gastric hypersecretion, bronchoconstriction	Hypotension, flushing, urticaria, abdominal pain; (peptic, colic) diarrhea, malabsorption
Heparin	Anticoagulant, inhibition of platelet aggregation	Prolonged bleeding time
Tryptase	Endothelial cell activation, fibrinogen cleavage, mitogenic for smooth muscle cells	Osteoporosis/osteopenia, disruption of cascade systems (clotting, etc.)
Chymase	Converts angiotensin I to II, lipoprotein degradation	Hypertension
Newly synthesized		
Leukotrienes	Increased vascular permeability, bronchoconstriction, vasoconstriction	Bronchospasm, hypotension
Prostaglandins	Vasodilatation, bronchoconstriction	Flushing, urticaria
Cytokines		
Stem cell factor	Growth and survival of mast cells, chemotaxis of KIT^+ cells	Mast cell hyperplasia, focal aggregates
Tumor necrosis factor-α	Activation of vascular endothelial cells, cachexia, fatigue	Weight loss, fatigue
Transforming growth factor-β	Enhanced production of connective tissue components	Fibrosis
IL-5	Eosinophil growth factor	Eosinophilia
IL-6	Growth and survival of mast cells	Fever, bone pain, osteoporosis/osteopenia
IL-16	Lymphocyte accumulation	Focal aggregates

IL = interleukin.

Heparin stabilizes and regulates secretory granule proteases. In addition, it binds to antithrombin III, inhibiting activation of the clotting cascade. Heparin binding also regulates and stabilizes cytokines and growth factors. Heparin-mediated effects include bleeding diathesis, osteopenia, and osteoporosis.

NEWLY SYNTHESIZED MEDIATORS Newly formed, membrane-derived lipid mediators, produced by mast cell activation, include prostaglandin D_2 (PGD_2), cysteinyl leukotrienes, and platelet-activating factor (PAF). These mediators have profound effects in both the immediate and late allergic reactions.[18,19] Receptors for PGD_2 are present on vascular and perivascular cells and mediate effects including bronchospasm, vasodilation, vasopermeability, and inhibition of platelet aggregation.[20] Flushing in response to niacin is mediated by PGD_2.[21] Cysteinyl leukotrienes increase vascular permeability and cause bronchoconstriction.[22–24] These mediators also are responsible for the long-lasting wheal and flare in response to injection of antigen in human skin.[23,24] Leukotrienes are believed to contribute to abdominal symptoms in patients with SM.

PAF is a potent inducer of bronchoconstriction mediated through microvascular leakage in the airways and the subsequent development of submucosal edema. Numerous cells synthesize PAF, including endothelial cells, neutrophils, and macrophages. PAF reproduces many aspects of inflammation by functioning as a chemotactic agent for eosinophils,[25] neutrophils,[26] and mast cells.[27]

Mast cells similarly produce and release a number of cytokines that may contribute to the pathologic features of mastocytosis. Tumor necrosis factor causes cachexia and vascular instability. Transforming growth factor-β contributes to tissue fibrosis, abnormal bone remodeling, osteopenia, and eosinophilia.[28] IL-4 is implicated in IgE synthesis and the development of a T helper 2 phenotype. IL-5 is instrumental in the recruitment and survival of eosinophils that contribute to tissue damage. IL-6 has been linked to the pathogenesis of osteoporosis[29] and is elevated in the plasma of patients with SM.[30–32] Evidence for the mast cell's role in innate immunity is shown by the production of IL-1β, IL-6, and other chemokines in response to pathogens and their products.[4,33,34]

MASTOCYTOSIS

Mastocytosis is a condition characterized by mast cell hyperplasia in one or more of the following organs: the bone marrow, liver, spleen, lymph nodes, gastrointestinal tract, and skin. Clinically, the disease is often accompanied by evidence of constitutive mast cell activation. This evidence includes pruritus, flushing, urtication, abdominal pain, nausea, vomiting, diarrhea, musculoskeletal pain, vascular instability, headache, and neuropsychiatric difficulties. Mastocytosis may present at any age and demonstrates a slight male-to-female predominance. The prevalence of the disease is unknown, and familial occurrence appears unusual.

TABLE 150-2
World Health Organization Classification of Mastocytosis[a]

VARIANT TERM	ABBREVIATION	SUBVARIANTS
Cutaneous mastocytosis	CM	Urticaria pigmentosa Diffuse CM Mastocytoma of skin
Indolent systemic mastocytosis	ISM	Smoldering SM Isolated bone marrow mastocytosis
Systemic mastocytosis with an associated clonal hematologic non-mast cell lineage disease	SM-AHNMD	SM-acute myelogenous leukemia SM-myelodysplastic syndrome SM-myeloproliferative disease SM-chronic myelomonocytic leukemia SM-non-Hodgkin lymphoma
Aggressive systemic mastocytosis	ASM	
Mast cell leukemia Mast cell sarcoma Extra-cutaneous mastocytoma	MCL	Aleukemic MCL

[a]For details of the WHO classification of mastocytosis, see Valent P et al: *World Health Organization Classification of Tumours: Pathology and Genetics of Tumours of the Haematopoietic and Lymphoid Tissues*, edited by Jaffe ES et al. Lyon, IARC Press, 2001.

MASTOCYTOSIS AT A GLANCE

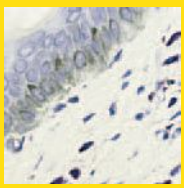
- The hallmark of mastocytosis is a pathologic accumulation of mast cells.
- Mastocytosis occurs at any age.
- The skin is the most commonly involved organ system.
- Classification of mastocytosis is critical for selection of appropriate therapy.

MASTOCYTOSIS SYNDROMES

Mastocytosis represents a disease spectrum characterized by a diverse phenotypic expression, along with pathologic and genetic findings that affect prognosis. Table 150-2 represents an updated consensus classification of the variants of mastocytosis, adopted by the World Health Organization (WHO) in 2001.[35] The most common forms are cutaneous mastocytosis (CM) and indolent SM (ISM), both of which have a good prognosis. The prognosis in patients with other variants is less optimistic. In children, the skin is the most common organ involved and is usually the only clinical manifestation of the disease, particularly with a mastocytoma or limited urticaria pigmentosa (UP). SM occurs much more commonly in adults and rarely in children. It is diagnosed on the basis of bone marrow histopathology outlined by the WHO consensus panel (Table 150-3). ISM is diagnosed when criteria for mastocytosis are met, and there is no evidence of an associated clonal hematologic disorder or severe liver disease, hypersplenism, or significant lymphadenopathy. In most cases, symptomatic management is adequate for CM and ISM.

SM with an associated clonal hematologic non-mast cell lineage disease (SM-AHNMD) is rarely observed in children. In this group, examination of the bone marrow and peripheral blood reveals the hematologic abnormality. The prognosis for these patients is determined by the course of the associated hematologic dis-

MASTOCYTOSIS SYNDROMES AT A GLANCE



- Prevalence unknown, considered an unusual disorder.
- Generally benign in children.
- In adults, most commonly associated with a somatic mutation in KIT, the receptor for stem cell factor that promotes mast cell proliferation.
- Cutaneous manifestations may occur alone or in association with systemic disease.
- Cutaneous findings consist of hyperpigmented macules, papules, or nodules, or a diffuse infiltration of the dermis.
- Related features may be flushing, pruritus, hypotension, nausea, dyspepsia, and diarrhea.
- Most common extra-cutaneous tissues involved are the bone marrow, liver, spleen, and lymph nodes.
- May be associated with myeloproliferative and myelodysplastic disorders.
- Treatment depends upon variant of disease.

order. Patients with aggressive SM (ASM)[36] have poor prognostic features, including impaired liver function, hypersplenism, and malabsorption, but they do not have a distinctive hematologic disorder or mast cell leukemia (MCL).

TABLE 150-3
Diagnostic Criteria for Systemic Mastocytosis (Major and One Minor or Three Minor Criteria Are Needed)[a]

Major
- Multifocal dense infiltrates of mast cells in bone marrow and/or other extra-cutaneous organs

Minor
- More than 25% of the mast cells in bone marrow aspirate smears or tissue biopsy sections are spindle shaped or display atypical morphology.
- Detection of a codon 816 c-kit point mutation in blood, bone marrow, or lesional tissue.
- Mast cells in bone marrow, blood, or other lesional tissue expressing CD25 or CD2.
- Baseline total tryptase level of greater than 20 ng/mL.

[a]For details of the WHO classification of mastocytosis, see Valent P et al: *World Health Organization Classification of Tumours: Pathology and Genetics of Tumours of the Haematopoietic and Lymphoid Tissues*, edited by Jaffe ES et al. Lyon, IARC Press, 2001.

Patients with ASM have rapidly increasing mast cell numbers and are difficult to manage medically. Their prognosis is less favorable than that of patients with ISM. MCL is a rare variant of SM. MCL is characterized by multiorgan failure and in bone marrow smears; mast cells represent greater than 20 percent of the nucleated cell population. Mast cells also account for 10 percent or more of peripheral blood nucleated cells.[37,38] Mast cell sarcomas are rare; they have localized destructive growth, and distant spread is possible. Mast cells in these tumors are highly atypical and immature. Extra-cutaneous mastocytomas are very rare, usually localized to the lung, and consist of mature mast cells.

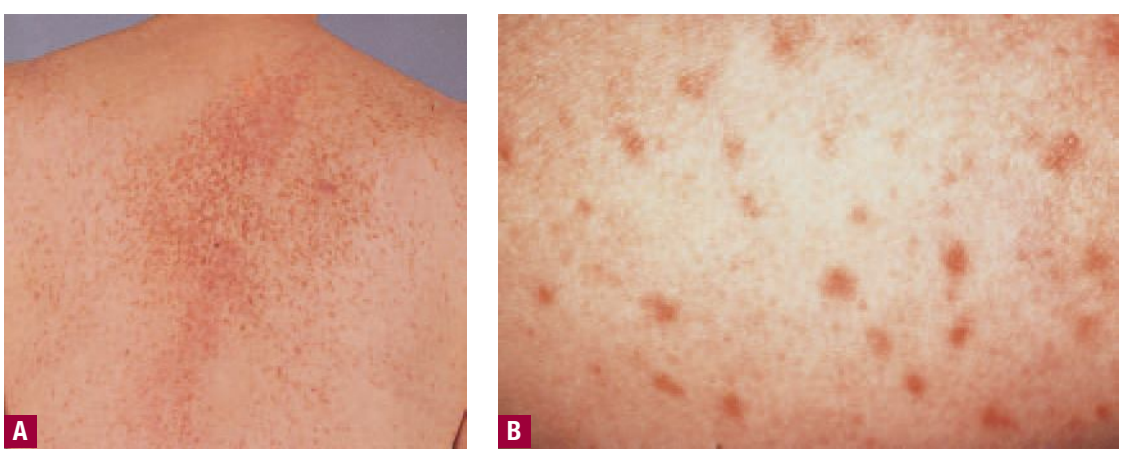
▲ **FIGURE 150-1** Mastocytoma on the sole of a child.

Clinical Manifestations

All categories of mastocytosis share clinical features caused by the excess production of mast cell–dependent mediators, although some aspects of disease may predominate in a specific category. The skin, gastrointestinal tract, lymph nodes, liver, spleen, bone marrow, and skeletal system are responsible for the most significant management problems. The respiratory tract, genitourinary, and endocrine systems are seldom involved. Furthermore, patients with mastocytosis do not suffer from recurrent bacterial, fungal, or viral infections, even though mast cells release mediators such as histamine that inhibit immune responses in vitro.

Solitary mastocytomas are brownish nodules, which, when traumatized, may cause systemic symptoms such as flushing and hypotension (Fig. 150-1). The onset is generally before age 6 months, and it is unusual to develop subsequent skin lesions more than 2 months after the presentation of the initial lesion.[39]

UP is the most common skin manifestation of cutaneous disease in both adults (Fig. 150-2) and children (Fig. 150-3;



▲ **FIGURE 150-2** Urticaria pigmentosa in an adult with indolent systemic mastocytosis. **A.** Hundreds of lentigo-like macules are seen on the back of this adult. If vigorously rubbed, these lesions will show urtication and become erythematous, raised, and pruritic. **B.** Close-up.

▲ **FIGURE 150-3** Urticaria pigmentosa in a child with cutaneous disease only.

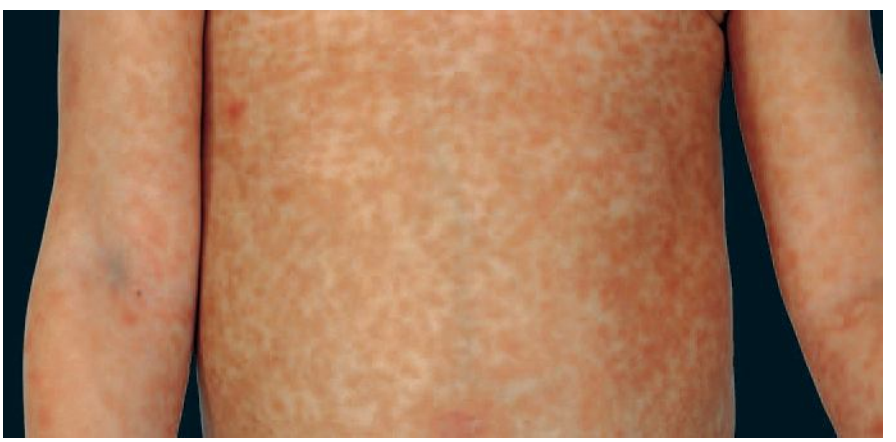
▲ **FIGURE 150-5** Diffuse cutaneous mastocytosis in a child.

see eFig. 150-3.1 in on-line edition) but the size and number are more variable in children with CM and typically more uniform in adults and children with systemic disease (Fig. 150-4). UP lesions are seen in greater than 90 percent of patients with ISM and in fewer than 50 percent of patients with SM-AHNMD or ASM. The lesions of UP are yellow-tan to reddish-brown macules or slightly raised papules scattered over the body with generally less involvement of the sun-exposed areas. Also generally spared are the palms, soles, face, and scalp. Mild trauma, including scratching or rubbing of the lesions, usually causes urtication and erythema around the macules; this is known as *Darier sign*. Many infants or young children have limited disease with few complaints, except for recurrent wheals at the same location. These often occur at sites of friction at the site of the lesion(s) such as at the edge of the diaper area.

Diffuse CM (DCM) is seen initially almost exclusively in infants (Fig. 150-5), although it may persist into adult life. The skin may be thickened with a peau d'orange appearance with a reddish-brown discoloration without discrete lesions. Dermographism with formation of hemorrhagic blisters is common.

Telangiectasia macularis eruptiva perstans is observed in fewer than 1 percent of patients with mastocytosis and is seen almost exclusively in adults. It appears as red-brown telangiectatic macules with irregular borders (see eFig. 150-5.1 in on-line edition). The occurrence of Darier sign and pruritus is variable, and this form of mastocytosis is least likely to blister.

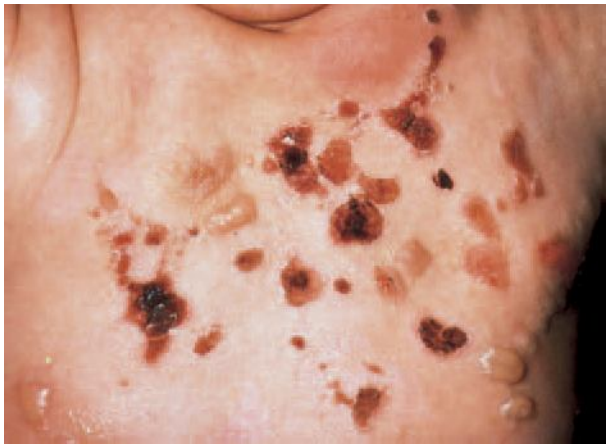
Bullae in mastocytosis may erupt spontaneously or in association with infection and immunization and necessitate distinguishing mastocytosis from other bullous diseases of childhood (Fig. 150-6; Box 150-1). Mastocytosis may also be exacerbated by changes in climatic temperature, skin friction, and ingestion of hot beverages, spicy foods, alcohol, or certain drugs. Formation of bullae is a characteristic limited to pediatric-onset cutaneous disease. With mastocytoma, the tendency to blister usually abates after the first few years and, with UP, by puberty in the majority of affected children. The diagnosis is confirmed by characteristic skin histopathology (Fig 150-7).



▲ **FIGURE 150-4** Urticaria pigmentosa systemic pediatric-onset disease.

Related Clinical Findings

Non-cutaneous disease is quite uncommon during childhood, although gastrointestinal involvement is the most frequent non-cutaneous feature. Gastric hypersecretion caused by elevated plasma histamine with resultant gastritis and peptic ulcer disease is the most common problem in both children and adults.[40] Diarrhea and abdominal pain are also frequent. Malabsorption is limited to a subset of patients with advanced disease. Significant hepatic disease in adults and children with ISM is relatively infrequent. Serious manifestations of hepatic



▲ **FIGURE 150-6** Bullous eruption on the back of a child with diffuse cutaneous mastocytosis.

and splenic involvement, including portal hypertension and ascites associated with liver fibrosis,[41] are more common in patients who have SM-AHNMD or ASM. Splenic involvement is present in about one-half of patients with mastocytosis with evidence of systemic disease.[42,43] Markedly increased splenic weights (greater than 700 g) generally occur in patients who fit into unfavorable categories of mastocytosis, including ASM or SM-AHNMD. Anemia, leukopenia, thrombocytopenia, and eosinophilia may occur in association with systemic disease and suggest SM-AHNMD, ASM, or MCL.

Patients with mastocytosis sometimes experience flushing or vascular collapse, even if there is widespread cutaneous involvement. In occasional patients, such reactions may be provoked by triggers of mast cell release, including alcohol, aspirin, narcotics, iodinated contrast media, insect stings, or other significant allergic triggers, exercise, or infections. Cutaneous responses to intradermal histamine are unchanged in patients with UP.[44]

Musculoskeletal pain affects 19 percent to 28 percent of patients. In patients with severe or advanced disease, pathologic fractures may occur. Neuropsychiatric abnormalities have been reported.[45,46] These include decreased attention span, memory impairment, headache, and irritability. Depression as a consequence of chronic disease or possibly mediated by mast cell products is a possibility. There is no clear psychopathology that exists in children with mastocytosis.[45]

Biopsies and Laboratory Testing

In patients with UP, mast cells are found in increased numbers in the dermal papillae beneath UP macules and papules, particularly near blood vessels (see Fig. 150-7).[47] Mast cells may distribute in a band-like infiltrate of the papillary dermis (see eFig. 150-7.1 in on-line edition) or appear as nodular infiltrates from the papillary dermis to subcutaneous tissues. On average, there is a 15- to 20-fold increase in mast cells beneath those lesions, but in occasional patients, only a two- to fourfold increase in mast cells is found. These observations highlight the importance of correlating the gross skin examination with skin mast cell numbers and to avoid the diagnosis of UP solely on the basis of small increases in dermal mast cells. Mast cells may also be found in increased numbers in the normal-appearing skin between lesions of UP.

Mast cell infiltration in DCM is observed around blood vessels and throughout the dermis. In patients with DCM, the band-like infiltrates may be indistinguishable from some lesions of UP or from tissue obtained from mastocytomas. Cutaneous mast cell hyperplasia in patients with telangiectasia macularis eruptiva perstans is present around the capillary venules of the superficial plexus. The biopsy of these lesions reveals increased numbers of perivascular mast cells. However, mast cell numbers are relatively low.

Histologic sections of jejunal biopsies show moderate blunting of the villi; however, significant mast cell hyperplasia is uncommon. Biopsies of affected spleen most commonly show a peritrabecular distribution of mast cell infiltrates and fibrosis. Eosinophilic infiltrates are also noted, as are areas of extramedullary hematopoiesis. Bone marrow lesions typically consist of multifocal clusters or aggregates of tryptase-positive mast cells, often interspersed with eosinophils, and T and B lymphocytes (Fig. 150-8; see eFig. 150-8.1 in online edition). Systemic pediatric-onset disease is infrequently associated with the classic bone marrow pathology seen in adult-onset SM. The mast cell aggregates may be poorly defined with less than 15 mast cells per aggregate and distributed along perivascular and/or peritrabecular areas.

The most common chemical abnormality is an elevated level of alkaline phosphatase, which must be distinguished from bone-derived alkaline phosphatase, which may also be ele-

Box 150-1

Differential Diagnosis of Cutaneous Mast Cell Disease

Most Likely

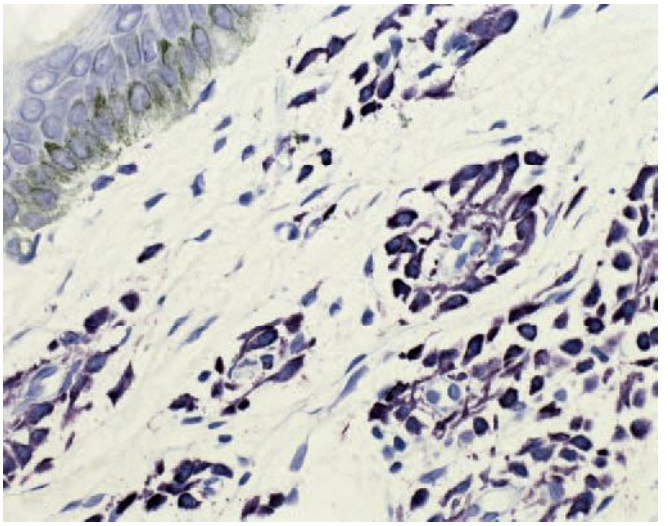
- Diffuse or localized hyperpigmented macules
  - Café-au-lait spots
  - Neurofibromatosis
  - Albright syndrome
  - Multiple cutaneous lentiginosis
- Bullous lesions
  - Chronic bullous disease of childhood
  - Linear immunoglobulin A dermatosis
- Solitary or multiple papules or nodules
  - Congenital nevus
  - Juvenile xanthogranuloma

Consider

- No lesions
  - Idiopathic flushing
- Diffuse or localized hyperpigmented macules
  - Post-inflammatory hyperpigmentation
  - Secondary syphilis
  - Chronic urticaria
  - Atopic dermatitis
- Bullous lesions
  - Staphylococcal infection
  - Drug eruption
  - Incontinentia pigmenti
  - Bullous pemphigoid
- Solitary or multiple nodules

Always Rule Out

- No lesions
  - Identifiable causes of anaphylaxis
  - Idiopathic anaphylaxis
- Diffuse or localized hyperpigmented macules or papules
  - Secondary syphilis
  - Addison disease
  - Lentigo
- Bullous lesions
  - Bullous impetigo of infancy
  - Incontinentia pigmenti
- Solitary or multiple nodules
  - Leukemia
  - Lymphoma
  - Neuroblastoma



▲ **FIGURE 150-7** Histopathology of urticaria pigmentosa, toluidine blue.

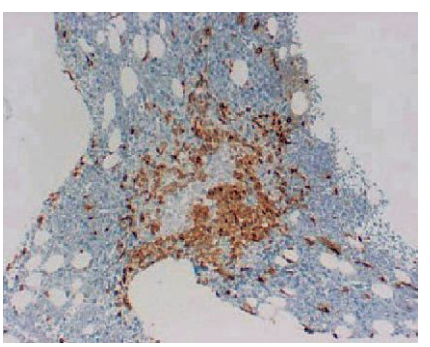
vated. Despite the infrequency of significant hepatic disease, liver function tests are somewhat above normal in about one-half of all patients with extra-cutaneous disease.[41] Elevated levels of plasma[48,49] or urinary histamine or histamine metabolites,[50] PGD_2 metabolites in the urine,[51] or serum tryptase[52] isolation are not diagnostic, but do raise the index of suspicion of SM. Other surrogate markers of disease are serum IL-6 levels,[31] and soluble SCF receptor (CD117) and IL-2 receptor (CD25) levels. The levels of the latter receptors are highly correlated with the severity of bone marrow pathology.[53]

Bone marrow infiltration with mast cells may induce bone changes that cause radiographically detectable lesions, particularly in adults. The proximal long bones are most often affected, followed by the pelvis, ribs, and skull. Skeletal scintigraphy (bone scan) is more sensitive than a radiographic survey in detecting and locating active lesions.[54] Roentgenographic abnormalities of the gastrointestinal tract fall into three major categories: peptic ulcers; abnormal mucosal patterns such as mucosal edema, multiple nodular lesions, coarsened mucosal folds, or multiple polyps; and motility disturbances.

Diagnosis (Fig. 150-9)

Mastocytosis is diagnosed on the basis of history, clinical manifestations, histopathology, and laboratory evaluation, and categorized using the classification schema from the WHO consensus panel. Biopsy in the pediatric patient is not needed if the clinical features of skin lesions are typical and Darier sign is positive. Mastocytosis in a prepubertal child is generally benign and does not require extensive evaluation to detect systemic involvement if the history and physical examination suggest no evidence of involvement beyond the skin. In contrast, the presence of non-cutaneous features or disease onset in adolescents or adults necessitates full evaluation, particularly performing a complete blood count and serum tryptase level (see Fig. 150-9 and Table 150-3).

CM is confirmed by a lesional skin biopsy (see Clinical Manifestations). Blind skin biopsies must be interpreted with caution because other skin conditions, including atopic dermatitis, and recurrent episodes of anaphylaxis may be associated with a two- to fourfold increase in dermal mast cells.[47] Similarly, this type of increase may also be seen at skin sites involved in scleroderma,[55] chronic urticaria,[56] and prolonged antigenic contact.[57] Other diseases with similar cutaneous characteristics must be considered in the differential diagnosis of mastocytosis (see Box 150-1). In adults suspected of having SM, the diagnosis of a carcinoid tumor or pheochromocytoma should be ruled out. Note that patients with mastocytosis do not excrete increased amounts of 5-hydroxyindoleacetic acid. Patients with carcinoid tumor or pheochromocytoma do not have histologic evidence of significant mast cell proliferation and should have normal serum tryptase levels.[52]



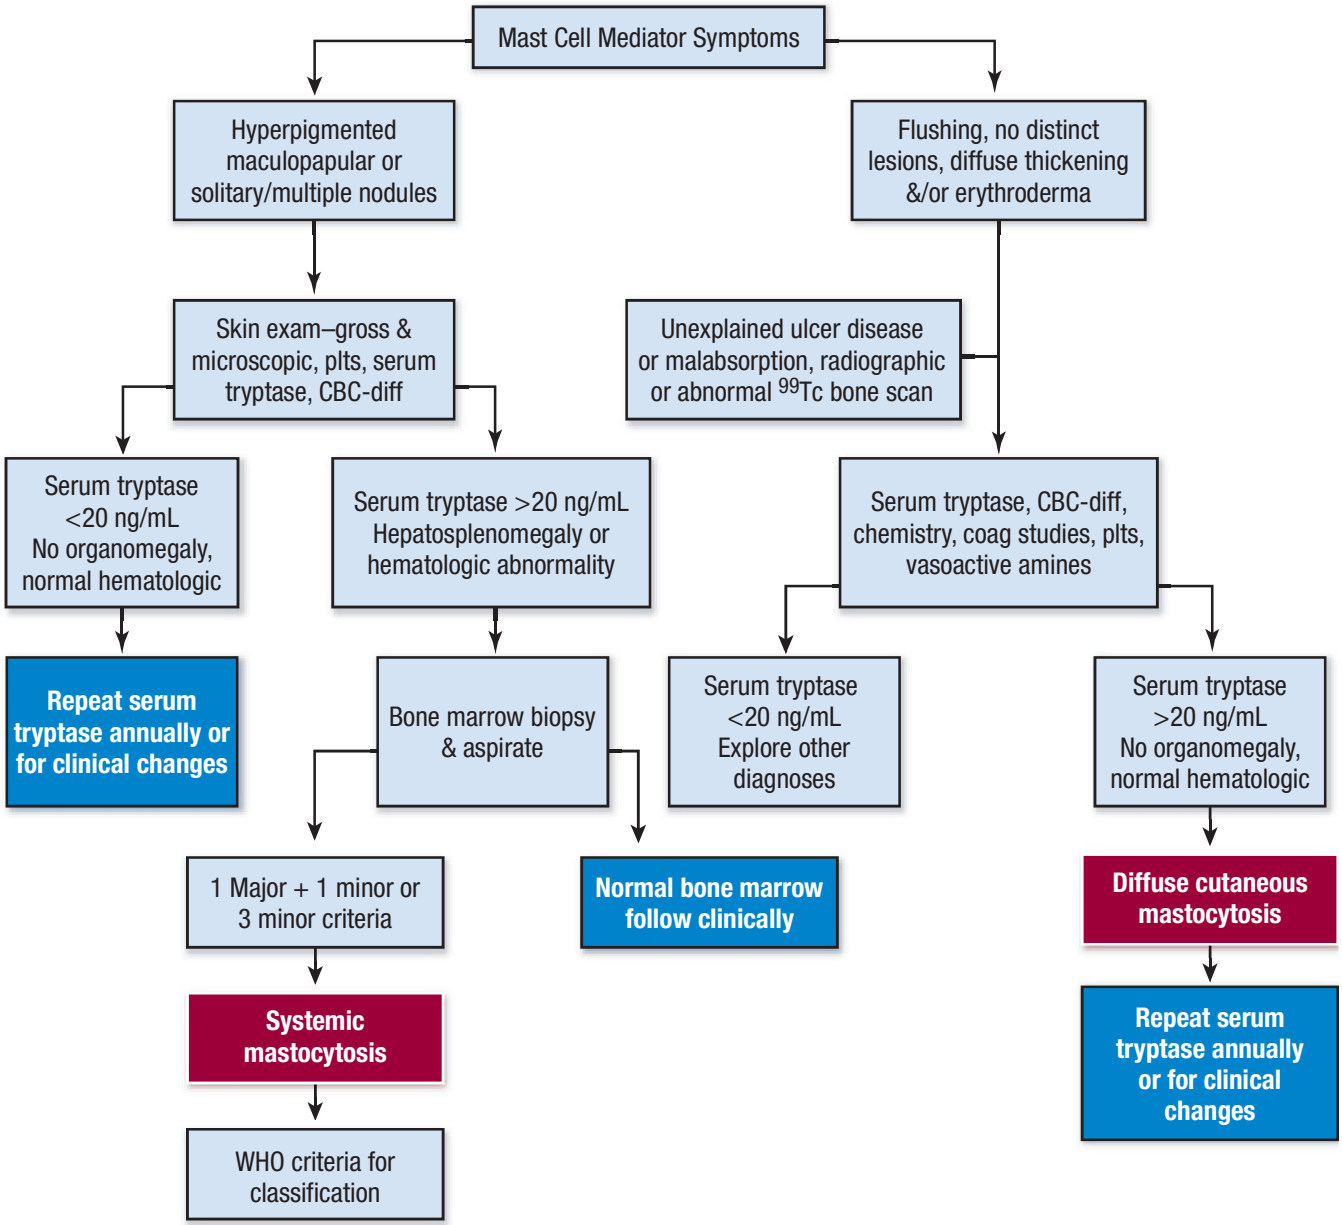
▲ **FIGURE 150-8** Classic mastocytosis bone marrow lesion (100×), tryptase stain.

Mastocytosis should be suspected in patients without skin lesions if they have one or more of the following: unexplained ulcer disease or malabsorption, radiographic or ^{99}technetium bone scan abnormalities, hepatomegaly, splenomegaly, lymphadenopathy, peripheral blood abnormalities, or unexplained flushing or hypotension. This constellation of symptoms is not unique to mastocytosis and may occur in other disease processes (Box 150-2). SM is usually diagnosed by performing a bone marrow biopsy and aspirate with demonstration of the major criterion, a classic lesion consisting of multifocal dense mast cell aggregates, and one minor criterion. Mastocytosis may also be diagnosed if three minor criteria are present (see Table 150-3). Minor criteria include atypical mast cell morphology, detection of codon 816 mutations in Kit, expression of CD2 and/or CD25 by bone marrow aspirate mast cells, and a total serum tryptase of > 20 ng/mL. A bone marrow biopsy in those with pediatric-onset disease is not recommended unless there is evidence of systemic disease as demonstrated by hepatosplenomegaly, lymphadenopathy, unexplained peripheral blood abnormalities, or an elevated serum tryptase (> 20 ng/mL). The most specific technique for identifying mast cells is immunostaining with anti-tryptase monoclonal antibody. In trephine core bone marrow biopsies, decalcification interferes with subsequent attempts to visualize mast cell granules with metachromatic stains, thereby necessitating immunostaining to detect tryptase.

Other tissue specimens, such as lymph nodes, spleen, liver, and gastrointestinal mucosa, define the extent of mast cell involvement, but are usually obtained only as dictated by necessity. For example, gastrointestinal biopsies are obtained only if a gastrointestinal workup is indicated, and lymph nodes are biopsied only if lymphoma is considered.

Treatment

The management of patients with all variants of mastocytosis includes counseling patients and care providers as to



▲ **FIGURE 150-9** Algorithm for a diagnostic evaluation of new-onset mastocytosis (especially in adolescents and adults). CBC = complete blood cell count; Tc = technetium; WHO = World Health Organization. [a]For details of the WHO classification of mastocytosis, see Valent P et al: *World Health Organization Classification of Tumours: Pathology and Genetics of Tumours of the Haematopoietic and Lymphoid Tissues*, edited by Jaffe ES et al. Lyon, IARC Press, 2001.

the features of disease, avoidance of factors provoking mediator release, management of chronic symptoms such as pruritus and gastric hypersecretion, treatment of acute episodes of vascular collapse and, when indicated, cytoreductive therapy to address the sequelae of disabling organ infiltration by mast cells and to track any associated hematologic disorder (Boxes 150-3 and 150-4).

There is currently no generally recognized safe and effective mast cell ablative therapy, nor are there effective mast cell stabilizing drugs. The treatment of mastocytosis is in part focused on symptomatic relief. In young children with mastocytomas that become reactive intermittently or in children with UP that is minimally symptomatic, no therapy is needed. Having alcohol-free diphenhydramine at home, however, is recommended. Chronic administration of H_1 antihistamines (hydroxyzine, cetirizine, and fexofenadine) is helpful in reducing pruritus, flushing, and reflex tachycardia by controlling vascular tone and permeability.[58] H_2 antihistamines, in addition to H_1 blockers, may assist in controlling pruritus, flushing, and wheal formation. H_2 antagonists (cimetidine or ranitidine) are also used in the management of excess gastric secretion, which results in gastritis and peptic ulcer disease.

If gastrointestinal symptoms persist, proton pump inhibitors may be effective in relieving symptoms of diarrhea and gastric hypersecretion.[58] Disodium cromoglycate (cromolyn sodium) inhibits the degranulation of mast cells and may have some efficacy in the treatment of mastocytosis, particularly in relieving gastrointestinal complaints in children.[59] Cromolyn sodium does not lower plasma or urinary histamine levels in patients with mastocytosis. Both ketotifen and azelastine, antihistamines with mast cell-stabilizing properties, help by relieving the pruritus and wheal-ing associated with mastocytosis (not available in systemic formulations in the

United States). However, neither drug appears to offer an advantage over a standard antihistamine such as hydroxyzine.[60,61] Low-dose aspirin has been used in some patients to reduce flushing, tachycardia, and syncope. However, aspirin must be used with caution, as it may cause vascular collapse in some patients with mastocytosis and exacerbate peptic ulcer disease. Anti-leukotrienes are effective in some patients in controlling symptoms of flushing, diarrhea, and abdominal cramping.[58]

It is known that glucocorticoids decrease tissue mast cell numbers by reducing the production of SCF by resident cells in the skin.[62] Potent topical glucocorticoids, such as 0.05 percent betamethasone dipropionate ointment, under plastic-film occlusion for 8 hours per day over 8 to 12 weeks can be used to treat extensive cutaneous disease. Mast cell numbers decrease as the lesions clear. These lesions eventually recur after discontinuation of therapy,[63] although the treatment may lead to improvement in the cutaneous lesions for up to 1 year. Topical calcineurin inhibitors may also improve the appearance

Note: Avoidance of triggering factors such as heat, friction, or drugs.

and tendency to wheal of mast cell lesions. Oral glucocorticoids have demonstrated some efficacy in patients with malabsorption and ascites.[64] After control is achieved, glucocorticoid therapy should be tapered to the lowest effective dose. Systemic corticosteroids can also be administered for treating severe CM that is not responsive to antihistamines alone. A 1-month course may be sufficient to cause improvement for a prolonged period.

Musculoskeletal pain, seen in approximately 25 percent of patients with SM, is managed with aspirin and nonsteroidal anti-inflammatory drugs, while using caution to avoid patients who are aspirin sensitive. Osteoporosis should be treated with calcium and vitamin D supplementation and, when appropriate, the addition of estrogen replacement or bisphosphonates as determined by monitoring bone density.

Epinephrine is used to treat episodes of vascular collapse or bronchoconstriction with respiratory distress. Patients with extensive mastocytosis should carry epinephrine, be prepared to self-administer this drug, and have a plan for emergency management. If subcutaneous epinephrine is insufficient, intensive therapy for vascular collapse should be instituted. Patients with recurrent episodes of vascular collapse may be prophylactically placed on H_1 and H_2 antihistamines to lessen the severity of attacks. Episodes of vascular collapse may be spontaneous but have also occurred after stings from insects or after administration of iodinated contrast media. In the latter case, premedication is recommended before such procedures.

Methoxypsoralen with ultraviolet A light relieves pruritus and whealing after 1 to 2 months of treatment.[65,66] Improvement is associated with a temporary decrease in dermal mast cells. Pruritus recurs within 3 to 6 months after treatment is stopped. Photochemotherapy should be used only in instances of extensive cutaneous disease that do not respond to other forms of therapy. Some patients report a diminution in the number or intensity of cutaneous lesions after exposure to natural sunlight.

Cytoreductive therapy is considered in patients with associated organopathy as seen in SM-AHNMD, ASM, and MCL. The risk-benefit must be carefully considered due to the dose-limiting toxicities of these drugs. IFN-α may be considered for ASM with and without associated hematologic malignancy. In a prospective study,[67] IFN-α was most efficacious in ameliorating symptoms associated with mast cell mediator release. In other reports, variable clinical responses included a reduction in bone

marrow infiltration,[68–72] regression of ascites and hepatomegaly, improvement in skin lesions, and improved bone density.[67,69,73] Improvement was often transitory. 2-Chlorodeoxyadenosine may be considered in patients with progressive disease that is refractory to interferon-α. Its use is restricted by the associated myelosuppression. 2-Chlorodeoxyadenosine has been shown to be efficacious in reducing ascites, mediator-associated symptoms, and bone marrow mast cell burden.[74]

Tyrosine kinase inhibitors such as imatinib inhibit growth of neoplastic cells through receptors such as KIT, ABL, and PDGFR tyrosine kinases[75] and was also found to be successful in the treatment of a patient with a transmembrane mutation in KIT at the F522C position.[76] Imatinib does not appear to inhibit mast cells expressing the D816V mutation. PKC412, disatinib, and AMN107 are tyrosine kinase inhibitors that demonstrated in vitro inhibition of mast cell lines with and without the D816V mutation. PKC412 inhibitory effects were superior in the D816V$^+$ cell line as compared to AMN107.[77] PKC412, disatinib, and AMN107 are in clinical trials to determine their efficacy in mastocytosis.

Splenectomy may improve survival in patients with forms of mastocytosis that have a poor prognosis.[78] Radiotherapy has been used to treat refractory bone pain in advanced disease.[79] Nonmyeloablative bone marrow transplantation may be considered for gravely ill patients, although a recent report using this therapy in three patients with advanced SM showed no sustained improvement despite inducing a graft versus mast cell state.[80]

Prognosis

Pediatric-onset cutaneous disease usually has a favorable prognosis and at least 50 percent of cases of childhood-onset UP reportedly resolve by adulthood.[81,82] Furthermore, children born of mothers with ISM reportedly are free of disease.[83] Adults with UP usually progress gradually to systemic disease and rarely develop hematologic disease.[83] DCM may be associated with ISM. Older patients with UP who experience fading of their lesions continue to exhibit bone marrow lesions typical of their diagnosis, whether ISM or SM-AHNMD.[84] Patients with SM-AHNMD have a variable course dependent on the prognosis of their hematologic disorder. With MCL, mean survival is generally less than 6 months. With ASM, mean survival is 2 to 4 years without therapy. The prognosis appears to improve with aggressive symptomatic management.

SECTION 26

SKIN MANIFESTATIONS OF INTERNAL ORGAN DISORDERS

CHAPTER 151

The Skin and Disorders of the Alimentary Tract, the Hepatobiliary System, Kidney, and Cardiopulmonary System

Graham A. Johnston
Robin A. C. Graham-Brown

Diseases of the skin frequently indicate, or associate with, diseases of the alimentary tract, the hepatobiliary system, the kidneys, and the cardiopulmonary system. Just as a full physical examination should be part of a full dermatologic assessment, it is important to examine the skin in a patient presenting with a systemic problem. This chapter is presented in the same order that a physician performing a full physical examination might approach the patient. The cutaneous manifestations that indicate internal disease are discussed for each step of the examination.

GENERAL SKIN CHANGES

Alterations in Skin Quality

The presence of pallid, dry, rough, scaly skin that is usually itchy in patients with malabsorption, chronic renal disease, or chronic hepatic disease is non-specific. Asteatotic eczema may develop. Some patients itch without any visible abnormality of their skin.

CARDIAC DISEASE ***Ehlers-Danlos Syndrome.*** (See Chap. 139) Hyperelastic velvety skin that rebounds to the original position after being stretched, "cigarette-paper" scars, and hyperextensible joints are characteristic of the Ehlers-Danlos syndrome. Mitral and tricuspid prolapse, dilatation of the aorta and pulmonary artery, arterial rupture, myocardial infarction, and emphysema may accompany this syndrome.[1]

Cutis Laxa. Progressive looseness of the skin with pendulous folds and droopy eyelids may be associated with generalized hyperelastosis, leading to aortic dilatation and rupture, congestive heart failure, or cor pulmonale with pulmonary artery stenosis and progressive emphysema.

Pseudoxanthoma Elasticum. The skin of patients with pseudoxanthoma elasticum is thick, lax, and yellowish, especially over the axillae, antecubital area, and neck. Yellow patches may occur on mucous membranes, especially the labia. The arteries may be calcified, and the aortic and mitral valves thickened. Angina pectoris and claudication are frequent symptoms.[2]

Progeria. In Werner syndrome (progeria), the skin appears atrophic and tight: there is marked loss of subcutaneous tissue, with leg ulceration and coronary atherosclerosis; death by myocardial infarction at an early age is common.

LIVER DISEASE In chronic liver disease, hormone-induced changes of the skin include loss of forearm, axillary, and pubic hair in both sexes. Men may experience a decreased rate of growth of facial hair, pectoral alopecia, and female pubic hair distribution, as well as loss of libido, testicular atrophy, and oligospermia. Striae distensae occur in both men and women (Fig. 151-1). Gynecomastia, together with Dupuytren contracture and swelling of the parotid gland, is

DISORDERS OF THE ALIMENTARY TRACT, THE HEPATOBILIARY SYSTEM, KIDNEY, AND CARDIOPULMONARY SYSTEM AT A GLANCE

- A full physical examination should be part of a full dermatologic assessment.
- It is important to examine the skin in a patient presenting with a systemic problem.
- Look for generalized changes in skin quality first.
- Then examine specific organ systems systematically.
- The majority of causes of jaundice can be found on clinical history and examination.
- In both abdominal pain and gastrointestinal bleeding, there can be cutaneous findings that suggest the underlying cause.
- Some cardiopulmonary syndromes have specific dermatologic clues.
- Remember dermatologic drugs as a cause of systemic symptoms.

▲ **FIGURE 151-1** Widespread striae in a 16-year-old boy with chronic active hepatitis.

associated with cirrhosis. Many of these changes occur more commonly in those with alcoholic cirrhosis.

Patients with chronic alcoholism also develop a "pseudo-Cushing syndrome," even in the absence of liver disease; signs include facial mooning, truncal obesity, and proximal muscle wasting.[3] These changes may regress if the patient discontinues alcohol.

Patients with chronic liver disease often have telangiectatic changes, mainly on light-exposed skin. Numerous tiny telangiectases sometimes give the impression of a diffuse, almost exanthematic redness. They are known as "dollar paper markings" after the small threads visible in paper money held up against the light. They fade on pressure with a glass slide and rarely pulsate.

RENAL DISEASE The skin of patients with chronic renal failure (CRF) is typically dry, often with ichthyosis-like scaling. This may result in part from altered vitamin A metabolism in CRF[4–6] along with the fluid volume shifts of dialysis.

Color Changes

Skin color is altered in CRF. The skin is pale from anemia and often exhibits a distinctive gray-yellow hue due to accumulation of carotenoid and nitrogenous pigments (urochromes) in the dermis.

CYANOSIS An increase in the absolute amount of desaturated (reduced) hemoglobin results in a purple-blue discoloration of the skin. Cyanosis is classified into "central" and "peripheral" types: the terms referring to the level of arterial oxygen saturation rather than the anatomic source of cyanosis. Thus, central cyanosis occurs in states that produce low arterial oxygen saturation, such as congenital heart disease with intracardiac or intrapulmonary right-to-left shunting, or severe lung disease. Peripheral cyanosis occurs when there is normal arterial oxygen saturation but reduced blood flow, such as low-output cardiac failure and local vasoconstriction. Pulmonary embolism may result in a combination of central cyanosis caused by intrapulmonary shunting and peripheral cyanosis caused by low cardiac output.

Central cyanosis is usually visible on warm areas of the skin such as the tongue, oral mucosae, and conjunctivae. Peripheral cyanosis is seen on cooler areas such as the nose, lips, earlobes, and fingertips. In the anemic patient, detection of cyanosis may be impossible because the absolute amount of reduced hemoglobin is not increased. Cyanosis fades when pressure is applied because the coloration is within the blood vessels.

ERYTHEMA Redness of the skin is caused by an increase in the amount of saturated hemoglobin, an increase in the diameter or actual number of skin capillaries, or a combination of these factors. Edema of the face, arms, and hands associated with redness and/or cyanosis may indicate obstruction of the superior vena cava due to mediastinal disease.

Polycythemia may produce the characteristic "ruddy" complexion, but may also cause a peculiar ruddy cyanosis. This is most pronounced on the tongue, lips, nose, earlobes, conjunctivae, and fingertips. It is due to increased amounts of saturated hemoglobin producing erythema, with increased amounts of desaturated hemoglobin producing cyanosis because of the inability of the body to fully oxygenate the increased absolute amounts of hemoglobin. The absence of nail clubbing may help differentiate patients with polycythemia vera from those patients with cardiopulmonary disease who develop secondary polycythemia. In addition, the hypervolemic state of polycythemia vera is associated with increased stroke volume and may lead to high-output cardiac failure. Pulmonary emboli may result from venous thrombosis secondary to hyperviscosity.

FLUSHING Paroxysmal intense flushing of the face, neck, chest, and abdomen, often with telangiectases of the face and neck, may occur in patients with carcinoid tumors (see Chap. 154), systemic mastocytosis (see Chap. 150), and pheochromocytoma (see Chap. 154), and Sipple syndrome.

PIGMENTARY CHANGES In addition to jaundice (see Jaundice below), both diffuse and circumscribed pigmentary changes may occur in chronic liver disease. A diffuse muddy gray color in patients with long-standing cirrhosis is due to basal cell melanin.

Cirrhosis. Melanosis is common in primary biliary cirrhosis (PBC) and may be an early presenting sign. It initially involves exposed areas, but it gradually becomes generalized. Blotchy, circumscribed areas of dirty brown pigmentation are also occasionally evident. Accentuation of normal freckling and areolar pigmentation can occur. Localized linear pigmentation may appear in the creases of the fingers and palms. Pigmentation resembling chloasma may localize to the perioral and periorbital areas. Guttate hypomelanosis, a condition in which small white macules, sometimes with a central spider, appear on the skin of the buttocks, back, thighs, and forearms, may occur in cirrhosis and, rarely, in PBC.[7] The yellow and orange lesions of dermal, subcutaneous, and tendon xanthomas and also xanthelasma (see Chap. 135) are common in PBC and can be extensive.

Hemochromatosis. The generalized metallic gray or bronze-brown color of the skin in hemochromatosis can be striking. There is accentuation in sun-exposed and traumatized skin, and occasionally there is buccal and conjunctival pigmentation.[8]

The etiology and pathogenesis of hyperpigmentation in chronic liver disease remain obscure. The pigmentation in PBC is due predominantly to the presence of excess melanin with no stainable iron. In hemochromatosis, pigmentation results not only from the presence of hemosiderin in the skin, but also from excess melanin. After phlebotomy, histologic siderosis and pigmentation decrease, even though melanosis remains histologically.

Vitamin Deficiency. (See Chap. 130) Pellagra gives rises to lichenified and often deeply pigmented skin in sun-exposed sites and can develop in patients with alcoholic liver disease. Vitamin B_{12} deficiency causes pigmentation of the distal extremities in a glove and stocking distribution. Diffuse hyperpigmentation occurs in folate deficiency. Kwashiorkor produces generalized depigmentation.

JAUNDICE (Table 151-1) In jaundice, raised plasma bilirubin produces a generalized coloration of the skin, mucous

TABLE 151-1
Functional Classification of Jaundice

- Unconjugated hyperbilirubinemia
  - New and infant
    - "Physiologic"—functional hepatic immaturity
    - Hemolysis—Rh, ABO, sepsis, drug factors
    - Prematurity
    - Transient familial hyperbilirubinemia—maternal steroid inhibitors
    - Crigler-Najjar syndrome—glucuronyl transferase deficiency (hereditary)
  - Adult
    - Excess bilirubin production
      - ~ Hemolysis
        Congenital
        Acquired
      - ~ Dyserythropoietic—"shunt" hyperbilirubinemia
    - Deficient conjugation
    - Familial
      - ~ Constitutional hepatic dysfunction (Gilbert syndrome)
      - ~ Crigler-Najjar syndrome type II
    - Acquired
      - ~ Posthepatic
      - ~ Associated disease—cardiac, enteric, metabolic
      - ~ Drug-induced
  - Diagnostic features
    - Serum-conjugated bilirubin less than 15% of total
    - Absence of bilirubinuria
    - Low to normal urine urobilinogen
    - Absence of other liver function disturbances
    - Normal morphologic features of liver
- Conjugated hyperbilirubinemia
  - Hepatic cell damage
    - Acute—viral, toxic, anoxic, metabolic
    - Chronic—cirrhosis, metabolic
  - Impaired bile excretion
    - Extra-hepatic obstruction
    - Intrahepatic cholestasis—atresia, viral, drugs, hormones, pregnancy, benign recurrent cholestasis
  - Familial (defect confined to bilirubin excretion)
    - Dubin-Johnson syndrome—excretory defect and cell pigment
    - Rotor syndrome—excretory defect and no pigment
  - Diagnostic features
    - Serum-conjugated bilirubin more than 15% of total
    - Bilirubinuria common
    - Urine urobilinogen often elevated
    - Other liver functions often abnormal in hepatic cell damage and impaired bile excretion
    - Characteristic morphologic abnormalities of liver

membranes, and other body tissues varying in hue from faint golden to dark green-yellow. Both jaundice and pigmentation are most prominent in extrahepatic biliary obstruction and in PBC.

Pathogenesis. Jaundice results from increased cellular or connective tissue binding of bilirubin and its metabolites in the skin. Bilirubin has an affinity for elastin, but circulates almost exclusively as a tightly bound complex with albumin. Eighty-five percent of bilirubin comes from the degradation of heme, the remainder from other heme-containing proteins such as myoglobin and cytochromes. Jaundice results from an imbalance between the tissue production and hepatic clearance of bilirubin.

Tissue-serum equilibration is slow, and so the intensity of clinical jaundice often fails to reflect the concurrent serum bilirubin level. Hyperbilirubinemia may, therefore, antedate the onset of detectable jaundice, and jaundice may persist despite falling or normal serum bilirubin levels. The correlation between skin color and serum pigment levels is especially poor in newborns. The intensity of jaundice and levels of serum bilirubin in patients with biliary atresia, acquired bile duct obstruction, or defective bilirubin conjugation tend to stabilize despite continued pigment production. Hyperbilirubinemia and jaundice secondary to raised intrahepatic pressure may occur in patients in congestive cardiac failure.

Clinical Features. Clinically detectable jaundice appears when sufficient amounts of bilirubin become tissue-bound. Involvement of the sclerae differentiates jaundice from other causes of skin pigmentation, including carotenemia, the yellow skin pigmentation produced by quinacrine and busulfan, and lycopenemia due to the ingestion of tomato juice.

The urine becomes dark yellow and then brown as conjugated serum bilirubin rises. Because most of the brown color of normal feces is produced by urobilins derived from degradation of bilirubin in the intestine, the jaundice of impaired bilirubin excretion or bile obstruction is associated with "clay-colored" stools. Degradation of bilirubin occurs with exposure to ultraviolet radiation, which is the rationale for phototherapy to prevent kernicterus in severe neonatal jaundice.

The jaundice of biliary obstruction resolves after the obstruction is relieved. Jaundice in patients with acute hepatitis resolves spontaneously. The jaundice of chronic liver disease may improve after transplantation. Jaundice in chronic active hepatitis can decrease after glucocorticoid therapy. Neonatal jaundice may respond to phototherapy (see Chap. 238).

Pruritus

CHOLESTATIC PRURITUS ***Pathogenesis of Cholestatic Pruritus.*** One of the most common and distressing symptoms of hepatobiliary disease is pruritus. Although retained cutaneous bile acids have been implicated, there is a poor correlation between the plasma bilirubin and the severity of pruritus. However, the partial relief of itching by bile salt chelating resins and the disappearance of pruritus when liver cells fail suggest that the liver manufactures at least one of the agents contributing to pruritus.

Opiate agonists, such as morphine, induce pruritus. Animal studies show that the intracerebral presence of morphine induces pruritus that is reversed by the opiate antagonist nalaxone,[9] demonstrating that opiate agonists induce scratching

of central origin. In addition, the administration of the opioid antagonist, nalmefene, to patients with PBC produces a reaction similar to that of opiate withdrawal, and the injection of plasma from patients with PBC into monkeys produces pruritus. Taken together, these studies suggest that opioidergic tone increases in cholestasis.[9] These studies do not indicate which agent contributes to the pruritus of cholestasis and whether it originates peripherally (e.g., in the liver) or centrally.[10]

Clinical Features. Pruritus ranges from mild and transient to severe and prolonged. Pruritus more commonly occurs in conditions causing cholestasis. Pruritus may be debilitating in patients with PBC, mechanical biliary obstruction, or intrahepatic obstruction. However, in viral hepatitis, itching is frequently missed as an early sign of the disease until it occurs in the later, icteric phase. Drugs, especially erythromycin, oral contraceptives, phenothiazines, chlorpropamide, para-aminosalicylic acid, and nitrofurantoin, induce cholestasis accompanied by pruritus. Pruritus is the presenting symptom in more than 50 percent of cases of PBC and may precede jaundice by months or even years.

Pruritus may be transient or continuous and may occur without jaundice. It is usually most marked on the extremities and only rarely involves the neck and face, and genitalia. There is little correlation between the severity of cholestasis and the severity of perceived pruritus, and a spontaneous decrease in the intensity of pruritus may signal the development of hepatocellular failure rather than improvement. Scratching does not relieve the pruritus of cholestasis, and there may be no visible skin changes except excoriations, although in chronic cases lichenified plaques, nodular prurigo, or perforating collagenoses occur.

Management. Pruritus rapidly decreases when cholestasis secondary to mechanical bile duct obstruction is relieved. Drugs to relieve cholestasis, such as ursodeoxycholic acid, do not consistently relieve pruritus, nor do the anion exchange resins cholestyramine and colestipol, which are thought to bind intestinal pruritogens and prevent them making their way to the skin.

Hepatic enzyme inducers, including phenobarbital and rifampicin, may induce the metabolism of pruritogens: the latter has been shown to be relatively efficacious in randomized controlled trials.[11] Antihistamines or topical steroids have no proven efficacy, but sedating antihistamines or ultraviolet light can help. Trials of plasmapheresis and charcoal hemoperfusion are inconclusive.

Neurotransmitter receptor antagonists, such as oral nalmefene, may be useful in the long-term control of the pruritus of cholestasis[12]; intravenous naloxone has short term efficacy,[13] as has oral naltrexone.[14]

RENAL PRURITUS The incidence of renal pruritus is reported to be as high as 90 percent of patients undergoing hemodialysis.[15–17]

Pathogenesis of Renal Pruritus. Renal pruritus is thought to be caused by a combination of increased serum histamine, vitamin A, and parathyroid hormone (PTH); mast cell hyperplasia; peripheral polyneuropathy; and xerosis.[16–18] Clinically the skin may appear normal or demonstrate a variety of lichenified or hyperkeratotic lesions.[19]

Management. Topical moisturizers alleviate pruritus associated with xerotic skin. Topical glucocorticoids and ultraviolet phototherapy[20–22] are often used to suppress inflammation in treated areas. Topical capsaicin depletes substance P from nerve endings, thereby suppressing itch sensation.[23] Improving the efficacy of dialysis and/or changing the dialysate concentration may help to alleviate pruritus.[24] Some patients have responded to treatments with intravenous lidocaine, heparin, and cholestyramine.[23] Surgical options include subtotal parathyroidectomy, electric needle stimulation, and renal transplantation. Erythropoietin lowers plasma histamine concentrations with subsequent improvement in pruritus.[25] Preliminary studies indicate that oral evening primrose oil,[26] endocannibinoids,[27] and topical tacrolimus ointment[28] may each have a therapeutic effect.

Alterations in Sweating

Sweating may be prominent in a number of cardiopulmonary states such as acute myocardial infarction, cardiogenic shock, left ventricular failure, massive pulmonary emboli, and pulmonary edema. Pallor and clamminess or coldness of the extremities and exposed surfaces are also often found. Excessive sweating may suggest pheochromocytoma when associated with hypertension.

The sodium and chloride content of sweat is increased in patients with cystic fibrosis and may lead to an increase in skin wrinkling after immersion, as when bathing.[29]

Skin Changes in Malignancy

Many skin changes occur in association with malignancies. Dry skin (acquired ichthyosis) with asteatotic dermatitis as well as hyperpigmentation may occur in malignancy.

DERMATOMYOSITIS (See Chap. 152) Adult-onset dermatomyositis is associated with underlying malignant disease in a significant minority of cases.[30] Blind computed tomography scans may help uncover occult malignancy in these patients.[31] Pancreatic, gastric, and colorectal cancers are the third most common after bronchogenic and ovarian cancers in Europe and North America. In China, nasopharyngeal carcinoma is common. The rash and myopathy can regress after removal of the tumor.

Interstitial lung disease occurs[32] with bronchiolitis obliterans, subcutaneous emphysema, and spontaneous pneumothorax. Upper pharyngeal weakness can lead to chronic aspiration, and exertional dyspnea can occur because of weakness of the respiratory muscles. Lung disease is associated with Anti-Jo-1 antibodies.

ACANTHOSIS NIGRICANS In two-thirds of patients with acanthosis nigricans and cancer, the tumor is gastric. The changes may regress if the tumor, usually an adenocarcinoma of the stomach or bowel, is removed.

HYPERTRICHOSIS LANUGINOSA Excessive growth of lanugo hair is a rare complication of gastrointestinal cancer.

OTHER SKIN CHANGES IN MALIGNANCY (See Chap. 154) Diverse cutaneous paraneoplastic syndromes may arise from underlying tumors.[33] They may precede, coincide with, or follow the diagnosis of cancer and often indicate a poor prognosis. They include reactive erythemas, such as erythema gyratum repens and necrolytic migratory erythema; the vascular dermatoses (Trousseau syndrome); and papulosquamous disorders, including tripe palms (Fig. 151-2), palmar hyperkeratosis, acquired ichthyosis, pityriasis rotunda, Bazex syndrome, florid cutaneous papillomatosis, the sign of Leser-Trélat, and extra-

▲ **FIGURE 151-2** Patient with "tripe hands" due to adenocarcinoma of the jejunum.

mammary disease. Migratory superficial thrombophlebitis occurs in association with neoplasia, particularly carcinoma of the pancreas. Glucagonoma is one of the amine precursor uptake and decarboxylation cell tumors. It usually arises in the islet cells of the pancreas and occurs in association with a distinctive necrolytic migratory erythema.

Any tumor may metastasize to the skin. The scalp is a common site. Metastases at the umbilicus (Sister Joseph nodules) occur particularly with carcinoma of the stomach, colon, or ovary (Fig. 151-3).

Erythroderma (See Chap. 23)

The systemic effects of erythroderma can be considerable. Patients can develop hypothermia, hypoalbuminemia, hypovolemia, secondary sepsis, the initial stages of renal failure, and high-output cardiac failure with secondary effects on hepatic function. Death from sepsis, cardiac failure, adult respiratory distress syndrome, and capillary leak syndrome occur.[34]

SPECIFIC ORGAN AND SYSTEM CHANGES

Nails (See Chap. 87)

Lindsey's, or half-and-half, nails are normal in their distal 50 percent and white in the proximal 50 percent and found in CRF.

In malabsorption or malnutrition, nails grow more slowly, become brittle, and may develop fissures.[35,36] Multiple pigmented bands can appear. Koilonychia often indicates iron deficiency, even without anemia. White nails, thought to be due to selenium deficiency, have occurred with total parenteral nutrition.

Flushing of the nail beds that is synchronous with the heartbeat is a sign of aortic regurgitation called *Quincke pulsation*.

NAIL CHANGES IN LIVER DISEASE Nail abnormalities are a less constant physical sign than spider nevi or liver palms. In cirrhosis, however, a number of changes may occur: clubbing, curved nails, thickened nails, longitudinally ridged nails, white nails, watch-glass deformity, flattened nails, white bands, striations, and brittleness.[36]

▲ **FIGURE 151-3** Umbilical metastasis (Sister Joseph nodule) from intra-abdominal adenocarcinoma.

▲ **FIGURE 151-4** Terry's white nails in a patient with cirrhosis.

White nails may occasionally be seen in healthy individuals or in association with systemic disease, including congestive heart failure, diabetes, cryoglobulinemia, Raynaud syndrome, and systemic sclerosis. Intensely white nails (Terry's nails) are characteristic of cirrhosis (Fig. 151-4).[37] Thumbs and forefingers are often most affected. The whiteness does not alter with nail growth or with compression of digital vessels and is thought to be due to the opacity of the nail plate itself. The so-called *watch-glass deformity* may accompany white nails (Fig. 151-5).

Azure lunulae, a bluish color of the lunular portion of nails, occurs in hepatolenticular degeneration (Wilson disease). Azure lunulae and corneal changes resembling Kayser-Fleischer rings may also be evident in patients with argyria or after treatment with busulfan or antimalarials.[36]

The characteristic nail changes of lichen planus (see Chap. 26), including longitudinal ridging, pterygium formation, and permanent nail loss, occur both with and without skin changes in PBC (see Cutaneous Manifestations of Primary Biliary Cirrhosis).

Splinter hemorrhages also occur in cirrhosis. Flat or spoon nails are less common in patients with liver disease. The nails are flat or concave, pale in color, and frequently show longitudinal ridging. In hemochromatosis, koilonychia is probably the most common of the nail abnormalities, but it is not related to anemia.[36]

NAIL CLUBBING Nail clubbing most commonly occurs in patients with bron-

▲ **FIGURE 151-5** Flat white nails with slight convex watch-glass deformity, showing a distal pink band in a patient with liver disease.

▲ **FIGURE 151-7** Yellow nail syndrome. There is thickening, increased curvature, and yellowish discoloration of all fingernails. This patient had lymphedema of the extremities and bronchiectasis with multiple recurrent respiratory infections.

chogenic carcinoma, suppurative lung disease, endocarditis, and congenital heart disease, but it may be idiopathic or familial (Fig. 151-6). Clubbing is quite common in all forms of cirrhosis, especially PBC and chronic active hepatitis. Signs include beaking or distal curvature of the nail. There may be loss of the angle between the nail and cuticle. Sponginess or "floating" of the nail when pressure is applied is also characteristic, and the size of the terminal tuft may increase.

Anatomically, there is an increased thickness of the nail bed. This is due to edematous infiltration of the soft parts of the terminal segment followed by hyperplasia of the dermal fibrovascular tissue with increased vascularity.[36]

YELLOW NAIL SYNDROME Yellow nail syndrome is the triad of yellow nails, primary lymphedema, and pleural effusion. The characteristics of the nails include thickening, transverse ridging, diminished growth, increased curvature with a "hump," and onycholysis. The lunulae and cuticles may be absent. The color may vary from pale yellow to green (Fig. 151-7). The nail changes are secondary to congenitally hypoplastic lymphatics,[38] leading to lymphedema, which is characteristically slowly progressive and somewhat asymmetric, with induration and hyperkeratosis extending to the thighs. Periodic lymphangitis is frequent and may contribute to the swelling.

Respiratory findings include sinusitis, bronchiectasis, and pleural effusions. Patients may have frequent upper respiratory infections and pneumonia. The appearance of pulmonary features and lymphedema may be late, and lymphoma or sarcoma has been reported.

Fingers: Erythromelalgia

Erythromelalgia (labile hyperthermia) is a chronic clinical syndrome that is characterized by recurrent attacks of burning pain in the hands and/or feet with redness and warmth.[39] There may be swelling that extends to the elbows and knees. Erythromelalgia may be primary or secondary to a disorder such as atherosclerosis, hypertension, and polycythemia. Symptoms are thought to be caused by vascular dysfunction, including arteriovenous shunting and reduced capillary perfusion with subsequent tissue hypoxemia.[40] Management includes analgesia, controlling secondary and underlying factors, and use of drugs such as aspirin and calcium channel blockers.[41] A possible role for high-dose oral magnesium has been proposed[42] and the use of a combination gel of 1 percent amitriptyline and 0.5 percent ketamine to treat refractory erythromelalgia pain.[43]

◀ **FIGURE 151-6** Clubbing of fingernails.

Hands

HYPERTROPHIC OSTEOARTHROPATHY Hypertrophic osteoarthropathy often has clubbing as a feature, but in addition there is associated arthralgia and/or arthritis of the fingers, wrists, knees, and ankles. There is a painful periostitis with subperiosteal new bone formation on x-ray. There may be pitting edema, shiny skin, increased sweating, and paronychial thickening. Hypertrophic osteoarthropathy is most often secondary to malignant tumors of the chest.

Pachydermoperiostosis, a primary form, is frequently familial. Its onset is around puberty, and it has a number of cutaneous manifestations. Distinctive thickening and furrowing of the skin of the scalp, forehead, and cheeks may create leonine facies. Other features include excessive sweating, especially of the hands and feet, severe seborrhea of the scalp and face, and dermatitis of the hands and feet. Familial clubbing alone may also be found and may represent a partial expression of this syndrome. Thyroid acropachy (see Chap. 152) may mimic osteoarthropathy but is most often painless.

REFLEX SYMPATHETIC DYSTROPHY The shoulder-hand syndrome is a painful

periarthritis or adhesive capsulitis of the shoulder ("frozen shoulder"), usually on the left side, associated with erythema, increased sweating, shiny induration, edema, tenderness, pain, and immobility of the ipsilateral hand. Reduction of finger flexion, loss of movement, temperature changes, sensory disturbances, and hair/nail growth changes have been reported.[44] Neurotrophic ulcerations of the fingers and thickening of the palmar aponeurosis with nodules and/or Dupuytren contracture may be late sequelae.[45] Predisposing conditions include arterial embolization, cerebrovascular accidents, and protective disuse of the arms for any reason.[46]

Palms: Palmar Erythema

There are two clinical forms of palmar erythema. In the first (Fig. 151-8), there is an exaggeration of normal mottling; the hands are warm and bright red, especially on the palm, the dorsae of the hands, the fingers, and the nail bases. In the second, there is well-demarcated redness of the hypothenar eminence that gradually spreads to the fingertips and then to other areas of the palm. The soles of the feet may show similar changes. The mottling blanches on pressure and flushes synchronously with the pulse rate under a glass slide. Patients may complain of throbbing or tingling. "Liver palms" occur not only in liver disease, but also in pregnancy and thyrotoxicosis. An accompanying change in those with cirrhosis is atrophy of the muscles of the thenar and hypothenar eminence. This is of myogenic rather than neurogenic origin.[47]

▲ **FIGURE 151-8** Palmar erythema showing the characteristic blotchy redness.

▲ **FIGURE 151-9** Spider nevi in a patient with cirrhosis.

Face: Spider Nevus

The spider nevus, or spider angioma, is the most representative and classic vascular lesion of chronic liver disease. Clinically, it has a central arteriole from which numerous small, twisted vessels radiate (Fig. 151-9). Spider nevi range in size from a pinhead to 2 cm. Larger lesions can be seen to pulsate when pressed with a glass slide. Pressure over the central arteriole causes blanching of the whole lesion. Spider nevi are characterized by the abnormal permanent dilatation of end vessels. Histologically, spider nevi consist of a central ascending arteriole ending in a thin-walled ampulla beneath the epidermis from which small arterial branches radiate outward into the papillary dermis.[3]

Spider nevi are most common on the face, neck, and upper part of the chest (i.e., over the region drained by the superior vena cava; see Fig. 151-9). They may be seen in 15 percent of healthy adults and not infrequently in children, where they tend to affect the hands and fingers. They may appear in large numbers during pregnancy, but usually disappear after parturition. They may also be seen in thyrotoxicosis or due to oral contraceptives.

In liver disease, spider nevi can regress with improvement of the underlying condition, although they are more likely to persist. Spider nevi are more common in patients with alcoholic cirrhosis than in those with viral or idiopathic cirrhosis. In alcoholic cirrhosis, they are associated with the presence of esophageal varicosities, and their presence may be a useful predictive marker for the future risk of esophageal bleeds.[48]

Traditionally, vascular spider nevi and palmar erythema (see Palms: Palmar Erythema) have been attributed to estrogen excess, particularly because they also occur during pregnancy and because estrogens have an enlarging, dilating effect on the spiral arterioles of the endometrium. This also explains the spider nevi seen in men receiving estrogen therapy for prostatic cancer. Patients with nonalcoholic cirrhosis have been shown to have higher plasma estradiol–testosterone ratios and substance P levels than healthy controls do,[49] and levels of substance P or vascular endothelial growth factor[50] may have an etiopathogenic role. In alcoholic cirrhosis, the presence of alcoholism and elevated serum bilirubin are both important predictors of the presence of spider nevi.[51]

Eyes

Corkscrew scleral vessels (tortuous small arteries that traverse the margins of the ocular sclerae) can develop in patients with chronic liver disease.

Mouth and Esophagus: Dysphagia

When dermatologic diseases extend into the pharynx and esophagus, dysphagia may occur. Symptoms resulting from infections of the esophagus occur in patients taking oral or inhaled glucocorticoids or in those who have an immunodeficiency. *Candida albicans* is the most frequent pathogen, although opportunistic viruses can also be responsible.

Extensive esophageal involvement, with blisters, erosions, and strictures, can occur in hereditary epidermolysis bullosa, particularly in the recessive dystrophic and junctional forms.[52] The acquired immunobullous disorders can affect mucosae. Dysphagia is most troublesome in cicatricial pemphigoid where half of patients have pharyngeal involvement and up to 13 percent esophageal involvement.[53]

Esophageal lichen planus has been reported only in women, typically middle-aged with oral involvement. Therapeutic dilatation can lead to a Koebner-like exacerbation of the stricture.[54] Esophageal involvement also occurs in Darier disease, sometimes in association with esophageal carcinoma,[55] and in acanthosis nigricans. The mucosae may be extensively involved in Stevens-Johnson syndrome and toxic epidermal necrolysis.

In Behçet disease, isolated mucosal ulcers can occur at any point along the gastrointestinal tract.[56] A typical site is the ileocecal region. Oral ulceration, occurring at least three times in a 12-

month period, is usually evident on the nonkeratinized epithelium and can be difficult to distinguish from the mouth ulceration associated with Crohn disease.

In Plummer-Vinson (Paterson-Kelly) syndrome, a postcricoid web is associated with koilonychia, angular stomatitis, a sore tongue, and, usually, iron deficiency. Up to 10 percent of patients with a postcricoid web develop carcinoma at the site. Tylosis is exceedingly rare, but 95 percent of patients develop esophageal cancer.[57]

Up to 90 percent of patients with systemic sclerosis have gastrointestinal involvement, but this is sub-clinical in one-third. Dyspepsia due to gastroparesis is common; decreased peristalsis, esophageal dilation, and stricture formation occur. Gastric antral vascular ectasia is a rare manifestation that may cause significant bleeding.[58] In dermatomyositis and polymyositis, decreased esophageal motility and difficulty swallowing are indications for urgent treatment with the systemic administration of glucocorticoids and immunosuppressive drugs. Vasculitic ulcers in the mouth and pharynx infrequently occur in systemic lupus erythematosus (SLE).

Ears

EARLOBE CREASE The presence of a diagonally positioned skin crease along the earlobe, either unilateral or bilateral, suggests an increased risk for coronary artery disease in men younger than 60 years of age.[59]

RELAPSING POLYCHONDRITIS (See Chap. 160) Relapsing polychondritis is characterized by inflammation and destruction of cartilage and connective tissues, including those of the cardiopulmonary system. It is idiopathic but is frequently associated with other immunologic disorders such as SLE. Auricular chondritis with pain, swelling, and redness of the pinna but complete sparing of the lobes is characteristic. Respiratory tract involvement may begin with hoarseness or tenderness of the anterior trachea. Degeneration of the laryngeal, tracheal, and/or bronchial rings may lead to progressive insufficiency or to sudden collapse. Cardiac involvement includes degeneration of the aortic ring with valvular insufficiency and aneurysmal dilatation. "Floppy" mitral valve syndrome also occurs. Pericardial and myocardial abnormalities have been reported.

Hair

EFFECTS OF NUTRITION Malnutrition causes hair to grow more slowly, fall out more easily, and become gray. The hair root diameter and the proportion of anagen hairs decrease. Lanugo hair may develop. Kwashiorkor, a form of protein-energy malnutrition, causes hair to become hypopigmented, varying from red-yellow to white, and curly. There may be alternating bands of pale and dark hair.[35] Total parenteral nutrition has been associated with hair loss and pigmentation of remaining hair. Type II vitamin D–dependent rickets is associated with alopecia totalis.

MALE BALDING Frontoparietal male pattern baldness is more prevalent in men admitted with nonfatal myocardial infarction.[59] Vertex hair loss may be more strongly associated with cardiovascular risk factors such as hypertension and hypercholesterolemia.[60]

Cardiovascular System (Table 151-2)

Cardiac output frequently increases in patients with cirrhosis, and total peripheral resistance may decrease.

CORONARY HEART DISEASE: FAMILIAL HYPERLIPIDEMIA (See Chap. 135) Familial hyperlipidemias comprise a group of metabolic disorders with elevated plasma cholesterol and/or triglycerides and are associated with a high incidence of coronary heart disease. Cutaneous xanthomata are also seen and are also associated with a high incidence of coronary heart disease.

CARDIOMYOPATHY: NAXOS DISEASE Naxos disease is an autosomal recessive mutation in desmoplakin, a desmosomal protein important in cell adhesion.[61] Generalized striate keratoderma are seen, particularly on the palmoplantar epidermis (see Chap. 48), with woolly hair and dilated left ventricular cardiomyopathy leading to arrhythmias, heart failure, and early sudden death.

ATRIAL MYXOMA Atrial myxomas, the most common primary tumors of the heart, are benign hamartomatous intracardiac tumors. The cardiopulmonary findings include, in order of frequency, congestive heart failure, mitral murmur, chest pain, pulmonary edema, and pulmonary emboli. Additionally, valvular insufficiency, constrictive pericarditis, conduction blocks, and arrhythmias may occur.

TABLE 151-2
Diseases with Both Cutaneous and Cardiac Involvement

- Joint and connective tissue diseases
  - Rheumatoid arthritis
  - Systemic lupus erythematosus
  - Reiter syndrome
  - Behçet disease
  - Systemic scleroderma
  - Dermatomyositis
  - Rheumatic fever
  - Ehlers-Danlos syndrome
  - Cutis laxa
  - Marfan syndrome
  - Periarteritis nodosa
  - Multicentric reticulohistiocytosis
- Metabolic diseases
  - Hemochromatosis
  - Amyloidosis
  - Fabry disease
  - Carcinoid tumors
  - Myxedema
  - Hyperlipidemias
  - Hyperthyroidism
- Nevoid or genetic disorders
  - Progressive lentigines (Moynahan syndrome)
  - Watson syndrome
  - Neurofibromatosis
  - Tuberous sclerosis
  - LEOPARD syndrome
  - NAME/LAMB/Carney complex
  - Danoff syndrome
- Infectious diseases
  - Varicella
  - Gonococcemia
  - Subacute and acute bacterial endocarditis
  - Chagas disease
  - Diphtheria
  - Miscellaneous (protozoal, viral, rickettsial, and bacterial infections)
- Diseases of uncertain etiology
  - Sarcoidosis
  - Whipple disease
  - Kawasaki disease
  - Degos disease

LAMB = *l*entigines, *a*trial *m*yxoma, and *b*lue nevi; LEOPARD = *l*entigines, *e*lectrocardiogram conduction defects, *o*cular hypertelorism, *p*ulmonary stenosis, *a*bnormalities of genitalia, *r*etardation of growth, and sensorineural *d*eafness; NAME = *n*evi, *a*trial *m*yxoma, and neurofibroma *e*phelides. Modified and reprinted with permission from *Dermatologic Capsule & Comment*, edited by Fitzpatrick TB. September 1987, p 9.

Variable murmurs can be an important clue. Other systemic findings include fever, cachexia, arthralgia, clubbing, hypergammaglobulinemia, and leukocytosis.

The cutaneous manifestations of atrial myxomas may be dramatic. In addition to

▲ **FIGURE 151-10** Lentiginous lesions in the atrial myxoma syndrome complex. This child has the LAMB syndrome (*l*entigines, *a*trial myxoma, *m*ucocutaneous myxomas, and *b*lue nevi).

biphasic digital color changes on cold exposure, skin lesions may simulate collagen vascular disease or vasculitis with tender, violaceous, non-blanching, annular, and serpiginous lesions of the digital pads, as well as splinter hemorrhages presenting as a systemic vasculitis or infective endocarditis. Characteristic pruritic, erythematous papules as well as cyanosis and ecchymosis of the extremities may also occur. Histologically, myxomatous emboli with large pale cytoplasm and stellate nuclei may be found among occluded blood vessels. Mucocutaneous pigmented lesions, including lentigines (Fig. 151-10), melanocytic nevi, and dermal myxomatous nodules, have been described (NAME/LAMB/Carney complex).[62]

LEOPARD SYNDROME Multiple lentigines syndrome is an autosomal dominant disorder comprising *l*entigines, *e*lectrocardiogram conduction defects, *o*cular hypertelorism, *p*ulmonary stenosis, *a*bnormalities of genitalia, *r*etardation of growth, and sensorineural *d*eafness (LEOPARD syndrome). Electrocardiographic features include axis deviation, prolonged P-R interval, bundle branch block, and complete heart block. Hypertrophic cardiomyopathy appears to be the most common anatomic abnormality. Subaortic stenosis is the most common valvular lesion.

SUBACUTE BACTERIAL ENDOCARDITIS The cutaneous manifestations of bacterial endocarditis include Osler's nodes, Janeway lesions, subungual splinter hemorrhages, cutaneous purpura and petechiae, and conjunctival petechiae (Roth's spots).

Petechiae are the most common manifestation with small, red or violaceous non-blanching macules especially on the heels, shoulders, and legs.

▲ **FIGURE 151-11** Osler's nodes (*arrows*).

Osler's nodes and Janeway lesions may both present as erythematous or hemorrhagic macules, papules, or nodules (Fig. 151-11). However, although Osler's nodes are exquisitely painful, tender, and located distally on the digital tufts, Janeway lesions are non-tender and located proximally on the palms and soles. Histologically, Osler's nodes are a perivasculitis or necrotizing vasculitis without microabscess formation or other evidence of infection or emboli, whereas Janeway lesions have been described as a vasculitis with microabscess formation. Both are found in patients with other conditions, particularly SLE, gonococcemia, hemolytic anemia, and typhoid fever.

COLLAGEN VASCULAR DISEASE AND THE HEART ***Systemic Lupus Erythematosus.*** Pericarditis may be more common in patients with drug-induced lupus or photosensitive discoid lesions. Myocarditis is often undiagnosed and may be associated with prolonged P-R intervals, heart block, and arrhythmias. Valvular heart disease in patients with SLE, most often of the Libman-Sacks type, is frequently associated with anti-phospholipid antibodies.[63] Diastolic murmurs may occur with mitral stenosis or aortic insufficiency, but the onset of a new diastolic murmur should provoke a search for subacute infective endocarditis. Splinter hemorrhages, Osler's nodes, Janeway lesions, and Roth's spots may occur in SLE *per se* without infection. SLE is associated with complete heart block in newborns because of placental transfer of maternal antibodies, especially the anti-Ro antibody.[64] The newborn infants of patients with SLE or of clinically normal but Ro-antibody–positive mothers may also have distinctive evanescent eruptions, including prominent telangiectasia and periorbital erythema.[64]

Systemic Sclerosis. Acute or chronic pericarditis is an important feature of systemic sclerosis. Pericardial effusions may be occult, and constrictive pericarditis and tamponade may occur. Additionally, small-vessel involvement of the myocardium may lead to fibrosis.[65] Fibrosis of the conduction system may cause arrhythmias and sudden death.

Respiratory System

PULMONARY ARTERIOVENOUS FISTULAS Pulmonary arteriovenous fistulas are congenital abnormalities of capillary development that may not become clinically apparent until late adolescence. Osler-Weber-Rendu disease[66] is an autosomal dominant trait, characterized clinically by punctate, linear, or spider-like telangiectasias of the skin, especially the upper body, oral and nasal mucous membranes, and nail beds (Fig. 151-12). The radiating arms surrounding an elevated punctum are the most characteristic feature, especially on the lips and tongue. They are distinguished from spider nevi in that they do not pul-

▲ **FIGURE 151-12** Osler-Weber-Rendu disease. Note the punctate and splinter-like telangiectasia on the lips and tongue.

sate. Recurrent epistaxis is the most frequent presenting symptom and may begin in early childhood or adolescence. The liver and gastrointestinal and central nervous systems can be involved (see Disorders of Both Skin and Liver), and recurrent hemorrhage may result. Bleeding may be enhanced by an associated von Willebrand disease. In those with an arteriovenous fistula of the lungs, pulmonary bruits accentuated by inspiration can be heard.

In cirrhosis, arteriovenous shunting may occur within the lungs (the hepatopulmonary syndrome),[67] liver, and extremities. These arteriovenous malformations, including spider nevi, may regress after transplantation.[68]

LARVA MIGRANS (See Chap. 207) Cutaneous larva migrans may cause mild respiratory symptoms and be associated with transient pulmonary infiltrates and a peripheral eosinophilia (Löffler syndrome). Visceral larva migrans, or toxocariasis, may lead to granulomatous involvement of the liver, lungs, heart, muscle, brain, and eyes. Marked eosinophilia, hyperglobulinemia, pneumonitis with wheezing, recurrent bronchitis, fever, and tender hepatomegaly frequently occur. Skin lesions may present as patchy urticaria or erythematous papular eruptions.

FAT EMBOLISM SYNDROME Petechiae, respiratory insufficiency, and cerebral dysfunction after long bone fracture are termed the *fat embolism syndrome*. Petechiae alone after fractures should suggest this syndrome. The petechiae are most common on the neck, axillae, shoulders, chest, and conjunctivae and often appear before other manifestations. They begin on the second or third day after injury and appear in crops. When widespread, they tend to herald more significant cerebral and pulmonary dysfunction. Histologically, fat globules are present within the dermal and pulmonary vessels. Respiratory involvement includes cyanosis, hemoptysis, and pulmonary edema. Jaundice and thrombocytopenia may occur.[69]

LIPOID PROTEINOSIS (HYALINOSIS CUTIS ET MUCOSAE) (See Chap. 137) Skin changes include confluent, waxy papules, plaques, and scarring, particularly on the face. The tongue is enlarged. Oropharyngeal and laryngeal mucous membranes are usually affected early in the course of the disease, during infancy or childhood. Hoarseness due to laryngeal infiltration is often the initial finding and may progress to obstruction and respiratory insufficiency. The trachea and main stem bronchus may be thickened and studded with warty projections.

MULTICENTRIC RETICULOHISTIOCYTOSIS (See Chap. 149) Multicentric reticulohistiocytosis is an uncommon disorder presenting with characteristic mucocutaneous lesions consisting of deeply set, firm, small papules, and a deforming arthritis in association with systemic symptoms such as fever, malaise, weight loss, and myopathy. Neurofibroma-like, soft, sessile, larger lesions have been reported as has an association with malignancy.[70] The cardiopulmonary complications include pleural effusions, pulmonary infarctions, pericarditis, angina pectoris, myocardial infarction, and congestive heart failure.

SARCOIDOSIS (See Chap. 153) Cardiac involvement in sarcoidosis may be occult and results from myocardial or conduction system granulomata. Ventricular arrhythmias and conduction disturbances present as palpitations and syncope. Congestive heart failure and chest pain occur as do cardiomyopathy or cor pulmonale. The prognosis for patients with cardiac involvement is unfavorable. Sarcoidosis affecting the pulmonary system may be suggested by lupus pernio with involvement of the hilar nodes, bronchi, and/or alveoli resulting in obstructive and/or restrictive dysfunction and respiratory failure.[71] Indwelling vascular catheters can, rarely, disintegrate into pieces that embolize into small pulmonary vessels and lymphatics, causing granulomatous changes and dyspneic symptoms. These lesions have also been reported in the skin.[72]

AMYLOIDOSIS (See Chap. 133) Systemic amyloidosis may cause waxy induration of the skin, and, when stroked, the skin may become hemorrhagic ("pinch purpura"). A biopsy of clinically normal skin might demonstrate amyloid deposition within the vessels in up to 50 percent of patients.

Cutaneous involvement occurs most often in the primary and myeloma-associated types, and therefore serves as a marker for cardiopulmonary involvement. Congestive heart failure with cardiomegaly or a restrictive cardiomyopathy occur. Pathologically, there is infiltration of the endocardium, myocardium, pericardium, valves, and coronary vessels.[73] Senile amyloidosis may also affect the heart but is often asymptomatic.

Respiratory tract involvement is also most common in primary and myeloma-associated types. Macroglossia may impede respiration; the larynx and trachea may become infiltrated, causing stridor; and bronchial and parenchymal involvement cause asthma-like symptoms.

LYMPHOMATOID GRANULOMATOSIS (See Chap. 146) Lymphomatoid granulomatosis is a rare angiocentric and angiodestructive, Epstein-Barr virus-associated B-cell lymphoproliferative disorder, varying from an indolent process to an aggressive large cell lymphoma. The skin is the extrapulmonary organ most commonly involved. The disease also affects the lungs, heart, central nervous system, and kidneys. Although many patients remain asymptomatic, cough, dyspnea, and chest pain may occur. Chest x-rays show transient infiltrates, which may progress to nodules that cavitate and cause profuse hemoptysis.

COLLAGEN VASCULAR DISEASE AND THE LUNGS The pulmonary complications of the various collagen vascular diseases may sometimes be associated with a specific cutaneous sign or constellation of features.

Rheumatoid Arthritis. Extra-articular manifestations of rheumatoid arthritis, especially in the lungs, appear to correlate with subcutaneous nodules and vasculitic skin lesions. Skin lesions are also associated with high-titer rheumatoid factor, hypocomplementemia, cryoimmunoglobulinemia, and hypereosinophilia. These occur more commonly in men with long-standing disease but may not correlate with current arthritis activity. The pulmonary symptoms include cough and hemoptysis.

Systemic Lupus Erythematosus. (See Chap. 156) Pleuritis may be present in one-half of patients with SLE, and pleural effusions also occur. Parenchymal lung involvement in SLE is usually a result of secondary factors such as infections or pulmonary emboli. Primary lung involvement in SLE may be classified as (1) diffuse interstitial pneumonitis, (2) acute pneumonitis, (3) intrapulmonary hemorrhage, (4) diaphragm dysfunction with decreased lung volume, (5) pulmonary hypertension with cor pulmonale, and (6) fibrosing alveolitis.[74]

Systemic Sclerosis. (See Chap. 158) Raynaud phenomenon, telangiectases, and dilated and distorted capillary loops of the nails are cutaneous clues. Exertional dyspnea chronic, nonproductive cough,

and pleuritic chest pain indicate lung involvement.[75] Pulmonary hypertension with cor pulmonale and congestive heart failure may develop independently of parenchymal disease. Esophageal dysmotility causing aspiration pneumonia is associated with a higher incidence of interstitial lung disease.[76]

Gastrointestinal System

On examining the abdomen in patients with cirrhosis, portal-systemic collateral vessels may be seen and are a clue to the existence of portal hypertension. Often, the umbilical vein is dilated and visible in the epigastrium, an occurrence more common than the well-recognized, but rare, caput medusae.

GASTROINTESTINAL BLEEDING Hematemesis, melena, or passing of fresh blood in the stools are signs of gastrointestinal bleeding (Table 151-3). The characteristic picture of hereditary hemorrhagic telangiectasia is of a familial pattern of epistaxis with telangiectases on mucosal surfaces (see Fig. 151-12) and arteriovenous malformations in multiple organs.[66] Hemorrhage from the gut, usually from the stomach or duodenum, occurs in up to 40 percent of patients and at an average age of 55 years.

Most cases of blue rubber bleb nevus syndrome (see Chap. 173) are sporadic, but there are families with autosomal dominant inheritance. The gastrointestinal venous malformations look and feel as their name suggests and project into the gut lumen, particularly that of the small intestine. In contrast to cutaneous lesions, they bleed easily, causing chronic anemia and, less commonly, acute hemorrhage.[77]

In the autosomal dominant vascular type of the Ehlers-Danlos syndrome, type IV, rupture of the bowel, often involving the sigmoid colon, accounts for one-quarter of all complications and 8 percent of all deaths.[1] Diverticula and hernias may also occur.

Thirteen percent of patients with pseudoxanthoma elasticum experience gastrointestinal bleeding, usually from the stomach. This is often the first clinical manifestation of the disease.[78]

The gut, particularly the small intestine, is a common site for Kaposi sarcoma. Although involvement is commonly asymptomatic, severe bleeding may occur.

Gastrointestinal bleeding in a patient with a dermatologic disease may be due to drug therapy. The systemic administration of glucocorticoids commonly causes dyspepsia; less commonly, it causes gastric erosions, ulceration, and hemorrhage. Methotrexate may cause enteritis, gastrointestinal ulceration, and hemorrhage.

ABDOMINAL PAIN (Table 151-4) Involvement of the sensory roots of the vertebrae T6-L1 in herpes zoster may produce abdominal pain even before skin lesions appear. Occasionally, herpes zoster in the distribution of S2, S3, and S4 is associated with perineal pain and disturbances of urination and defecation.

Acute attacks of urticaria or angioedema may present as abdominal pain. Edema of the bowel wall and mucosal thickening, often in association with free peritoneal fluid, is evident ultrasonographically, which avoids unnecessary surgery in acute cases.[79] This is especially true in hereditary angioedema where colicky abdominal pain and life-threatening laryngeal edema occur and require treatment with injection of purified C1 inhibitor concentrate[80] (see Chap. 37).

It is only in the rare variegate porphyria that skin involvement and attacks of abdominal pain co-exist (see Chap. 132). The skin shows changes identical to those in porphyria cutanea tarda (PCT). Pregnancy or drugs such as estrogen and griseofulvin may precipitate acute attacks. Although the detection of urinary uroporphyrin and fecal protoporphyrin indicates the diagnosis, plasma fluorescence with emission maxima at 626 nm is more sensitive in revealing the condition, even in patients who are in remission.[81]

One-third of patients with systemic mastocytosis (see Chap. 150) have gastrointestinal involvement. Symptoms include vomiting, abdominal pain, malabsorption, diarrhea, peptic ulceration, and gastrointestinal bleeding. Patients with more aggressive disease may develop hepatosplenomegaly with ascites and lymphadenopathy.[82–85]

Anderson-Fabry Disease (Angiokeratoma Corporis Diffusum). (See Chap. 136) Anderson-Fabry disease is a rare X-linked recessive multisystem lysosomal storage disorder caused by a deficiency of α-galactosidase A. Signs include severe, painful neuropathy; and progressive renal, cardiovascular, and cerebrovascular dysfunction. Gastrointestinal symptoms include abdominal pain and diarrhea. The diagnosis may be missed without the skin signs. Angiokeratomas may not appear until adolescence and, even then, can be subtle. Assay of α-galactosidase A is possible not only in established cases, but also before birth, and female carriers often are identifiable. Treatment with intravenous infusions of α-galactosidase A is safe and efficacious.[86]

Vasculitis. (See Chaps. 164 and 165) Henoch-Schönlein purpura is palpable, especially on the legs and buttocks, and may occur in conjunction with joint swelling. Up to 76 percent of patients have gastrointestinal involvement, ranging from colicky abdominal pain, nausea, and vomiting to bloody diarrhea, intussusception, and pancreatitis. Renal involvement is common, especially in patients with bloody stools.[87] Upper gastrointestinal endoscopy reveals multiple raised erythematous lesions or ulceration that resolves after systemic treatment with glucocorticoids.[88]

- Gastrointestinal tumors
  - Metastases
  - Dermatomyositis
  - Acanthosis nigricans
  - Hypertrichosis lanuginosa

Malignant atrophic papulosis is an idiopathic, systemic, obliterative vasculopathy. The characteristic skin lesions are recurrent crops of porcelain-white atrophic papules with an elevated erythematous border. These may have been present for years with no other apparent disease, although gut vessels are involved in half of the cases.[89] Clinically bleeding, abdominal pain, diarrhea, malabsorption, and bowel perforation with peritonitis occur.

Polyposis. True polyps are rare except in the colon and rectum. Polyp-like lesions that are hamartomatous or inflammatory occur in all parts of the gut. The term *hamartoma* implies a non-neoplastic tumor composed of tissue elements normally present in that organ. The hamartomatous polyposis syndromes (e.g., Peutz-Jeghers, Cronkhite-Canada) should be distinguished from the adenomatous polyposis syndromes (e.g., Gardner). In many of these syndromes, hamartomatous polyps of the gastrointestinal tract coexist with adenomas, and adenomas may develop within hamartomatous polyps, contributing to the frequent occurrence of adenocarcinoma in most of these syndromes.[90]

Gardner syndrome is an autosomal dominant disorder characterized by cutaneous cysts and pre-malignant adenomatous polyps, particularly in the colorectum. Duodenal and hepatic carcinoma can also occur. The cutaneous lesions frequently pre-date the gastrointestinal lesions and include solitary or multiple epidermoid cysts, fibromas, lipomas, pilomatricomas, facial osteomas, and distinctive ocular lesions.[91]

Peutz-Jeghers syndrome is autosomal dominant and characterized by small, darkly pigmented macules around the mouth, on the lips, buccal mucosa, and digits. A histologically unique type of hamartomatous polyp occurs, mainly in the small intestine, which predisposes to recurrent intussusception. Bleeding is relatively rare, but up to 2 percent of patients develop adenocarcinoma of the stomach, duodenum, and colon.[90] There is also an increased risk of malignancy in general.[92]

In Cronkhite-Canada syndrome, there is patchy alopecia and characteristic nail changes.[90] Inflammatory polyps are present in the stomach and bowel, and abdominal pains with a severe protein-losing enteropathy are common.

Both ulcerative colitis and Crohn disease present with abdominal pain, gastrointestinal bleeding, or diarrhea. Ulcerative colitis predisposes to carcinoma of the colon. The skin complications of the two diseases are similar, although some occur with different frequencies. Up to one-half of patients with pyoderma gangrenosum may have inflammatory bowel disease, although only 12 percent of patients with ulcerative colitis and 2 percent of patients with Crohn disease will develop the condition.[93] The severity and extent of ulceration in pyoderma gangrenosum may be linked to the activity of the underlying disease, and pyoderma gangrenosum can heal with effective treatment of the underlying bowel disease. Erythema nodosum is well recognized.

Oral granulomatous nodules are common in Crohn disease, where they may coalesce to give a "cobblestone" appearance. Crohn disease is one cause of granulomatous cheilitis, which may predate bowel disease by several years. Granulomas may also occur in the perineum, at colostomy and ileostomy sites, and in association with scars, sinuses, and fistulas. Very rarely, granulomas occur at sites not contiguous with the bowel, such as the trunk and limbs: the so-called *"metastatic" cutaneous Crohn disease*.[94] Aphthous ulcers may be a presenting feature. Bruising of the skin around the umbilicus (Cullen's sign) or in the flanks (Grey Turner's sign) are well-known features of acute pancreatitis, but occur in less than 3 percent of cases.[95] Chronic pancreatitis may cause tender, subcutaneous nodular areas of fat necrosis that may ulcerate.

GASTRIC BYPASS SURGERY Gastric bypass surgery or reduction with jejunoileal and jejunocolic anastomoses is used to treat morbid obesity. Dryness of the skin, hair loss, recurrent fever, arthralgia, and inflammatory and vasculitic skin lesions have been reported postoperatively. "Bowel bypass syndrome without bowel bypass" is recognized as the same constellation of symptoms but with other gastrointestinal disorders.[96]

CUTANEOUS EFFECTS OF MALABSORPTION OF SPECIFIC NUTRIENTS (See Chap. 130) Vitamin deficiency can follow intestinal surgery, pancreatic disease, malabsorption syndromes, and malnutrition, including malnutrition associated with alcoholism (Table 151-5).[35]

- Vitamin A deficiency causes xerotic wrinkled skin covered with fine scales, occasionally accompanied by deep erosions (dermomalacia).

TABLE 151-5
Malabsorption and Skin Disease

- Skin changes due to malabsorption
  - Non-specific
    - Acquired ichthyosis and pruritus
    - Hair and nail changes

    - Zinc
    - Essential fatty acids
    - Vitamins
- Malabsorption due to skin disease
  - Dermatogenic enteropathy
  - Collagen vascular disease
  - Dermatitis herpetiformis and celiac disease

- Deficiency of vitamin B_3 causes pellagra with its triad of diarrhea, dermatitis, and dementia.
- Vitamin B_{12} (cyanocobalamin) deficiency is common in ileal malabsorption syndromes such as pancreatic disease. There is a symmetric "glove and stocking" hyperpigmentation, but a lemon yellow pallor to the skin elsewhere.
- Vitamin C deficiency classically causes follicular keratoses, hemorrhage, and corkscrew hairs.
- Malabsorption of vitamin K occurs in obstructive jaundice and leads to impaired coagulation, resulting in cutaneous hemorrhage with ecchymoses and purpura.
- A diffuse hyperpigmentation, cheilitis, and perineal ulceration or dermatitis can occur in folic acid deficiency states. Theoretically, drugs used for dermatologic diseases such as methotrexate, a folate antagonist, can exacerbate folic acid deficiency.
- Iron deficiency presents with angular stomatitis, smooth painful tongue, and fragile/brittle nails, which have longitudinal ridging and lamellation. In marked iron deficiency, anemia koilonychia, a spoon-like convexity of the nails, develops. Hair changes include diffuse scalp alopecia with brittle, split hairs. All take a long time to resolve on replacement therapy.
- Zinc deficiency can result from acrodermatitis enteropathica, malabsorption, or a lack of zinc in long-term parenteral nutrition. Acrodermatitis enteropathica usually presents at weaning or in very early infancy

with dermatitic or vesicobullous lesions of the hands, on the feet, and around the mouth and anus, together with progressive alopecia and "failure to thrive."

MALABSORPTION DUE TO SKIN DISEASE Malabsorption can result from poor intestinal peristalsis in systemic sclerosis or chronic obliteration of mesenteric vessels in polyarteritis and other forms of vasculitis. In diffuse scleroderma and systemic sclerosis, 8 percent of patients develop malabsorption or recurrent intestinal pseudo-obstruction, usually within 3 years of disease onset.[65,97] Vasculopathy interferes with peristalsis and leads to malabsorption by allowing bacterial colonization higher up the bowel than is usual.

Small-bowel tumors produce a variety of hormones and vasoactive amines, of which the best characterized is serotonin. The most common tumors are in the appendix, rectum, and ileum, where they are usually multiple. Episodic flushing, wheezing, or diarrhea does not occur until the vasoactive amines reach the systemic circulation. Therefore, flushing usually indicates metastasis to the lymph nodes or liver or a primary tumor at a different site (e.g., lung or ovary).[98,99]

Hepatobiliary System

Skin lesions occurring in association with liver disease are usually not specific to a particular disease. The most florid cutaneous lesions appear in patients with chronic active hepatitis or alcoholic liver disease, but may also occur in physiologic states, such as spider nevi, in pregnant women. There may be no visible skin changes in patients with severe liver disease and, conversely, dramatic cutaneous manifestations may develop in those with minimal hepatic dysfunction.

HEPATITIS AND THE SKIN Cutaneous striae may appear in patients with chronic hepatitis, whatever the underlying cause and even before glucocorticoid therapy (see Fig. 151-1). Pyoderma gangrenosum, urticaria, vasculitis, acne, scleroderma, and splinter nail hemorrhages occur, depending on the underlying cause of the hepatitis.

The clinical features of infection with the different hepatotropic viruses that cause acute viral hepatitis are similar. In the pre-icteric phase, malaise, lethargy, nausea, and abdominal pain occur. A discrete, transient, maculopapular, urticarial, or petechial rash may develop, together with arthritis or arthralgia. These symptoms may worsen with the appearance of jaundice, dark urine, and pale stools. Malaise and fatigue may persist for some time after resolution of the disease.

Hepatitis A. Transmission of hepatitis A virus takes place via the fecal-oral route. Although relapses occur, hepatitis A does not progress to chronic hepatitis.

Hepatitis B. Hepatitis B virus (HBV) is transmitted by percutaneous and permucosal routes. It is endemic in many countries, and health care professionals are at risk. A recombinant DNA vaccine is available, but has been associated with cutaneous side effects.[100–102] Five percent of HBV-infected subjects become carriers, and 90 percent of infants born of infected mothers develop chronic infection.

There are four main cutaneous associations of hepatitis B: (1) a serum sickness-like syndrome, (2) cryoglobulinemia, (3) polyarteritis nodosa, and (4) papular acrodermatitis of childhood. The serum sickness-like syndrome occurs in approximately 10 percent of patients in the pre-icteric phase of acute hepatitis B infection. Urticaria may be the predominant or sole feature, but is usually accompanied by a low-grade fever, arthralgia of the peripheral joints, proteinuria, and hematuria. There may be vasculitis.

Both HBV and hepatitis C virus (HCV) infection are associated with cryoglobulinemia, although HCV infection is more common. Mixed cryoglobulinemia in HCV infection is usually of type III,[103] and the cryoglobulinemia may indicate the presence of active viral replication.[104] Patients develop recurrent purpura, acrocyanosis, arthralgia, lymphadenopathy, peripheral neuropathy, and hepatosplenomegaly. Renal involvement is common. Histopathologically, there is a necrotizing vasculitis.[104]

Polyarteritis nodosa can occur in the acute phase of HBV infection, or it may not present for several years. Circulating immune complexes containing hepatitis B surface antigen and immunoglobulin occur. Leukocytoclastic vasculitis may develop.

Papular acrodermatitis (Gianotti-Crosti syndrome) usually affects children. The appearance of monomorphic, flat-topped, erythematous papules on the face and limbs is characteristic. This eruption is self-limiting and asymptomatic in most, but may be accompanied by lymphadenopathy.[105] Other infectious agents and immunizations have been implicated in papular acrodermatitis.[106] Sweet syndrome has recently been reported with both acute[107] and chronic HBV infection.

Hepatitis C. The majority of cases of posttransfusion hepatitis have been due to HCV infection, but screening has reduced the number of new cases dramatically. Cutaneous manifestations of acute and chronic HCV infection include leukocytoclastic vasculitis, usually due to cryoglobulinemia (see Hepatitis B); cutaneous necrosis[104]; pruritus[108]; acquired angioedema[109]; PCT; erythema nodosum; urticaria; erythema multiforme; and polyarteritis nodosa.[110]

Lichen planus occurs more commonly in patients infected with HCV,[111] although studies disagree on the incidence.[112] There is an increased frequency of the HLA-DR6 allele in Italian patients with HCV-associated oral lichen planus,[113,114] suggesting that host factors may play a part in this association.

DISORDERS OF BOTH SKIN AND LIVER (Table 151-6) Argininosuccinic aciduria is a rare autosomal recessive disorder characterized by ataxia, seizures, severe mental retardation, hepatomegaly with liver dysfunction, and brittle hair. Dermatomyositis may be the presenting sign of a primary[115] or secondary hepatic tumor. In eruptive neonatal angiomatosis, multiple angiomas may occur anywhere on the skin surface; in addition, vascular lesions may occur in internal organs, including the liver. Both acute and chronic phases of graft-versus-host reactions may have prominent effects on both skin and liver, most commonly in patients receiving bone marrow transplants. In hereditary hemorrhagic telangiectasia, arteriovenous fistulas can cause shunting, and "cirrhosis" (i.e., multiple small telangiectatic hepatic vessels) occurs.[66] Several of the histiocytoses, including Langerhans cell histiocytosis and malignant histiocytosis, may involve both skin and liver. Immunodeficiency states may result in multiple infections of skin and liver. Examples include congenital disorders (e.g., ataxia-telangiectasia, Chédiak-Higashi syndrome, chronic granulomatous disease) and acquired disorders (e.g., acquired immunodeficiency syndrome).

Hepatomegaly occurs in systemic mastocytosis.[82–85] In Kawasaki disease, children may develop upper abdominal pain associated with hepatobiliary

TABLE 151-6
Diseases with Both Cutaneous and Hepatic Involvement

changes, non-specific elevation of liver enzyme levels due to vasculitic changes, or bile duct inflammation.[116] Sarcoidal infiltration of the liver may accompany the cutaneous signs of sarcoidosis. Hepatic granulomas may also occur in tuberculosis, glandular fever, and syphilis, or as a side effect of drugs such as phenylbutazone, allopurinol, and the sulfonamides. True syphilitic hepatitis is rare and presents with pruritus and cholestatic jaundice.

Patients with SLE can have abnormal liver tests.[117] The most common cause is drug-induced hepatitis. Thrombotic conditions, including Budd-Chiari syndrome and venoocclusive disease, occur with or without lupus anticoagulant. Rare abnormalities include nodular regenerative hyperplasia, perihepatitis, and hepatic or splenic rupture. Autoimmune hepatitis, PBC,[118] granulomatous hepatitis, cryptococcal infection, porphyria, or idiopathic portal hypertension[119] may also occur.

Cholestatic hepatitis occurs as a rare complication of Stevens-Johnson syndrome and may precede the skin signs.[120]

Angiomyolipomas are frequently seen on ultrasound examination of the livers of patients with tuberous sclerosis, but are usually asymptomatic. Liver function abnormalities are common in patients with vinyl chloride disease and may be associated with hepatosplenomegaly, cirrhosis, and, rarely, angiosarcoma.

Cutaneous Manifestations of Primary Biliary Cirrhosis. The basis for a diagnosis of PBC is a clinical picture of a middle-aged female with jaundice and pruritus, cholestatic liver function tests, antimitochondrial antibodies, and histologic changes in the liver of inflammatory duct destruction with fibrosis and cirrhosis. Severe itching may antedate other features of biliary cirrhosis by months or years.

The combination of the CREST syndrome (*c*alcinosis cutis, *R*aynaud phenomenon, *e*sophageal dysfunction, *s*clerodactyly, and *t*elangiectasia) and PBC occurs more often than would be expected by chance and has been termed *Reynolds syndrome*. Patients have a higher incidence of anticentromere antibodies (especially the antiprotein C isotype) and Sjögren syndrome.[121]

Lichen planus has a well-recognized association with PBC and may occur in either the presence or the absence of penicillamine treatment for PBC. It can resolve following liver transplantation.[122] Cutaneous xanthomas also occur with PBC. Rarely, both lichenoid and xanthomatous changes appear in the same lesion.[123]

EFFECTS OF SKIN DISEASE ON THE LIVER

Several systemic complications occur as a consequence of skin disease, and some of them reflect abnormalities of hepatic function.

Extensive Loss of Skin. Patients may lose large areas of skin because of thermal burns, immunobullous disease, or toxic epidermal necrolysis. In experimental animal models, extensive thermal injury results in a halving of the hepatic arterial blood flow.[124] Postburn sepsis amplifies this injury and induces portal hypertension.[125] This may, in turn, account for a gut barrier dysfunction (the so-called *dermatogenic enteropathy*), but research has not convincingly demonstrated this relationship in humans with extensive skin disease.

Psoriasis. The high incidence of abnormalities of the liver architecture in patients with psoriasis has been attributed to alcohol misuse. Psoriasis is more common than expected in alcoholic cirrhosis than in cirrhosis due to other causes.[8,126] Those who misuse alcohol are said to have a unique, acral, distribution of psoriasis.[8] Alcohol appears not only to trigger psoriasis, especially in men, but also to influence the course of the disease, as heavy drinkers have more severe, extensive, inflamed disease. Patients who decrease alcohol consumption may decrease the extent of their disease and increase their response to treatment.[126]

Dermatitis Herpetiformis. Results of liver function tests are sometimes abnormal in patients with dermatitis herpetiformis[127] and can also occur secondary to treatment or as a result of associated conditions.[128]

Skin Cancer. Primary cutaneous neoplasms, including melanoma, squamous cell carcinoma, Merkel cell tumor, and Kaposi sarcoma, occasionally metastasize to the liver.

HEPATOTOXIC EFFECTS OF DRUGS USED IN THE TREATMENT OF SKIN DISEASE

Several drugs used in managing patients with skin disease are hepatotoxic (Table 151-7). Many others, such as antimalarials or terbinafine, warrant caution in patients with hepatic impairment.

Patients who have psoriasis and who are undergoing long-term treatment with methotrexate have a high frequency of liver fibrosis and cirrhosis,[129] especially if their total doses exceed 1.5 g (see Chaps. 18 and 228). Those with a history of alcohol misuse, impaired renal function, diabetes, and obesity are at higher risk. Diagnosis of fibrosis is histologic and requires liver biopsy. The morbidity of liver biopsy can be as high as 10 percent, and the mortality up to 0.1 percent.[130] In hepatic fibrosis, the synthesis of predominantly type III collagen is increased, and the amino terminal propeptide of type III procollagen (PIIINP) is cleaved off and released into the circulation.[131,132] Because it is now possible to measure serum PIIINP levels accurately, this test has become a valuable non-invasive marker of active hepatic fibrogenesis during methotrexate treatment of psoriasis.[133] Thus, the number of liver biopsies taken in patients with normal serial serum PIIINP levels can be reduced to a minimum.[134]

Renal System

The cutaneous manifestations of renal disease are primarily encountered in patients with CRF. In contrast, only two skin changes—edema and uremic frost—occur in acute renal failure (ARF). Edema is a particular feature of ARF with nephrotic syndrome. Uremic frost results from eccrine deposition of urea crystals on the skin surface of individuals with severe uremia. It is now rare

TABLE 151-7
Hepatotoxic Drugs Used in the Treatment of Skin Diseases

Drug	Indication	Side Effect
Azathioprine	Bullous disorders, dermatomyositis	Raised liver enzymes
Cyclosporin	Psoriasis, dermatitis	Raised liver enzymes
Cyproterone acetate	Hirsutism and virilization	May worsen pre-existing dysfunction
Danazol	Hereditary angioedema	May worsen pre-existing dysfunction and porphyria
Dapsone	Dermatitis herpetiformis, erythema elevatum diutinum, granuloma faciale, and others	May cause dapsone syndrome (rash, eosinophilia fever hepatitis). Avoid in porphyria
Griseofulvin	Fungal infections	May worsen pre-existing liver disease
Ketoconazole	Fungal infections	Raised liver enzymes and hepatitis
Methotrexate	Psoriasis, sarcoidosis	Cirrhosis
Minocycline	Acne	Hepatitis
Retinoids	Acne, psoriasis, disorders of keratinization	Elevated liver enzymes, increases hepatotoxicity of methotrexate
Stanozolol	Hereditary angioedema	May worsen pre-existing dysfunction and porphyria
Terbinafine	Fungal infections	Hepatitis

because of the wide availability of acute hemodialysis.

CALCIFICATION Metastatic calcification of the skin in CRF results from secondary or tertiary hyperparathyroidism. Abnormally elevated levels of PTH may trigger deposition of crystalline calcium pyrophosphate in the dermis, subcutaneous fat, or arterial walls.[135] Vascular calcification is common in patients with long-term CRF and seldom symptomatic. Occasionally, however, calcified vessels may thrombose acutely, resulting in a syndrome that has been called *calciphylaxis*. This acute thrombosis produces livedoid areas that are excruciatingly painful due to ischemia, and quickly become hemorrhagic and ulcerate (Fig. 151-13). Calciphylaxis is associated with a high mortality, particularly when the skin of the trunk is involved.[135] PTH is usually markedly elevated. The serum calcium and phosphate levels, and the calcium-phosphate product, are frequently only minimally elevated and may be normal. Treatment of calciphylaxis includes analgesia débridement of gangrenous tissue, and parathyroidectomy.[135,136]

In addition to vascular calcification and calciphylaxis, nodular calcification may occur in the skin and fat of patients with CRF. These calcium deposits are identical to calcinosis cutis in other disorders such as tumoral calcinosis or CREST syndrome. The involved skin may ulcerate, but this process occurs in a subacute fashion, without livedo or ischemic pain.

BULLOUS DISEASE OF HEMODIALYSIS (See also Chaps. 91 and 132) PCT has been described in patients with CRF undergoing hemodialysis.[137] Although the etiology of this phenomenon is still unclear, inadequate clearance of plasma-bound porphyria precursors by urine excretion or hemodialysis[138] may lead to porphyrin deposition in the skin manifested clinically as photosensitivity and subepidermal bullae.[139–141] Patients undergoing hemodialysis may also produce or be exposed to compounds that alter normal heme synthesis.

Bullous dermatosis of dialysis or pseudoporphyria may occur in up to one-fifth of patients undergoing hemodialysis[137,139,141] This condition is often clinically indistinguishable from PCT with marked skin fragility and blister formation on sun-exposed skin. However, hypertrichosis is less common, and plasma porphyrin levels are typically normal.[137,139] Pseudoporphyria may also occur in some patients taking tetracycline, nabumetone, nalidixic acid, furosemide, and phenytoin.[139]

When treating PCT or pseudoporphyria, phlebotomy can reduce iron levels in the liver, allowing new hepatic uroporphyrinogen decarboxylase to be formed.[142] However, patients with end-stage renal disease often have significant anemia and cannot tolerate phlebotomy. Intravenous erythropoietin[141] may both lower total body iron stores and support phlebotomy as needed.[140,142] Chloroquine effectively clears porphyrins from the liver. In patients with CRF, however, porphyrins may not be effectively cleared by hemodialysis or excreted in the urine.[141] Deferoxamine may lower serum porphyrin levels in some patients.[140] Others may require renal transplantation to obtain complete resolution of symptoms.[140]

ACQUIRED PERFORATING DERMATOSES (See Chap. 67) Acquired perforating dermatosis can occur in association with CRF and diabetes mellitus.[143] This condition occurs in up to 10 percent of patients undergoing hemodialysis[47,144,145] and appears to be distinct from the four primary perforating disorders: elastosis perforans serpiginosa, Kyrle disease, perforating folliculitis, and reactive perforating collagenosis.[146] Clinically, patients develop hyperkeratotic papules with a central, crust-filled crater on the trunk and extensor surfaces, often in a linear distribution.[144] Simultaneous trans-epidermal elimination of both collagen and elastic fibers has been detected.[145]

Proposed mechanisms for the etiology of this process include diabetic microangiopathy, dysregulation of vitamin A or vitamin D metabolism, abnormality of collagen or elastic fibers, or inflammation and connective tissue degradation caused by dermal deposition of substances such as uric acid and calcium pyrophos-

◀ **FIGURE 151-13** Calciphylaxis. (Used with permission from Suzanne N. Granados, MD.)

phate.[147] Many authorities regard this entity as a response to trauma caused by scratching in chronic renal pruritus. Successful treatment depends on addressing the underlying etiology of pruritus. Topical and intralesional glucocorticoids, topical and systemic retinoids, cryotherapy, and ultraviolet light may be useful.[144,145]

NEPHROGENIC FIBROSING DERMOPATHY Nephrogenic fibrosing dermopathy (NFD), a recently described disorder,[148] resembles scleromyxedema in some of its aspects.[149] To date, NFD has been found only in patients with renal disease. Most affected individuals have been on hemodialysis, and many have restarted dialysis after failure of a renal transplant. NFD also has been described in a few patients with ARF. Clinically, patients progressively develop erythematous, sclerotic dermal plaques on the arms and legs, with sparing of the head and neck. Pruritus is a common feature. The histopathology of NFD similarly resembles that of scleromyxedema, with proliferation of fibroblasts in the dermis and subcutaneous septae, accompanied by increased dermal and septal collagen and mucin.[150] The etiology of NFD is unknown. All patients described have had persistent disease (even though renal failure resolved in some cases).

Lower Limbs

In acquired clotting defects, such as thrombocytopenia and vascular fragility, purpuric lesions, ranging from pinpoint-sized spots to large ecchymoses, occur. They may be transient and recurrent, and they are sometimes accompanied by follicular hyperkeratosis.[3]

CHOLESTEROL EMBOLI In patients with advanced atherosclerosis of the abdominal aorta, cholesterol crystals may microembolize to the lower extremities, particularly after invasive vascular procedures or surgery. The pulses may remain normal. Patients complain of pain in the legs, buttocks, and low back, as well as myalgia, restless legs, and abdominal symptoms. Livedo reticularis may affect the lower abdomen and back, buttocks, and legs. Ulcers on the legs and feet, surrounded by an erythematous or violaceous halo and a small scab, may be present. Digital cyanosis and gangrene may simulate necrotizing vasculitis (Fig. 151-14). Indurated plaques and nodules are firm, violaceous, painful, and necrotic in the center. Deep skin biopsy of areas of livedo reticularis or adjacent to nodules or ulceration reveal occlusions of arterioles by multinucleated, foreign-body, giant cells and fibrosis surrounding biconvex, needle-shaped clefts corresponding to the cholesterol crystal microemboli.[151]

◀ **FIGURE 151-14** Cholesterol emboli: blue toe and infarctions.

POSTBYPASS SKIN CHANGES Coronary artery bypass surgery is commonly performed using the superficial veins of the legs as donor-graft sites. Dermatitis has been reported to occur along the saphenous vein graft scars on the medial aspect of the legs 2 to 6 months after surgery. Patients have no history of venous stasis, thrombophlebitis, ankle edema, or skin disease. Examination reveals a reddish-brown, scaling and fissured dermatitis along the distal part of a well-healed saphenous vein graft scar. The dermatitis responds to topical steroids, but recurrence is usual, and most patients require continued treatment. The cause may be due to postoperative thrombophlebitis and stasis dermatitis.

Recurrent cellulitis may develop in the healed vein graft many months after surgery. Erythema may extend along the entire vein graft site, accompanied by pain and tenderness. Swelling may be significant. β-Hemolytic streptococcus has been isolated. The presence of tinea pedis has been reported, and patients should be assessed and treated before surgery.

DIABETES MELLITUS

Epidemiology

Diabetes mellitus (DM) is a major cause of morbidity and mortality in the United States. More than 19 million Americans have the disease, and approximately 11 percent ($92 billion) of all health care expenditures in the United States were directly attributable to the medical care of diabetes in 2002.[1,2] Men and women diagnosed with diabetes at age 40 years are expected to lose 12 and 14 life-years, respectively.[3] Of great importance, major studies show that tight glycemic control decreases retinopathy, neuropathy, nephropathy, and, possibly, coronary artery disease, all of which remain the major contributors to morbidity and mortality.[4,5] Likewise, tight glycemic control may have a beneficial effect on a subset of skin-related, diabetes-associated disorders.

Diabetes is characterized by a state of relative or complete insulin deficiency, leading to gross defects in glucose, fat, and protein metabolism. In type 1 diabetes (formerly insulin-dependent DM), an insufficiency of insulin occurs through a gradual, immune-mediated destruction of β islet cells in the pancreas, marked by autoantibodies. In type 2 diabetes (formerly non–insulin-dependent DM), chronic hyperglycemia occurs mainly through end-organ insulin resistance followed by a progressive decrease in pancreatic insulin release associated with aging. A fasting blood glucose level of ≥ 126 mg/dL or a random value of ≥ 200 mg/dL on two separate occasions confirms the diagnosis of diabetes. A genetic predisposition and a strong association with obesity exist in type 2 diabetes. In both types of diabetes, abnormalities of insulin and elevated blood glucose levels lead to metabolic, vascular, neuropathic, and immunologic abnormalities. Affected organs include the cardiovascular, renal, and nervous systems, the eyes, and the skin.

DIABETES MELLITUS AT A GLANCE

- The incidence of diabetes in America is increasing steadily with the epidemic of obesity.
- Eleven percent of health care expenditures in America are diabetes related.
- Metabolic abnormalities in glucose and insulin relate directly to diabetic thick skin, limited joint mobility, eruptive xanthomas, and acanthosis nigricans.
- Neuropathy, vasculopathy, and immune dysfunction associated with diabetes contribute directly to lower extremity ulcers and certain cutaneous infections.
- Diabetes-associated skin conditions without a known pathogenesis include: necrobiosis lipoidica, granuloma annulare, diabetic dermopathy, acquired perforating dermatosis, and bullosis diabeticorum.

Etiology and Pathogenesis

Nearly all patients with diabetes have cutaneous findings related to their condition, including those listed in Table 152-1. Some diabetes-associated skin conditions are a direct result of the related metabolic changes such as hyperglycemia and hyperlipidemia. Progressive damage to the vascular, neurologic, or immune systems also contributes significantly to skin manifestations. The mechanisms for other diabetes-associated skin conditions remain unknown.

Hyperglycemia leads to nonenzymatic glycosylation (NEG) of various structural and regulatory proteins, including collagen. Although NEG occurs normally with aging, the process is greatly accelerated in diabetes.[6,7] NEG leads to the formation of advanced glycation end products (AGEs) that are responsible for decreases in both acid solubility and enzymatic digestion of cutaneous collagen. Disorders such as diabetic thick skin and limited joint mobility (LJM) are thought to result directly from accumulation of AGEs.[8] Studies show that the degree of cutaneous AGEs correlates strongly with retinopathy, nephropathy, and other microvascular complications of diabetes.[9]

Derangements of immunoregulatory mechanisms also occur in diabetes. Hyperglycemia and ketoacidosis diminish chemotaxis, phagocytosis, and bactericidal ability of white blood cells.[10] Historically, infections were a major cause of death in the diabetic patient. This has changed dramatically with improved glucose control and antibiotic use. Despite these improvements, certain infections, such as malignant external otitis, necrotizing soft tissue infections, and the devastating disease of mucormycosis, occur more frequently in patients with diabetes.[11]

TABLE 152-1
Approach to Patient with Diabetes

Cutaneous findings in diabetes
- Acanthosis nigricans
- Limited joint mobility and scleroderma-like syndrome
- Scleredema diabeticorum
- Eruptive xanthomas
- Bacterial infections (streptococcal, malignant external otitis, necrotizing fasciitis)
- Fungal infections (candidal, onychomycosis, mucormycosis)
- Foot ulcers
- Necrobiosis lipoidica
- Granuloma annulare
- Diabetic dermopathy
- Acquired perforating disorders
- Bullosis diabeticorum

Related features
- Retinopathy
- Nephropathy
- Neuropathy
- Cardiovascular disease
- Peripheral vascular disease
- Hyperlipidemia
- Hypertension

Diagnosis
- In the absence of symptoms, the diagnosis must be confirmed by two separate abnormal tests, fasting blood glucose of ≥ 126 mg/dL or random value of ≥ 200 mg/dL.
- Hemoglobin A1C is increasingly being used in conjunction with fasting plasma glucose for the diagnosis of diabetes mellitus.

Management
- Diet and exercise.
- Referral to primary care provider or endocrinologist for medical management with either oral hypoglycemic agents or insulin.
- Always perform a foot examination.
- Address modifiable risk factors.

Metabolic abnormalities, including hyperinsulinemia, as is seen in early insulin-resistant type 2 diabetes, can contribute to cutaneous manifestations as well. The action of insulin on the insulin-like growth factor-1 (IGF-1) receptor appears to mediate the abnormal epidermal proliferation and resulting phenotype of acanthosis nigricans.[12] Dysregulated lipid metabolism occurs with diabetes-associated insulin deficiency. The activity of lipoprotein lipase (LPL) is directly dependent on insulin,[13] making insulin central to the processing of triglyceride-rich chylomicrons and very-low-density lipoproteins. In insulin-deficient diabetic patients, defective lipid processing can lead to massive hypertriglyceridemia, manifesting in the skin as eruptive xanthomas. Naturally, disorders of lipid processing also play an integral role in the vasculopathies of diabetes.

Macro- and microangiopathy contribute significantly to the cutaneous complications of diabetes. In patients with diabetes, there is increased "leakiness" or vessel wall permeability, decreased vascular responsiveness to sympathetic innervation, and less ability to respond to thermal and hypoxemic stress.[10] In combination with arteriosclerosis of large vessels, these microvascular abnormalities contribute to the formation of diabetic ulcers. In addition, a loss of cutaneous sensory innervation occurs with diabetes, predisposing patients to infection and injury. The loss of neuroinflammatory cell signaling plays a causal role in non-healing, lower extremity ulcers.[14] Patients with diabetes who lack lower extremity vibratory perception have a 15.5-fold increased probability of leg amputation.[15]

The cutaneous disorders associated with DM are characterized in the following section by disorders with evidence for metabolic, vascular, neurologic, or immunologic pathogenesis induced by glucose and insulin abnormalities and by disorders associated with diabetes, but without a clear pathogenesis (see Cutaneous Disorders of Diabetes Mellitus Associated with Metabolic, Vascular, Neurologic, or Immunologic Abnormalities).

CUTANEOUS DISORDERS OF DIABETES MELLITUS ASSOCIATED WITH METABOLIC, VASCULAR, NEUROLOGIC, OR IMMUNOLOGIC ABNORMALITIES

Acanthosis Nigricans (See Chap. 154)

EPIDEMIOLOGY Acanthosis nigricans is probably the most readily recognized skin manifestation of diabetes. Acanthosis nigricans is common in the general population, and most cases are linked to obesity and insulin resistance. In some cases, increased androgen production is also identified.[16,17] Drug-related and idiopathic acanthosis nigricans or familial acanthosis nigricans have been reported.[18] In general, though, acanthosis nigricans should be considered a prognostic indicator for developing type 2 diabetes.[19] In a large, population-based study from Galveston, Texas, acanthosis nigricans was present in 7 percent of school-age children.[17] This percentage increased to 66 percent of children who weighed 200 percent of their ideal body weight. In this study, fasting insulin levels correlated with the presence and severity of skin findings. The rate of acanthosis nigricans varies among different ethnic groups. In the Galveston study, despite similar obesity rates, the prevalence was lower in whites (0.5 percent) and Hispanics (5 percent) than in African American children (13 percent).[17] This finding suggests a possible genetic predisposition or increased sensitivity of the skin to hyperinsulinemia among certain populations.[19] Although historical data have emphasized the relationship between acanthosis nigricans and malignancy, a true association is rare. Only when the onset is particularly rapid, the clinical findings are florid, or in the non-obese or non-diabetic adult with acanthosis nigricans is an evaluation for malignancy beyond routine age appropriate screening warranted (see Chap. 154). In one author's experience with seeing more than 12,000 patients with cancer, only two developed acanthosis nigricans.[20]

ETIOLOGY AND PATHOGENESIS Advances are taking place in understanding the pathogenesis of acanthosis nigricans. Insulin clearly plays a central role in the presentation of acanthosis nigricans. In a subset of women with hyperandrogenism and insulin resistance with acanthosis nigricans, loss of function mutations in the insulin receptor or anti-insulin receptor antibodies can be found (type A and type B syndrome).[21] It is postulated that excess growth factor stimulation in the skin causes the aberrant proliferation of keratinocytes and fibroblasts that results in the phenotype of acanthosis nigricans.[16] In states of insulin resistance and hyperinsulinemia, acanthosis nigricans may result from excess insulin binding to IGF-1 receptors on keratinocytes and fibroblasts.[12] IGF-1 receptors are expressed on basal keratinocytes and are upregulated in proliferative conditions.[22] Studies show that high concentrations of insulin stimulate fibroblast proliferation through IGF-1 receptors in vitro.[23] Other members of the tyrosine kinase receptor family, including the epidermal growth factor receptor and the fibroblast growth factor receptor, have been implicated in acanthosis nigricans. Several genetic syndromes [Crouzon and SADDAN (*s*evere *a*chondroplasia with *d*evelopmental *d*elay and *a*canthosis *n*igricans)] with mutations in fibroblast growth factor receptor 3 result in acanthosis nigricans in the absence of hyperinsulinemia or obesity. Implicating this growth factor receptor in the pathogenesis of acanthosis nigricans.[22] In several reports of acanthosis nigricans associated with malignancy, evidence suggests that transforming growth factor-β released from the tumor cells may stimulate keratinocyte proliferation via the epidermal growth factor receptors.[24,25] Support for the role of different growth factors in the pathogenesis of acanthosis nigricans continues to accrue.

In addition to the direct effects of hyperinsulinemia on keratinocytes, insulin also appears to augment androgen levels in women. High insulin levels stimulate the production of ovarian androgens and ovarian hypertrophy with cystic changes.[21] Although associated with elevated androgen levels, the acanthosis nigricans in women with polycystic ovarian syndrome (PCOS) does not respond reliably to antiandrogen therapy, implicating the relative importance of hyperinsulinemia over hyperandrogenism in acanthosis nigricans. Several drugs have also been reported to cause acanthosis nigricans, including systemic glucocorticoids, nicotinic acid, and estrogens such as diethylstilbestrol.[16]

CLINICAL FINDINGS: CUTANEOUS LESIONS Clinically, acanthosis nigricans presents as brown to gray-black papillomatous cutaneous thickening in the flexural areas, including the posterolateral neck, axillae, groin, and abdominal folds. The distribution is usually symmetric. The affected skin has a dirty, velvety texture. In some cases, oral, esophageal, pharyngeal, laryngeal, conjunctival, and anogenital mucosal surfaces may be involved. In general, however, the back of the neck is the most consistently and severely affected area[19] (Fig. 152-1). The development of superimposed acrochordons in involved areas is well described (Fig. 152-2). In particularly florid cases, involvement on the back of the hands over the knuckles and even on the palms can be seen. When the palms are involved, the rugated appearance of

◀ **FIGURE 152-1** Acanthosis nigricans involving the neck.

the palmar surface has been called *tripe palms* and is usually associated with acanthosis nigricans seen in the setting of malignancy (see Chap. 154). In the majority of cases, the most important factor in diagnosing acanthosis nigricans is recognizing the usually associated hyperinsulinemia, which is a known risk factor for type 2 diabetes.

The histopathology of clinical lesions demonstrates papillomatosis and hyperkeratosis but minimal acanthosis. Hyperpigmentation of the basal layer has been variably demonstrated and the brown color of the lesions is attributed to the hyperkeratosis by most.[26,27]

TREATMENT Treatment of acanthosis nigricans is generally ineffective. Topical treatment with calcipotriol,[28] salicylic acid, urea, systemic and topical retinoids have all been used with anecdotal success.[29] When identifiable, treatment of the underlying cause may be beneficial. Improvement or resolution does occur with weight loss in some obese patients.[12,16] Medications that improve insulin sensitivity, such as metformin, have a theoretic benefit. Removal of an offending medication generally results in clearance of the skin.[30] In patients with acanthosis nigricans in association with malignancy, there is usually improvement following treatment of the underlying malignancy. The skin finding may present before or after the diagnosis of malignancy is made. When it is associated with malignancy, a tumor of intra-abdominal origin, usually gastric, is seen in the majority of cases[31] (see Chap. 154). It has been repeatedly described that patients' skin improves with chemotherapy and remits with recurrences.

▲ **FIGURE 152-2** Acanthosis nigricans involving the axilla with numerous acrochordons.

Diabetic Thick Skin

Several specific syndromes are associated with localized thickening of the skin in diabetes. The common underlying pathogenesis involves biochemical alterations in dermal collagen and mucopolysaccharides. The clinical syndromes are a result of increased deposition and improper degradation of these constituents, likely related to the formation of AGEs.

Limited Joint Mobility and Scleroderma-Like Syndrome

Diabetic LJM, or cheiroarthropathy, presents as tightness and thickening of the skin and periarticular connective tissue of the fingers, resulting in a painless loss of joint mobility. Initial involvement of the distal interphalangeal joints of the fifth digit usually progresses proximally to involve all fingers. Larger joints of the elbow, knee, and foot may be affected. The actual joint space, however, remains uninvolved, so that LJM is not a true arthropathy. This disorder is characterized by the "prayer sign," which is an inability to approximate the palmar surfaces and interphalangeal joint spaces with the hands pressed together and fingers separated (Fig. 152-3). In addition to joint contractures, the skin may appear thickened, waxy, and smooth with apparent loss of adnexa, resembling skin changes in scleroderma.

Thirty percent to fifty percent of adult patients with type 1 diabetes have LJM, and it is common in type 2 diabetes as well. LJM is associated with increased duration of diabetes and poor glucose

▲ **FIGURE 152-3** Limited joint mobility in a 31-year-old male patient with type 1 diabetes mellitus. The patient is unable to approximate the palmar surface of the proximal and distal interphalangeal joints with palms pressed together (known as the "*prayer sign*"). **A.** Ulnar view; only fingertips are approximated. **B.** Radial view; straining to press palms together.

control.[32,33] One longitudinal prospective study showed a 2.5-fold increase in the risk of LJM for every unit increase in the glycosylated hemoglobin.[33] In addition, it appears that LJM may be correlated with the presence of microvascular disease.[34]

Most important, the evidence indicates that intensive insulin therapy is central in prevention and, possibly, treatment of LJM and scleroderma-like syndrome. Long-term tight glycemic control leads to decreased skin AGEs,[9] and tight glycemic control is associated with delayed onset and severity of LJM.[33] On the basis of improvements in diabetes management, a fourfold reduction in the frequency of LJM over the last 20 years was reported.[35] Treatment for LJM is difficult and should focus on tight control of blood sugar as well as physical therapy to preserve active range of motion.

Although the scleroderma-like skin changes can occur independently, they often occur together with LJM in patients with diabetes. The scleroderma-like syndrome is not associated with systemic sclerosis but does correlate with the duration of diabetes, the severity of joint contractures, and retinopathy.[36] It seems likely that the historical description of "diabetic hand syndrome" represents a combination of LJM and the scleroderma-like syndrome.

Scleredema Diabeticorum (See Chap. 159)

Recognized in 1970 as a syndrome,[37,38] scleredema of diabetes (scleredema diabeticorum) presents with the insidious onset of painless, symmetric induration and thickening of the skin on the upper back and neck. Spreading to the face, shoulders, and anterior torso may occur. The skin retains a nonpitting, woody, *peau d'orange* quality. Identical changes occur with postinfectious scleredema, usually associated with streptococcal pharyngitis. In scleredema associated with infection, however, the onset is often sudden, and the symptoms usually remit over time. Scleredema diabeticorum affects 2.5 percent to 14 percent of patients with diabetes.[39,40] Scleredema diabeticorum is a disease of long-standing diabetes associated with obesity. Most patients have type 2 diabetes. This disorder has not been reported in children.

The pathogenesis of scleredema diabeticorum is postulated to be unregulated production of extracellular matrix molecules by fibroblasts, leading to thickened collagen bundles and increased deposition of glycosaminoglycans (GAGs, mainly hyaluronic acid). Studies using in vitro fibroblast analysis from involved skin have variably demonstrated increased synthesis of GAGs and type I collagen.[41] However, most of these reports involved non-diabetic patients with paraproteinemia and are based on small numbers of cases.

Patients with scleredema diabeticorum may experience decreased sensation to pain and light touch over the affected areas and difficulties with upper extremity and neck range of motion. Extreme cases may result in full loss of range of motion. Unlike in LJM and scleroderma-like syndrome, the presence of scleredema does not correlate with retinopathy, nephropathy, neuropathy, or principal vascular disease.[39] However, no large-scale prospective studies have been done. Most patients with scleredema diabeticorum become insulin dependent, are difficult to treat, and have multiple complications of diabetes.[41] Treatment for scleredema diabeticorum is usually unsuccessful. Case reports describe treatment with radiotherapy, low-dose methotrexate, bath psoralen and ultraviolet A light (PUVA), extracorporeal photopheresis, factor XIII, and prostaglandin E_1.[38,42,43]

Eruptive Xanthomas (See Chap. 135)

Eruptive xanthomas present clinically as 1- to 4-mm, reddish-yellow papules on the buttocks and extensor surfaces of the extremities (Fig. 152-4). The lesions occur in crops and may coalesce into plaques over time. Although eruptive xanthomas are generally asymptomatic, there is often underlying severe hypertriglyceridemia (> 1000 mg/dL) and potentially undiagnosed diabetes. Histologic and biochemical studies show that lipoproteins (mainly chylomicrons) in the blood permeate cutaneous vessel walls and accumulate in macrophages in the dermis.[44] Initially, triglycerides predominate in the skin lesions but, because triglycerides are mobilized more easily than cholesterol, the lesions contain progressively more cholesterol as they resolve.[44] Whether this mechanism plays a role in the atherosclerosis of large arteries is unknown.

Insulin is an important regulator of LPL activity. The degree of enzymatic dysfunction and subsequent clearing of serum triglycerides is proportionate to the amount of insulin deficiency and hyperglycemia.[13] Clearance of plasma lipoproteins depends on adequate insulin.[45] In uncontrolled diabetes, this inability to metabolize and clear triglyceride-rich chylomicrons and very-low-density lipoproteins can lead to plasma triglyceride levels in the thousands. Uncontrolled diabetes is a common cause of massive hypertriglyceridemia.

In addition to eruptive xanthomas, triglyceride levels above 4000 may cause lipemia retinalis. On funduscopic examination, lipemia retinalis appears as pale pink to white retinal arterioles and venules. The fundus may have a milky hue. Untreated, severe hypertriglyceridemia may also present clinically with abdominal pain, hepatosplenomegaly, pancreatitis, or dyspnea from decreased pulmonary diffusing capacity and abnormal hemoglobin oxygen affinity.[46] Treatment of hypertriglyceridemia involves strict dietary fat restrictions and control of the underlying diabetes. LPL activity returns to normal after treatment with long-term insulin or oral glucose-lowering agents.[13] The eruptive xanthomas respond rapidly and usually resolve completely in 6 to 8 weeks.[47]

Cutaneous Infections

In diabetic patients, there is not strong evidence for an increased susceptibility to

◀ **FIGURE 152-4** Eruptive xanthomas appear as yellow-orange papules and plaques on a male patient with type 2 diabetes mellitus. (Used with permission from Greg Raugi, MD.)

infections in general, but several skin infections do occur more commonly, with greater severity, or with a greater risk for complications in patients with DM. Joshi et al. have reviewed this subject.[11]

Much research has been undertaken on the pathogenesis of immune dysfunction in diabetes. Although some studies could not detect defects at the cellular level,[48] other studies show that leukocyte chemotaxis, adherence, and phagocytosis are impaired in patients with diabetes, especially during hyperglycemia and diabetic acidosis.[49] Further studies show that cutaneous T-cell function and response to antigen challenge are also decreased in diabetes.[11]

BACTERIAL INFECTIONS Diabetics are at a higher risk for contracting certain bacterial infections, including group A and group B streptococcal infections, necrotizing fasciitis, and malignant otitis media. The relation between diabetes and staphylococcal infections is controversial.

Group B Streptococcal Infections. (See Chap. 177) Group B streptococcus (*Streptococcus agalactiae*), a major cause of morbidity in neonates and pregnant women, is also a significant source of invasive bacterial infection in nonpregnant adults. Both retrospective and prospective population-based studies identify diabetes as a risk factor in these infections.[50,51] In a study of 424 nonpregnant adults with invasive group B streptococcal infection, 30 percent of cases occurred in patients with diabetes. The most common sites of infection were skin, soft tissue, and bone (cellulitis, foot ulcers, and decubitus ulcers).[51] In young adults, the presence of diabetes increases the risk of group B streptococcal infection 30-fold.[51] Despite therapy, approximately 20 percent of these cases are fatal.[50,51] In pregnancy, maternal diabetes (but perhaps not gestational diabetes alone)[52] increases the risk even more.[53]

Group A Streptococcal Infections. (See Chap. 177) In a prospective population-based surveillance of invasive group A streptococcal disease, the risk of infection was 3.7-fold greater in diabetics. Soft tissue infections were the most common clinical presentation for all patients.[54]

Staphylococcal Infections. (See Chap. 177) Historically, *Staphylococcus aureus* skin infections were associated with diabetes. Past recommendations even suggested testing patients with recurrent furunculosis or folliculitis for diabetes.[55] In a review, however, Breen and Karchmer[56] concluded that current data do not permit estimation of proportional risk of staphylococcal infections in patients with diabetes. They suggested that only subsets of patients with diabetes have increased staphylococcal carriage rates.[56]

Malignant External Otitis. Invasive "malignant" otitis externa is an uncommon, life-threatening infection of the external auditory canal with potential cranial bone and intracranial involvement. *Pseudomonas aeruginosa* is usually implicated, and preceding aural irrigation with tap water may play an etiologic role[57] (see Chap. 180). This painful infection, which occurs in older patients with diabetes, is characterized by purulent discharge, unilateral facial swelling, hearing loss, and granulation tissue in the ear canal. The presentation is surprisingly without fever.[11] This infection occurs almost exclusively in diabetics. Diagnosis is often delayed, and mortality rates are as high as 20 percent to 40 percent despite appropriate antibiotic therapy.[58] Surgical débridement of necrotic tissue in addition to antibiotic therapy is important. The extent of tissue involvement can be assessed using magnetic resonance imaging or computed tomography imaging studies, and early consultation with an otolaryngologist will facilitate the evaluation and management.[11]

Necrotizing Fasciitis. (See Chap. 179) Ten percent to sixty percent of all cases of necrotizing fasciitis occur in patients with diabetes.[59] Necrotizing fasciitis is a life-threatening bacterial infection of the soft tissues with spread along fascial planes. The perineum, trunk, abdomen, and upper extremities are most commonly involved.[10] Clinical presentation includes erythema, swelling, induration, necrosis, and possible bullae formation. The degree of pain and toxicity are often out of proportion to the severity of the findings. Although most cases are caused by polymicrobial infections (*Escherichia coli*, *Bacteroides*, *Peptostreptococcus*, and *Clostridium* sp.), approximately 10 percent of cases are monomicrobial, often due to streptococcal species.[11,60] Treatment includes urgent surgical débridement and appropriate broad spectrum antibiotics. Mortality rates of 40 percent have been reported.[11]

FUNGAL AND YEAST INFECTIONS ***Candidal Infections.*** (See Chap. 189) Most authors believe that mucocutaneous *Candida* infections occur more frequently among patients with diabetes, especially those with poorly controlled disease.[61] Intertrigo (axillary, inguinal, web space), vulvovaginitis, balanitis, paronychia, onychomycosis, glossitis, and angular cheilitis are most common. In one study, the clinical diagnosis of candidal paronychia was made in 9.6 percent of 250 diabetic women, compared to only 3.4 percent of non-diabetic women.[62] In addition to symptomatic vaginal yeast infections, asymptomatic carriage rates are also elevated in patients with diabetes.[61] Postmenopausal females with recurrent vulvo-vaginal candidiasis should undergo screening for diabetes. Treatment for candidal infections includes topical and oral antifungals. Patients with candidal paronychia should avoid wetting of the nails and use drying agents (e.g., 15 percent sulfacetamide in 50 percent ethanol, three to four drops, applied four times per day, and after each time hands get wet).[10]

Dermatophyte Infections. (See Chap. 188) Although two studies failed to show an overall increased prevalence of dermatophyte infections in patients with diabetes compared with control subjects,[63,64] Gupta et al.[65] demonstrated that the rate of toenail onychomycosis was 2.77 times greater for patients with diabetes as compared with controls. Onychomycosis has recently been demonstrated to be a significant predictor of foot ulcers in diabetics.[66] In patients with diabetes, aggressive diagnosis and treatment of tinea foot infections are important because of the potential portal of entry for subsequent bacterial infections.

Rhinocerebral Mucormycosis. (See Chap. 190) Rhinocerebral mucormycosis is caused by Zygomycetes (*Mucor* and *Rhizopus* sp.). It often presents with headache, fever, and lethargy, in addition to nasal congestion and facial-ocular pain and swelling. Subsequent findings include unilateral proptosis, ophthalmoplegia, and palate or nasocutaneous necrosis. Seventy-five percent to eighty percent of all cases occur in patients with diabetes,[67] and diabetic ketoacidosis is the most important risk factor.[11] Ketoacidosis reportedly blunts the normal inhibitory activity of serum against *Rhizopus*.[68] Amphotericin B and surgical débridement are the treatments of choice. Voriconazole, caspofungin, and other azoles are ineffective against the Zygomycetes. The investigational triazole, posaconazole, may be efficacious in these infec-

tions.[69] Mortality rates for mucormycosis are reportedly as high as 50 percent.[70] *Mucor* species have also been observed, complicating skin ulcers on the legs and hands of patients with DM.[61]

Diabetic Ulcers

EPIDEMIOLOGY Foot ulcers are a significant problem for patients with diabetes, occurring in 15 percent to 25 percent of diabetic patients.[71] Patients with diabetes have an estimated increased risk of lower extremity amputation that is 10 to 30 times greater than the general population. Lower-extremity ulcers were the proximal cause of amputation in 67 of 80 patients (84 percent) in a study by Pecoraro et al.[72] In diabetic patients with foot ulcers, 14 percent to 24 percent will eventually undergo amputation.[73] The attributable cost of treating a diabetic foot ulcer, excluding the cost of amputation, was estimated to be $28,000 in a 1999 U.S. study.[74]

ETIOLOGY AND PATHOGENESIS Many of the factors previously described in this chapter contribute to the pathogenesis of diabetic ulcers. Peripheral neuropathy, pressure, and trauma are felt to play prominent roles in the development of diabetic ulcers. Neuropathy (associated with uncontrolled hyperglycemia) is one of the major predictors of diabetic ulcers.[15] Patients with diabetes also suffer the loss of cutaneous sensory nerves.[75] The subsequent diminished neuroinflammatory signaling via neuropeptides to keratinocytes, fibroblasts, endothelial cells, and inflammatory cells may adversely affect wound healing.[76] Excessive plantar pressure develops from foot deformities (Charcot arthropathy), as a result of LJM related to NEG, and from callus formation. Ill-fitting shoes and socks were the most common reasons for foot ulcers in a study of 314 diabetic patients with ulcers.[77] By wearing running shoes, patients with diabetes had a measurable reduction of calluses in one study.[78] Callus formation is a sign of excess friction and often precedes foot ulcers. Once an ulcer develops, peripheral vascular disease and intrinsic wound healing disturbances contribute to adverse outcomes. Known factors associated with foot ulceration in the setting of diabetes include previous foot ulceration, prior lower extremity amputation, long duration of diabetes (> 10 years), impaired visual acuity, onychomycosis, and poor glycemic control. Boyko and colleagues have recently published a prediction model for foot ulceration based on the relative contributions of these factors.[66]

▲ **FIGURE 152-5** "Diabetic foot." Two larger ulcers overlying the first right and second left metacarpophalangeal joints in a 56-year-old man with diabetes of 20 years' duration. There is significant sensory neuropathy and peripheral vascular disease.

CLINICAL FINDINGS Callus formation precedes necrosis and breakdown of tissue over bony prominences of feet, usually on great toe and sole, over first and/or second metacarpophalangeal joints. Ulcers are surrounded by a ring of callus and may extend to underlying joint and bone (Fig. 152-5). Complications are soft tissue infection and osteomyelitis.

TREATMENT Treatment of diabetic ulcers requires modification of factors that contribute to ulcer formation, for example, stasis dermatitis, leg edema, and skin infection. Standard therapy for neuropathic diabetic ulcers includes débridement, off-loading (often non–weight bearing), moist wound care, and protective dressings (Fig. 152-6).

There has been substantial interest in developing adjunctive therapies for diabetic ulcers, including growth factors and skin replacement products, but data have not supported their use as a replacement for standard wound care. Recombinant platelet-derived growth factor for the topical treatment of diabetic foot ulcers demonstrates a modest benefit if used with adequate off-loading, débridement, and control of infection.[79] A large multicenter, clinical trial of a bilayered living skin equivalent[80] showed 56 percent healing at 12 weeks as compared with 38 percent healing for standard care. The most favorable published results for a monolayered living skin equivalent and platelet-derived growth factor (Becaplermin) show roughly comparable improvement in healing to that reported for bilayered living skin equivalents (Graftskin) when each is compared with standard care or placebo.[81] However, these technologies await definitive analysis of cost effectiveness compared with standard older approaches. Although studies are not available at this time to support their routine use, these biologic approaches may have a role in the treatment of large ulcers (> 2 cm) or ulcers poorly responsive to standard therapy.

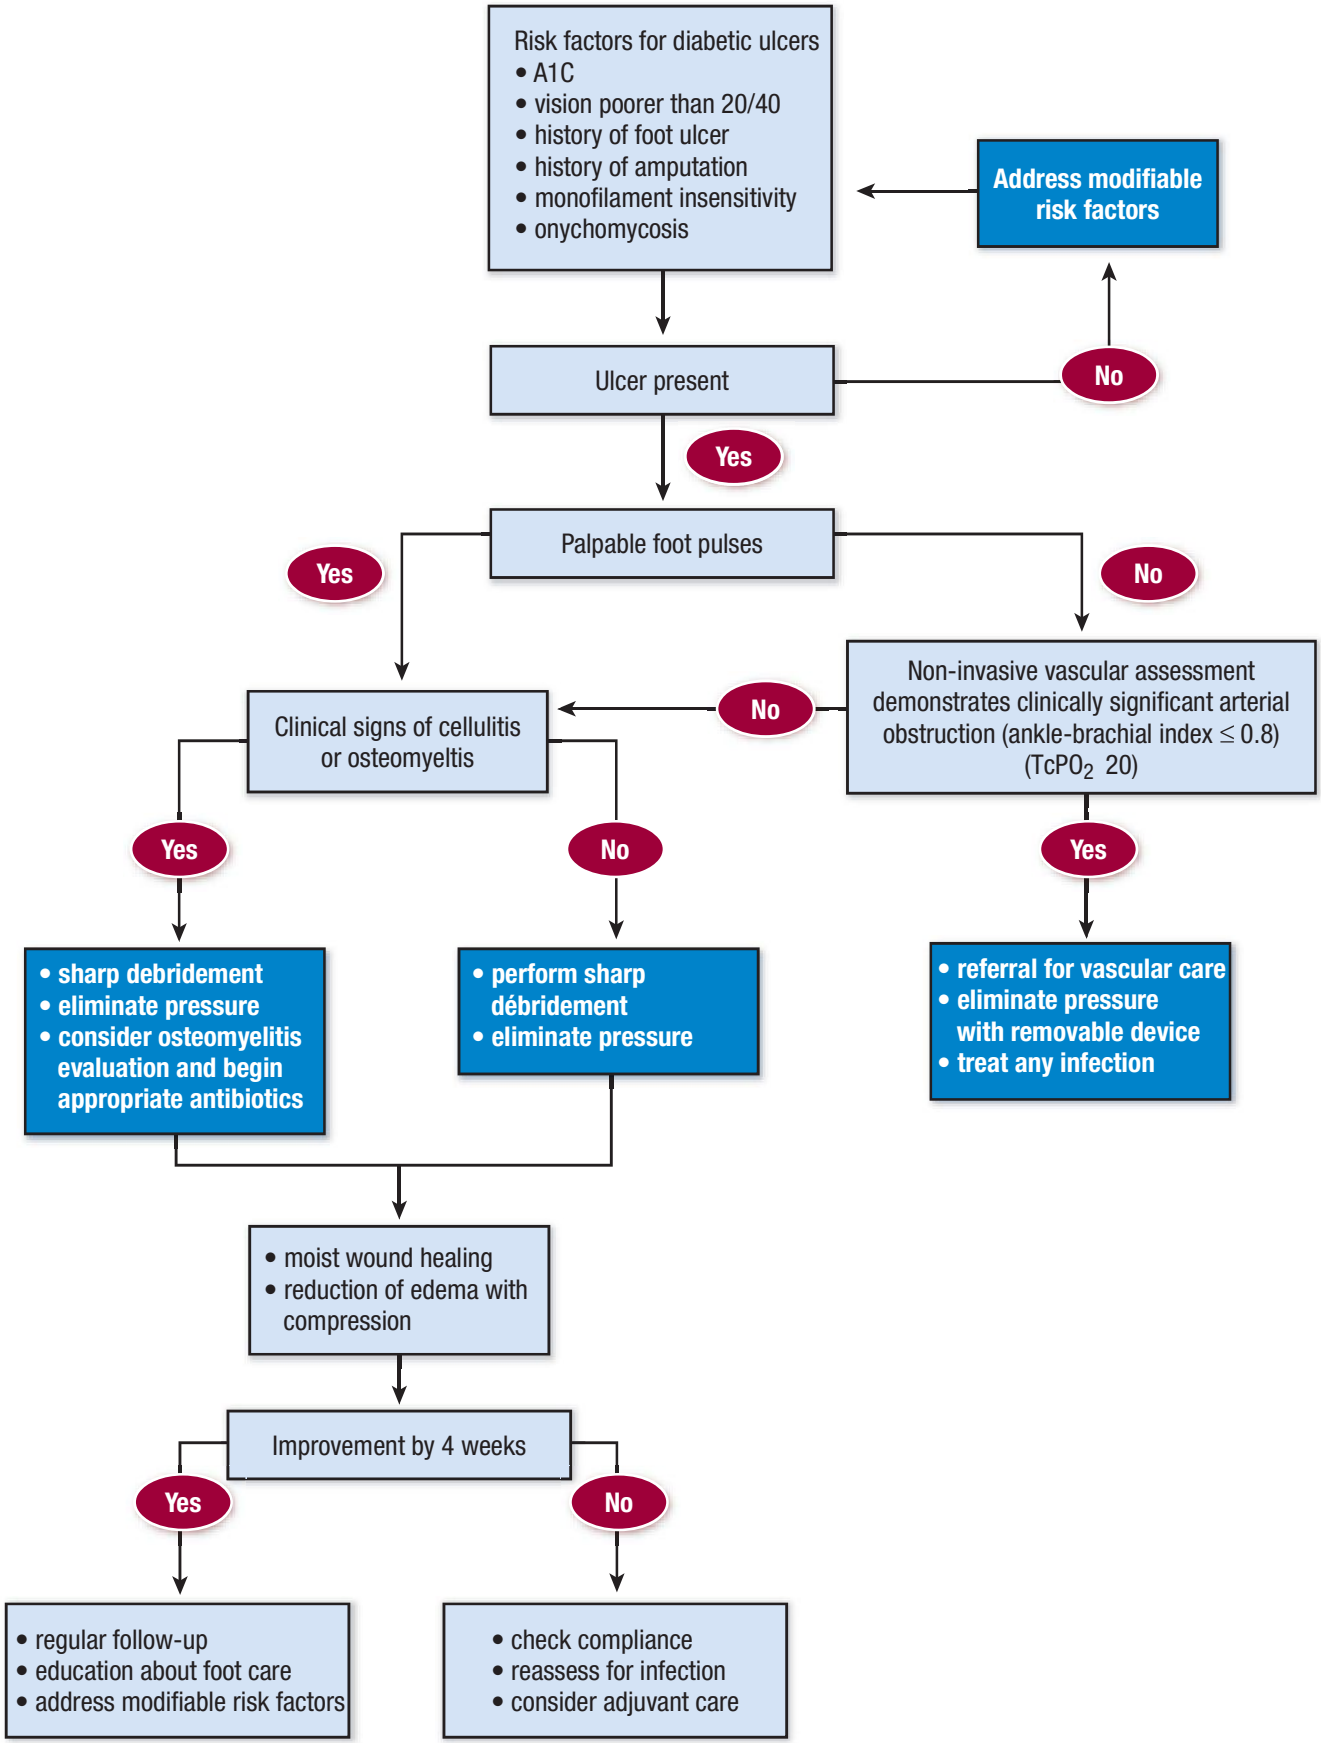
PREVENTION Ulcer prevention is the most important intervention physicians and other health care professionals can provide for diabetic patients. An excellent review of ulcer prevention was recently published by Singh et al.[71] Optimizing glycemic control is well supported to prevent the neuropathy that is so intimately associated with foot ulceration. In a recent study, the risk of a foot ulcer increased in nearly direct proportion to every 1 percent increase in hemoglobin A1C.[66] Foot examinations, including Semmes-Weinstein 10-g monofilament testing for neuropathy and clinical assessment for peripheral vascular disease, should be performed regularly in all patients with diabetes. If tinea pedis is present, it should be treated to prevent the associated skin barrier disruption. Smoking cessation should be encouraged. Patients should be counseled about the importance of daily foot care (Table 152-2).

Specialized ulcer care teams have published impressive results on the prevention and healing of ulcers.[82] This multidisciplinary team approach is becoming more important in the treatment of diabetic ulcers in large population centers. Patients with a history of ulceration are at high risk for reulceration (34 percent at 1 year, 61 percent at 3 years, and 70 percent at 5 years).[83] Intensifying education (formal foot care classes) and prevention efforts in this group along with lifelong surveillance is required.

DISORDERS ASSOCIATED WITH DIABETES MELLITUS BUT OF UNKNOWN PATHOGENESIS

Necrobiosis Lipoidica

EPIDEMIOLOGY AND PATHOGENESIS Coined by Urbach in 1932 as *necrobiosis lipoidica diabeticorum*, this disorder was named after characteristic histologic findings and was first described in patients with diabetes. Because not all patients have concurrent diabetes, the shortened term, *necrobiosis lipoidica* (NL), is preferred. Epidemiologic



▲ **FIGURE 152-6** Approach to the care of the diabetic foot and diabetic ulcers. A1C = hemoglobin A1C; $TcPO_2$ = transcutaneous oxygen tension.[178]

TABLE 152-2
General Foot Care Guidelines for Patients with Diabetes

- Examine feet every day, including areas between the toes.
- Regular washing of feet with careful drying, especially between the toes.
- Water temperature should always be less than 37°C (98.6°F) and checked first with the hand rather than the foot.
- Barefoot walking in- or outdoors and wearing of shoes without socks is discouraged.
- Daily inspection and palpation of the inside of the shoes for irregular surfaces or foreign objects.
- If vision is impaired, patients should not try to treat their feet (e.g., nails) by themselves.
- Emollients should be used for dry skin but not between the toes.
- Change stockings daily.
- Wearing of stockings with seams inside out or preferably without any seams at all.
- Nails should be cut straight across.
- Corns and calluses should not be cut by patients but by a health care provider.
- The patient must ensure that the feet are examined regularly by a health care provider.
- The patient should seek early health care attention for any blister, cut, scratch, sore, ingrown toenail, or dermatitis.

data show that the mean age of onset is around 30 years, with women representing three times more cases than men.[84] The most often quoted statistics concerning the association of NL with diabetes are from a 1966 retrospective study at the Mayo Clinic. Of 171 patients with NL, two-thirds had diabetes at diagnosis, and another 5 percent to 10 percent had glucose tolerance abnormalities.[84] However, in a 1999 study of 65 patients with NL, only 11 percent had diabetes after 15 years of follow-up.[85] Conversely, the prevalence of NL has been found to be only 0.3 percent to 3.0 percent in patients with diabetes.[84] Although lacking full concordance, NL definitely has a strong association with diabetes and remains a valid marker of the disease. The pathogenesis of this skin disease is unclear. Many etiologic mechanisms have been proposed and reviewed.[86] Evidence suggests that the degree of hyperglycemia and diabetic control does not correlate with the presence of NL.[87]

CLINICAL FINDINGS: CUTANEOUS LESIONS Classically, NL presents with one to several sharply demarcated yellow-brown plaques on the anterior pretibial region (Fig. 152-7). The lesions have a violaceous, irregular border that may be raised and indurated. Initially, NL often presents as red-brown papules and nodules that may mimic sarcoid or granuloma annulare (GA). Over time, the lesions flatten, and a central yellow or orange area becomes atrophic, and commonly telangiectasias are visible, taking on the characteristic "glazed-porcelain" sheen. Aside from the shins, other sites of predilection include ankles, calves, thighs, and feet. Fifteen percent of patients develop lesions on the upper extremities and trunk that tend to be more papulonodular. Although pain and pruritus have been reported, most lesions are asymptomatic. Anesthesia of the plaques does occur.[88]

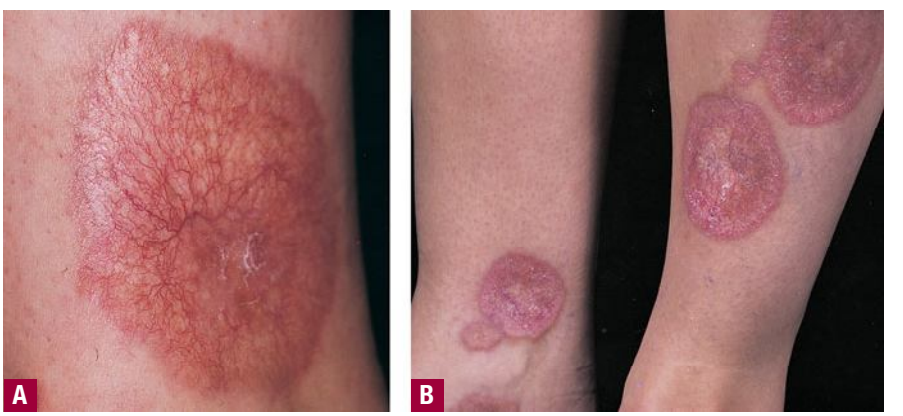
The clinical course is often indolent, with spontaneous remission in less than 20 percent of cases.[10] Over time, the plaques tend to stabilize, and formation of new lesions tapers off. However, the possibility of ulceration, a poor spontaneous remission rate, and cosmetic concerns lead patients to seek treatment. Ulceration, the most serious complication, occurs in approximately 13 percent to 35 percent of cases on the legs.[84,86] A few cases of squamous cell carcinoma arising in chronic ulcerative lesions of NL have been reported.[89] Multiple reports document the association of NL with GA and sarcoidosis.[90]

TREATMENT Treatment for NL is disappointing. At this time, only case reports and small, uncontrolled trials provide the basis for treatment decisions (see ref. 86). Early application of potent topical glucocorticoids might slow progression.[86] Although some authors[84] report improvement with intralesional injection of glucocorticoids to the active border, the risk of ulceration with this treatment modality should be considered. A few case reports and one series of six patients[91] showed benefit with short-term systemic glucocorticoids. Aspirin and dipyridamole have produced variable results.[86] Anecdotal reports exist that support the use of topical retinoids and topical PUVA. Treatment with fumaric acid esters in 18 patients was reported to improve lesions clinically and histologically.[92]

Given the generally benign nature of the lesions, physicians should consider the adage "do no harm." Focus should be on prevention of ulcers. When ulceration occurs in patients with NL, the same wound care principles apply as for all diabetic ulcers. Healing of ulcerated lesions with cyclosporine has been demonstrated in several patients.[93] Surgical excision down to fascia and split-thickness skin grafting remain as the last resort for very recalcitrant ulcers in NL.[94]

Granuloma Annulare (See Chap. 43)

EPIDEMIOLOGY AND PATHOGENESIS The association of GA with diabetes is weaker than that of NL. Although most patients with GA are in good health, without underlying systemic illness, an association with diabetes is supported in the literature. Dabski and Winkelmann[95] found diabetes in 10 percent of 1353 patients with localized GA and 21 percent of 100 patients with generalized GA. An additional small retrospective case-control study showed an increased prevalence of diabetes among patients with GA (18 percent) as compared with the prevalence in age-matched controls (8 percent).[96] Furthermore, there is an impression that diabetes is found more frequently in patients with adult onset GA and in those with general-



▲ **FIGURE 152-7** Necrobiosis lipoidica. **A.** A single orange plaque with atrophy of the overlying epidermis and arborizing telangiectasias is seen on the lower leg of a juvenile with diabetes mellitus; the crust marks an area of early ulceration. **B.** Older lesions with striking central atrophy involving both the dermis and epidermis.

ized or perforating GA, and that these patients tend to experience a more chronic, relapsing course of GA. The pathogenesis is unclear.

CLINICAL FINDINGS AND TREATMENT Clinical findings and treatment of GA are discussed in the on-line version and in Chap. 43.

Diabetic Dermopathy

ETIOLOGY AND PATHOGENESIS Atrophic skin lesions of the lower extremity, or shin spots, were first characterized and proposed as a cutaneous marker for diabetes in 1964.[100] Shortly after, Binkley coined the term *diabetic "dermopathy"* to correlate the pathologic changes with those of retinopathy, nephropathy, and neuropathy.[101] Since that time, controversy has existed about the disorder's etiology, specificity for diabetes, and association with other microangiopathic complications of diabetes.

The prevalence of shin spots in ambulatory patients with diabetes varies. In a population-based study from Sweden, diabetic dermopathy was found in 33 percent of patients with type 1 diabetes and in 39 percent of patients with type 2 diabetes, compared with 2 percent of controls.[102] In other studies, the prevalence rate for individuals without diabetes ranges from 1.5 percent for healthy medical students to 20 percent for a group of non-diabetic endocrine patients.[103] Diabetic dermopathy occurs more often in patients with an increased duration of diabetes and is more frequent in men.[103]

It is likely that the lesions are related to antecedent trauma. Lithner[104] induced diabetic dermopathy on the legs of diabetic patients with heat and cold injury, whereas non-diabetic control subjects healed without residual change. When questioned, most patients think that the changes are caused by injury, but they are often unable to detail preceding trauma.

CLINICAL FINDINGS, DIAGNOSIS, AND TREATMENT Diabetic dermopathy presents as small (< 1 cm), atrophic, pink to brown, scar-like macules on the pretibial areas (Fig. 152-8). The lesions are asymptomatic and clear within 1 to 2 years with slight residual atrophy or hypopigmentation.[100] The appearance of new lesions gives the sense that the pigmentation and atrophy are persistent.

An association seems to exist between diabetic dermopathy and the more serious complications of diabetes. In a study of 173 patients with diabetes, the incidence of shin spots correlated with the duration of diabetes and the presence of retinopathy, nephropathy, and neuropathy.[105] Diabetic dermopathy does not, however, correlate with obesity or hypertension in patients with diabetes.[103] No treatment is necessary for the individual atrophic tibial lesions. They are asymptomatic and are not directly associated with an increase in morbidity.

◀ **FIGURE 152-8** Diabetic dermopathy with hyperpigmented macules on the anterior lower legs.

Acquired Perforating Disorders (See Chap. 67)

The acquired perforating disorders comprise an overlapping group of disorders characterized by trans-epidermal elimination or "spitting" of altered dermal constituents. Included in this group are Kyrle disease, reactive perforating collagenosis, perforating folliculitis, and elastosis perforans serpiginosa.[106]

Clinically, these lesions appear as pruritic, keratotic papules mainly on the extensor surfaces of the extremities. Papules and nodules with a perforating component may also occur on the trunk and face. Many are follicular and contain a prominent central keratotic plug. The papules may be grouped, or coalesce to form verrucous plaques. Treatment for the perforating disorders is usually unsuccessful. Retinoic acid, topical glucocorticoids, and PUVA are partially successful.[107]

Bullosis Diabeticorum

ETIOLOGY AND PATHOGENESIS The abrupt, spontaneous development of blisters on the lower extremities without other demonstrable cause is a rare characteristic skin manifestation of diabetes. The pathogenesis of diabetic bullae is unknown. Patients with bullosis diabeticorum (BD) do not have a history of antecedent trauma or infection. One study found a decreased threshold to suction-induced blister formation in patients with diabetes.[108] Reduced suction blister time is also observed with increasing age in non-diabetic subjects.[109] Although a history of antecedent trauma is not elicited, this finding suggests a role of increased skin fragility in diabetic bullae. Perhaps the formation of AGEs leads to increased fragility.

CLINICAL FINDINGS, DIAGNOSIS, AND TREATMENT BD is characterized by the abrupt onset of bullae on the lower extremities, usually the toes, feet, and shins, arising in normal skin. Occasionally, the distal upper extremities are involved. The blisters are usually painless and not pruritic. Healing occurs within 2 to 5 weeks and rarely leaves scarring. The condition may recur as successive crops of bullae over many years. Studies of affected individuals excluded other blistering skin disorders, and revealed no abnormalities of porphyrin metabolism.[108] Histopathologic examination of the bullae shows an inconsistent level of separation varying from intraepidermal to sub-epidermal.[109] No immunopathologic features are consistently observed (Box 152-1).

BD runs a benign course without involvement of large body surface areas.

Box 152-1

Differential Diagnosis and Evaluation of Bullosis Diabeticorum

DIFFERENTIAL DIAGNOSIS

- Bullous impetigo
- Bullous pemphigoid
- Epidermolysis bullosa acquisita
- Porphyria cutanea tarda
- Bullous erythema multiforme
- Insect bite reaction

LABORATORY TESTS

- Skin biopsy for histology and immunofluorescence
- Bacterial cultures
- Screening for porphyrins

The only serious complication is that of secondary infection, which should be managed with culture and appropriate antibiotics if suspected. Otherwise, therapy is supportive. The real importance of this disorder is that of correct diagnosis because several of the blistering skin diseases have a high rate of morbidity and require potentially toxic systemic treatments. Even a negative workup is important. The patient should be educated, reassured, and good wound care implemented.

THYROID DISEASE

Epidemiology

Worldwide estimates of the prevalence of goiter (enlargement of the thyroid gland) range from 200 million to 800 million affected people. The majority of these worldwide cases are secondary to iodine deficiency. However, in industrialized countries where salt is routinely iodized, the main causes of goiter are autoimmune thyroiditis and nodular thyroid disease. The overall incidence of hyperthyroidism in the U.S. population is estimated at approximately 1 percent, but may be four to five times higher in older women.[110] Graves disease accounts for 60 percent to 80 percent of all cases of hyperthyroidism and was first described by Caleb Parry in 1825 (and later by Robert Graves in 1835) as an association between goiter, palpitations, and exophthalmos.[111] Although the incidence of Graves disease is similar between whites and Asians, it appears to be lower in blacks.[111] *Toxic adenoma* and *toxic multi-nodular goiter* refer to the hyperplastic growth of thyroid tissue that is functioning independent of thyrotropin (TSH) regulation, resulting in increased levels of thyroid hormone. Toxic multinodular goiter has been reported to be more common in areas of low iodine intake, particularly in patients older than the age of 50 years.[112] Population-based screening with laboratory testing found hypothyroidism in 4.6 percent of the U.S. population, although > 90 percent of individuals with tests consistent with hypothyroidism were normal clinically.[110]

The majority of thyroid disease is acquired, but thyroid disease can also be congenital. Congenital hypothyroidism is the most common treatable cause of mental retardation, and occurs in up to 1 in 3000 neonates worldwide due to either an absent or anatomically defective gland, inborn errors of thyroid metabolism, or iodine deficiency.[113] Congenital hyperthyroidism is much less common, and although 0.2 percent of pregnant women have Graves disease, only about 1 percent of the resultant neonates will have hyperthyroidism, with most cases resulting from the transfer of maternal thyroid-activating autoantibodies.[114]

Etiology and Pathogenesis

The metabolic regulation of every cell in the body relies on thyroid hormones, which is synthesized primarily in the thyroid gland. Hyperthyroidism (also known as *thyrotoxicosis*) results from the excess levels of thyroid hormones with resultant hypermetabolism, whereas hypothyroidism (or myxedema) is characterized by hypometabolism secondary to diminished levels of thyroid hormone. Thyroid hormones act on target tissues by activating cytoplasmic receptors that subsequently translocate to the nucleus and activate specific thyroid-responsive genes.[115] Thyroid hormone synthesis is heavily dependent on iodine and, consequently, changes in iodine intake can result in both hyperthyroidism and hypothyroidism.

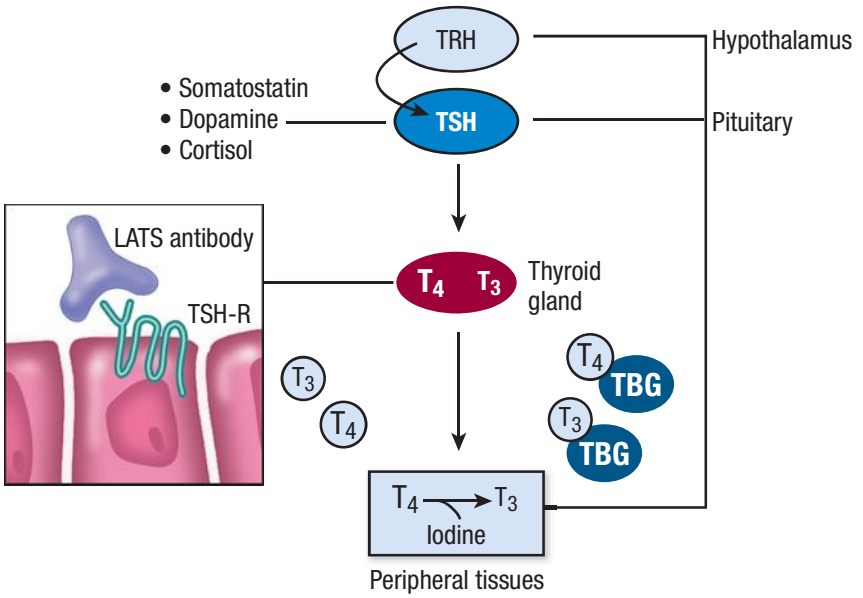
Synthesis of thyroid hormone is regulated by the pituitary via release of TSH in response to hypothalamic release of thyrotropin-releasing hormone (TRH). TSH acts on the thyroid gland by binding a G-protein–coupled receptor (TSH-R) to trigger thyroid hormone synthesis and release. Aberrant activation of TSH-R is thought to underlie the hyperthyroidism seen in Graves disease, where almost all patients have long-acting thyroid-stimulator auto-antibodies that bind and activate TSH-R.[116] Release of TSH is, in turn, stimulated by TRH, which also acts via a G-protein–coupled receptor. Administration of recombinant TRH followed by measurement of the response in TSH levels provides a useful test for distinguishing whether hypothyroid disease results from dysfunction of the hypothalamic-pituitary axis or the thyroid gland. Levels of TSH and TRH are both tightly controlled by circulating levels of thyroxine (T_4) and triiodothyronine (T_3), which provide feedback regulation. Persistent stimulation of the thyroid leads to the hypertrophy of the gland, known as *goiter* (Fig. 152-9).

The great majority of thyroid hormone in the blood is bound by plasma proteins, including thyroid-binding globulin, which is the major determinant of protein binding, and to a lesser extent transthyretin (formerly called *prealbumin*) and albumin. A variety of medical conditions and medications can alter levels of thyroid hormone binding proteins or peripheral conversion of T_4 to T_3 (which is responsible for most of thyroid hormone's effects), and subsequently alter the tissue availability of thyroid hormone independent of changes in thyroid hormone synthesis (Table 152-3). Thyroid hormone levels can be affected by a variety of medications, including several that are prescribed by dermatologists (Table 152-4).[117]

Hyperthyroidism can be broadly classified into two categories: high radioiodine (radioactive iodine) uptake and low radioiodine uptake. The presence of high radioiodine uptake indicates increased synthesis of thyroid hormone, while diminished or absent radioiodine uptake suggests either an extra-thyroidal source of thyroid hormone or the destruction of thyroid tissue with concomitant release of pre-formed thyroid hormone into the circulation. Evidence suggests that genetic predisposition as well as environmental factors, including infection, may play a role in the pathogenesis of autoimmune thyroid disease.[118] In the case of toxic adenoma, molecular studies have identified a high prevalence of TSH-R mutations, result-

THYROID DISEASE AT A GLANCE

- The most common cause of hyperthyroidism is Graves disease, characterized by the triad of autoimmune thyroid disease, eye disease, and thyroid dermopathy (pretibial myxedema).
- Toxic multinodular goiter is another cause of hyperthyroidism that should be considered, particularly in elderly individuals.
- Serious signs of thyrotoxicosis include atrial fibrillation and fever.
- Hashimoto thyroiditis and thyroid ablation for treatment of hyperthyroidism are the two most common causes of hypothyroidism.
- The best screening test for thyroid disease is thyrotropin, which is elevated in hypothyroidism and depressed or absent in hyperthyroidism.



▲ **FIGURE 152-9** The hypothalamic-pituitary-thyroid axis. LATS = long-acting thyroid-stimulator; T_3 = triiodothyronine; T_4 = thyroxine; TBG = thyroid-binding globulin; TRH = thyrotropin-releasing hormone; TSH = thyrotropin; TSH-R = thyrotropin G-protein–coupled receptor.

ing in a receptor that triggers thyroid hormone synthesis in the absence of bound TSH.[119]

Although some of the cutaneous findings seen in hyperthyroidism are indirect consequences of thyroid hormone's actions on other tissues, most of the skin manifestations of thyroid disease result from the direct effects of thyroid hormones on the keratinized epithelium of the epidermis, hair, and nails as well as effects on stromal cells in the dermis. Thyroid hormones are essential for optimal epidermal proliferation both in vitro and in vivo.[120] Thyroid hormones regulate genes involved in keratinocyte proliferation and also stimulate the expression of certain keratins.[120]

TABLE 152-3
Medical Conditions That Can Affect Thyroid Hormone Levels

Increased thyroid-binding globulin
- Pregnancy
- Infectious/chronic active hepatitis
- Biliary cirrhosis
- Acute intermittent porphyria

Decreased thyroid-binding globulin
- Chronic liver disease
- Severe systemic illness
- Active acromegaly
- Nephrosis

Decreased peripheral conversion of thyroxine to triiodothyronine
- Fasting/malnutrition
- Systemic illness
- Physical trauma
- Postoperative state

Approximately 95 percent of cases of hypothyroidism are thought to arise from defects in the thyroid gland itself, whereas the remaining cases result from defects in the hypothalamic-pituitary axis. Ironically, the most common cause of hypothyroidism without a goiter is the surgical or radioiodine-induced ablation of the thyroid gland for the treatment of Graves thyrotoxicosis. Cretinism occurs with untreated congenital hypothyroidism and does not have a goiter. The most common cause of hypothyroidism with a goiter in North America is Hashimoto thyroiditis. Less common causes of hypothyroidism include inherited defects in hormone synthesis or the ingestion of drugs that inhibit hormone synthesis, such as lithium or aspirin. Bexarotene, a retinoid-X-receptor agonist (see Chap. 229) used to treat cutaneous T-cell lymphoma, causes a central hypothyroidism with a decrease in TSH, followed by low levels of T_3 and T_4.[121] In rare cases, hypothyroidism can occur from decreased secretion of TSH, such as with pituitary failure, a tumor of the pituitary region, or postpartum pituitary necrosis (Sheehan syndrome). Inadequate secretion of TRH by the hypothalamus is another very rare cause of hypothyroidism.

Clinical Findings

CUTANEOUS MANIFESTATIONS OF HYPERTHYROIDISM (Table 152-5) Signs and symptoms of hyperthyroidism and hypothyroidism are variably present and

TABLE 152-4
Medications Affecting Thyroid Hormone Levels

Drugs that affect thyroid hormone secretion
- Lithium (decreases secretion)
- Iodide (can increase or decrease secretion)
- Amiodarone (can increase or decrease secretion)

Drugs that increase serum thyroid-binding globulin concentrations
- Estrogens/tamoxifen
- Heroin/methadone
- Fluorouracil

Drugs that decrease serum thyroid-binding globulin concentrations
- Androgens
- Anabolic steroids
- Slow-release nicotinic acid
- Glucocorticoids

Drugs that increase hepatic metabolism of thyroid hormone
- Phenobarbital
- Rifampin
- Phenytoin
- Carbamazepine

Drugs that decrease deiodination of thyroxine to triiodothyronine
- Propylthiouracil (used to treat hyperthyroidism)
- Amiodarone
- β Blockers
- Glucocorticoids
- Certain radiographic contrast dyes

Drugs that decrease thyrotropin
- Bexarotene

summarized in Table 152-6. The skin changes of hyperthyroidism have been likened to infant's skin and described as soft, warm, and velvety in texture. Pruritus can be a manifestation of thyroid disease, and laboratory screening for thyroid disease is often included in working up patients experiencing diffuse pruritus with no obvious rash. Scalp hair in hyperthyroid patients is described as soft and fine, and in certain cases may be accompanied by a diffuse non-scarring alopecia analogous to telogen effluvium. Patients with hyperthyroidism frequently have nail changes that are commonly described as soft, shiny, and brittle nails with an increased rate of growth. A small percentage of patients with hyperthyroidism will have Plummer's nails, which exhibit a concave shape with distal onycholysis (see Chap. 87). Plummer's nails can also be found in a variety of other conditions and are not pathognomonic for hyperthyroidism. Vitiligo appears to

TABLE 152-5
Approach to Patient with Hyperthyroidism

Cutaneous findings in hyperthyroidism
- Soft, velvety, infant-like skin
- Thyroid dermopathy
- Soft, fine with diffuse non-scarring alopecia
- Facial flushing
- Palmar erythema
- Hyperpigmentation
- Plummer's nails
- Thyroid acropachy
- Hyperpigmentation

Related features
- Hyperhidrosis
- Atrial fibrillation
- Ophthalmopathy
- Goiter
- High-output cardiac failure
- "Thyroid storm"

Diagnosis
- Best initial test is serum thyrotropin
- Other tests include serum free triiodothyronine, thyroxine, and antithyroid antibodies
- Radioactive iodine uptake and imaging

Management
- Appropriate surgical and endocrine consultation
- Propanolol for symptomatic treatment
- Propylthiouracil to inhibit thyroid hormone metabolism
- Methimazole to inhibit thyroid hormone synthesis
- Radioiodine ablation of the thyroid gland

be over-represented in patients with Graves disease, but not in patients with other forms of hyperthyroidism. Vitiligo may often predate the diagnosis of thyroid disease and does not improve with the treatment of the hyperthyroidism (see Chap. 72).

Thyroid dermopathy is most commonly seen with Graves disease but has been reported in hypothyroid patients as well. Pretibial thyroid dermopathy (in the past referred to as *pretibial myxedema*) is a classic manifestation of hyperthyroidism and Graves disease (Fig. 152-10). The term *thyroid dermopathy* is used in this chapter because the lesions can occur at any site on the body, are not limited to the pretibial region, and the name does not suggest myxedema as a cause.[122] Although there are reports of hyperthyroid patients who have presented with thyroid dermopathy as their initial finding, thyroid dermopathy is usually a later manifestation of thyroid disease. Almost all patients with thyroid dermopathy also have thyroid ophthalmopathy, another late manifestation of hyperthyroidism.[123] The clinical appearance of thyroid dermopathy can be quite varied. Classically, thyroid dermopathy occurs bilaterally as painless non-pitting nodules and plaques with variable coloring and a waxy, indurated texture (see Fig. 152-10). The distribution can range from very circumscribed to diffuse, but by far the most common location is on the extensor surfaces of the legs.[123] Some cases can exhibit a peau d'orange appearance as well. An extreme form of diffuse thyroid dermopathy has been termed the *elephantiasic* variant, which occurs in less than 1 percent of patients with Graves disease and is characterized by progressive thickening and gray-black hyperpigmentation of the pretibial skin accompanied by a woody, firm edema with nodule formation.[122] Biopsies of thyroid dermopathy reveal a thickened dermis with splayed collagen fibrils and abundant mucin, usually hyaluronic acid, in the interstitial space.

The exact pathophysiology underlying thyroid dermopathy is still unclear. Histologically, increased amounts of hyaluronic acid are seen in the dermis and the subcutis, leading to the hypothesis that fibroblasts or other cells in the dermis may be synthesizing increased levels of GAGs secondary to stimulation by activating autoantibodies. However, antibodies that bind TSH-R on fibroblasts can be seen in patients with and without thyroid dermopathy, indicating that other determinants are likely involved. The presence of dependent edema in the lower extremities may also contribute somehow to either the

▲ **FIGURE 152-10** Hyperthyroidism with thyroid dermopathy in a classic location on the anterior shins. Note that infiltrated plaques extend to the calf and are partially hyperkeratotic. An isolated nodule is also present on the dorsum of the foot.

TABLE 152-6
Symptoms, Clinical Findings, and Complications of Thyroid Disease

Symptoms, Clinical Findings, and Complications of Hyperthyroidism	Symptoms, Clinical Findings, and Complications of Hypothyroidism
Symptoms	Symptoms
• Unintentional weight loss	• Unexplained weight gain
• Heat intolerance/sweating	• Fatigue
• Palpitations	• Cold intolerance
• Agitation/emotional lability	• Constipation
• Multiple daily loose stools	• Dry skin
• Pruritus	• Muscle weakness
• Weakness	• Carpal tunnel syndrome
• Oligomenorrhea in women	• Hoarseness
Clinical findings and complications	• Decreased body temperature
• Goiter	• Facial swelling
• Tachycardia	• Menorrhagia in women
• Atrial fibrillation	Clinical findings and complications
• High-output cardiac failure	• Goiter
• Fine tremor	• Cold, doughy skin
• Hot sweaty extremities	• Bradycardia
• Ophthalmopathy	• Facial and finger swelling
• Agitation/confusion	• Slowed relaxation of deep tendon reflexes
• Muscle weakness/wasting	• Hair loss/lateral eyebrow loss
• "Thyroid storm" with fever, confusion, dehydration, and eventual death, if untreated	• Pericardial effusion
	• Myocardial infarction or congestive heart failure with aggressive thyroid hormone replacement
	• Coma and death without treatment

▲ **FIGURE 152-11** Graves disease. Note the proptosis of the eyes, thyroid acropachy, and the thyroid dermopathy on the pretibial region.

fibroblast stimulation or hyaluronic acid accumulation, and thus account for the tendency of thyroid dermopathy to occur in this anatomic site.

Thyroid acropachy refers to digital clubbing, soft-tissue swelling of the hands and feet, and the presence of characteristic periosteal reactions.[122] This very rare clinical finding is also associated with thyroid dermopathy and exophthalmos, and almost always presents after the diagnosis and treatment of hyperthyroidism (Fig. 152-11). Like thyroid dermopathy, thyroid acropachy has also been reported in hypothyroid conditions. Clubbing occurs most frequently on the first, second, and fifth metacarpals, the proximal phalanges of the hand, and the first metatarsal and proximal phalanges of the feet.[122] The radiologic findings are characterized by a lamellar periosteal reaction of the hands or wrists, with long bones only rarely involved. Because increased osteoblastic activity has been observed in the diaphyseal parts of small bones, the use of bone scan has been suggested as a sensitive way to aid in diagnosis.[124] The mechanisms underlying thyroid acropachy remain unknown, although interestingly, a large case series identified a disproportionately high percentage of smokers (80 percent) in patients with thyroid acropachy.[125]

The effects of thyroid hormone excess on other organ systems can also result in cutaneous findings. Hyperpigmentation similar to Addison disease has been seen with hyperthyroid disease, with resultant pigment in the palmar creases, gingiva, and buccal mucosa that is usually more prominent in individuals with darker skin. It has been postulated that the hyperpigmentation may be the result of increased corticotropin (ACTH) resulting from accelerated cortisol metabolism.[122] The cardiovascular effects of thyroid hormone excess include atrial fibrillation, increased cardiac output, and decreased peripheral vascular resistance, resulting in increased blood flow to the skin along with facial flushing and palmar erythema. The overall increased metabolism, along with changes in peripheral blood flow and temperature dysregulation, can also result in a generalized hyperhidrosis as well as high-output cardiac failure similar to that seen with Paget disease of bone.

There is extensive literature regarding the association between thyroid disease and urticaria[126] (see Chap. 37). Several studies have found a much higher incidence of thyroid disease in patients with chronic urticaria compared with control populations, although the mechanism behind this association remains unclear. Other dermatologic conditions have been reported in association with Graves disease, including dermatitis herpetiformis, Sweet syndrome, pemphigoid gestationis, vitiligo, pemphigus vulgaris, anetoderma, and mid-dermal elastolysis.[122]

CUTANEOUS MANIFESTATIONS OF HYPOTHYROIDISM (Table 152-7) In hypothyroidism, decreased core temperature and increased peripheral vasoconstriction cause the skin to be cool and pale. The skin is also xerotic, and the stratum corneum is poorly hydrated. Histologically, the epidermis is thin, and there is hyperkeratosis with follicular plugging. The generalized distribution of these findings can help distinguish these changes from those of atopic dermatitis and keratosis pilaris, which tend to be more prominent on the extremities. A fine wrinkling can also be seen. A yellow-orange discoloration of the skin can be seen secondary to the accumulation of β-carotene in the stratum corneum, possibly secondary to increased circulating carotene from diminished hepatic conversion of β-carotene to vitamin A.

Myxedema is the most classic finding associated with hypothyroidism and is distinct from the thyroid dermopathy seen with Graves disease. Myxedema occurs as a result of dermal accumulation

TABLE 152-7
Approach to the Patient with Hypothyroidism

Cutaneous findings
• Myxedema
• Cool temperature
• Doughy, dry skin with fine wrinkling
• Yellow-orange carotenemia
• Dry, brittle hair
• Slow growth of hair and nails
Related features
• Macroglossia
• Broadened nose, thickened lips, puffy eyelids
• Impaired wound healing
• Cretinism with congenital cases
• "Myxedema coma"
Diagnosis
• Best initial test is serum thyrotropin
• Other tests include serum free triiodothyronine and thyroxine
Management
• Appropriate endocrine consultation
• Oral thyroxine (usually in the range of 75–150 μg/day)
• Careful follow-up for heart, lung, and adrenal disease

of mucopolysaccharides, namely hyaluronic acid and chondroitin sulfate, and tends to resolve with treatment of the hypothyroidism. The myxedema tends to be generalized but can appear more striking in the extremities. Characteristic facial changes can be seen, including a broadened nose, thickened lips, puffy eyelids, and macroglossia with a smooth and clumsy tongue (Fig. 152-12). The skin can be doughy, swollen, and waxy, but without pitting. Wound healing is impaired in hypothyroidism.

The hair in hypothyroidism is coarse, dry, and brittle with slowed growth. Hair loss in the scalp can be either diffuse or patchy. Hypothyroidism can result in increased numbers of hair follicles in telogen, as well as telogen effluvium when the onset of hypothyroidism is abrupt. There can be loss of eyebrow hair in a characteristic pattern involving the outer third (see Fig. 152-12). Although body hair can be diminished, hypothyroidism can also result in increased lanugo hair on the back, shoulders, and extremities. The nails in hypothyroidism grow slowly and can be thickened and brittle with longitudinal and transverse striations. In patients with a goiter, hoarseness can result secondary to compression of the recurrent laryngeal nerve. With large goiters, tracheal or esophageal displacement can be seen. In extreme cases, large retrosternal goiters can cause Pemberton's sign, characterized by facial plethora suggestive of compression when patients raise their arms above their head.

▲ **FIGURE 152-12** Hypothyroidism. This patient has many of the characteristic features of hypothyroidism, including dry, pale skin; the absence of hair on the lateral third of the eyebrow; and puffiness of the face and lips due to accumulation of mucopolysaccharides in the dermis. The nose is broadened; the tongue is large, smooth, red, and clumsy; and there is drooping of the eyelids. Also, note the lack of facial expression that is the most pathognomonic of any of the features.

Hashimoto thyroiditis has been associated with several other dermatologic disorders, including alopecia areata, connective tissue disease (including lupus and dermatomyositis), bullous pemphigoid, dermatitis herpetiformis, and chronic mucocutaneous candidiasis (CMC).[127–131]

Laboratory Tests

The diagnosis of thyroid-related cutaneous disease is often suspected clinically, although in certain instances a skin biopsy may prove helpful in confirming the diagnosis. The clinical diagnosis of thyroid disease is confirmed by thyroid function tests. Serum levels of TSH are recommended as an initial screen, and any abnormalities in TSH should be followed up with measurements of serum T_4 and free T_3 to confirm whether the abnormal TSH truly reflects a thyroid disorder. Other tests that can be useful include in vitro T_3 resin uptake and measurements of antithyroid antibodies. This combination of tests will diagnose the vast majority of patients with suspected thyroid disease.

Treatment

The mainstay of treatment for the cutaneous findings of thyroid disease is normalization of thyroid function, either through replacement of thyroid hormone for hypothyroidism or through ablation of thyroid function for hyperthyroidism. Thyroid dermopathy and thyroid acropachy can be a chronic problem even in patients who are treated effectively for their thyroid disease, and the current treatment options can be classified as either experimental or palliative at best. Complete or partial remission of cutaneous findings can be seen even in the absence of any localized topical treatment.[132] Reported treatments of thyroid dermopathy include topical corticosteroids, systemic corticosteroids, intralesional corticosteroids, intralesional octreotide, intravenous (IV) immunoglobulin, plasmapheresis, compression therapy, and even surgical excision.[132,133] The success of these therapies is still controversial and based on small uncontrolled case series or anecdotal reports.

PARATHYROID DISEASE

AT A GLANCE

- The most common cause of hypercalcemia in outpatients is hyperparathyroidism, while the most common cause of hypercalcemia in hospitalized patients is malignancy.
- The most common causes of hypocalcemia are vitamin D deficiency and surgically induced hypoparathyroidism.
- Calciphylaxis is most commonly seen in the setting of secondary hyperparathyroidism of renal failure.

Epidemiology

The annual incidence of primary hyperparathyroidism has decreased in the past two decades to about 20 cases per 100,000, potentially reflecting a decrease in the use of ionizing radiation to the neck, which is a known risk factor for developing primary hyperparathyroidism.[134] The majority of cases occur in individuals older than 45 years of age, with an approximate 2:1 female-male predominance. In the outpatient setting, parathyroid disease accounts for almost all cases of hypercalcemia. In hospitalized patients, parathyroid disease accounts for approximately one-third of all cases of hyperparathyroidism, while the majority of other cases are accounted for by malignancy. Together, hyperparathyroidism and malignancy account for greater than 90 percent of all cases of hypercalcemia.

Etiology and Pathogenesis

Parathyroid hormone (PTH) is secreted by the parathyroid gland in response to low levels of serum calcium and acts as one of the main regulators of calcium levels in the body. Elevations of PTH (hyperparathyroidism) are associated with hypercalcemia, whereas decreased levels of PTH (hypoparathyroidism) are associated with hypocalcemia. PTH acts through varying mechanisms that include the stimulation of vitamin D production, stimulation of calcium absorption in the gastrointestinal tract, regulation of renal absorption of calcium and phosphate, and direct regulation of calcium mobilization from bone. Circu-

lating free calcium acts on the parathyroids via a G-protein–coupled receptor to control the release of PTH. Released PTH then acts in target tissues by binding another G-protein–coupled receptor, the PTH receptor, resulting in changes in calcium metabolism. Because problems with PTH result primarily in alterations of circulating calcium, it is not surprising that the skin manifestations of parathyroid disease are primarily changes resulting from calcium dysregulation. The skin is likely a site of PTH action, although the exact effects of PTH on skin are not understood. Keratinocytes express a PTH-related peptide (PTHrP) that has been implicated in regulating keratinocyte growth and differentiation and utilizes the same receptors as PTH.[135–138] Although PTHrP has been associated with normal wound healing, elevated PTHrP can also be seen in the setting of certain squamous cell carcinomas.[137,139,140] The elevated PTHrP with squamous cell carcinoma can result in malignancy-related hypercalcemia in these patients.

Primary hyperparathyroidism results from abnormal function of the parathyroid gland, resulting in increased levels of PTH. In 80 percent of diagnosed cases, the cause of hyperparathyroidism is a result of either parathyroid hyperplasia, parathyroid carcinoma, or parathyroid adenoma. Pseudohyperparathyroidism occurs when PTH or a PTH-like molecule (for instance PTHrP) is secreted from a non-parathyroid tissue such as occurs in malignancy.

Secondary hyperparathyroidism occurs most commonly in the setting of renal disease. Resistance of end organs to PTH results in hypersecretion of PTH and consequent hypocalcemia and hyperphosphatemia. Secondary hyperparathyroidism is found in almost all patients with chronic renal failure requiring dialysis. Secondary hyperparathyroidism can also be associated with idiopathic hypercalciuria as well as with certain medications, including oral contraceptives and long-term furosemide therapy. In renal patients with long-term secondary hyperparathyroidism, hyperplastic parathyroid tissue can become autoactivated, resulting in tertiary hyperparathyroidism. This condition is characterized by persistent hypersecretion of PTH and resultant osteomalacia despite hypercalcemia.

Primary hypoparathyroidism occurs primarily from iatrogenic causes such as the removal of the parathyroid glands during a thyroidectomy. There are also several genetic and non-genetic congenital causes of primary hypoparathyroidism, although these are much less common. Secondary hypoparathyroidism refers to decreased PTH secretion secondary to a primary process that causes hypercalcemia.

TABLE 152-8
Physical Findings Associated with Hypercalcemia and Hypocalcemia

Hypercalcemia
- Anorexia
- Nausea and vomiting
- Constipation
- Hypotonia
- Lethargy and coma

Hypocalcemia
- Increased neuromuscular irritability and tetany
  - Chvostek's sign: induced tetany of the facial muscles induced by tapping on the zygoma
  - Trousseau sign of hypocalcemia: carpal spasm with inflation of blood pressure cuff above systolic value
- Peripheral and perioral paresthesias
- Seizures
- Bronchospasm/laryngospasm
- Lengthening of QT interval on electrocardiogram

Clinical Findings

Parathyroid disease most often presents in the setting of altered calcium metabolism. The physical findings and symptoms associated with hyper- and hypocalcemia are shown in Table 152-8. As for hypercalcemia and hyperparathyroidism, skin manifestations are rarely seen but can be impressive and dramatic. An approach to a patient with suspected hyperparathyroidism is outlined in Table 152-9. Cutaneous calcinosis (sometimes referred to as *calcinosis cutis* or *metastatic calcinosis*) is thought to be related to elevated calcium and phosphate[141] (see Chap. 138). Subcutaneous calcifications can be found in a symmetric distribution, often overlying large joints or in linear arrayed papules and plaques that are normally of skin color and hard on palpation (Fig. 152-13). These lesions can be pruritic. Chronic urticaria has been associated with hyperparathyroidism as well.[142] Signs of hyperparathyroidism in association with cutaneous skin tumors, such as angiofibromas, collagenomas, and lipomas, should engender a workup for multiple endocrine neoplasia type 1 (MEN1), which is caused by mutations in the MEN1 gene and characterized by tumors of the anterior pituitary, the pancreas, and the parathyroid. The finding of somatic (non-germline) mutations and loss of heterozygosity of the MEN1 gene in 20 percent to 30 percent of spontaneous parathyroid tumors further supports a role for this gene in parathyroid oncogenesis.[143] The differential diagnosis is of hypercalcemia is shown in Box 152-2.

TABLE 152-9
Approach to the Patient with Suspected Hyperparathyroidism

Cutaneous findings
- Cutaneous (metastatic) calcinosis
- Calciphylaxis

Related disorders
- Renal disease
- Multiple endocrine neoplasia type 1 with angiofibromas, collagenomas, and lipomas
- History of head/neck irradiation

Diagnosis
- Serum calcium and serum parathyroid hormone
- With suspected malignancy, serum parathyroid hormone-related peptide

Management
- Identify underlying cause of hyperparathyroidism.
- Appropriate endocrine, surgery, and nephrology consultation.
- Hospitalization for acute cases with hypercalcemia.
- Aggressive fluid management to treat hypercalcemia, with forced diuresis.
- Phosphate replacement as warranted.
- Dialysis for acute renal failure.
- Calciphylaxis warrants aggressive management of wounds and infection.
- Surgical parathyroidectomy.

Calciphylaxis is a rare but life-threatening cutaneous condition associated

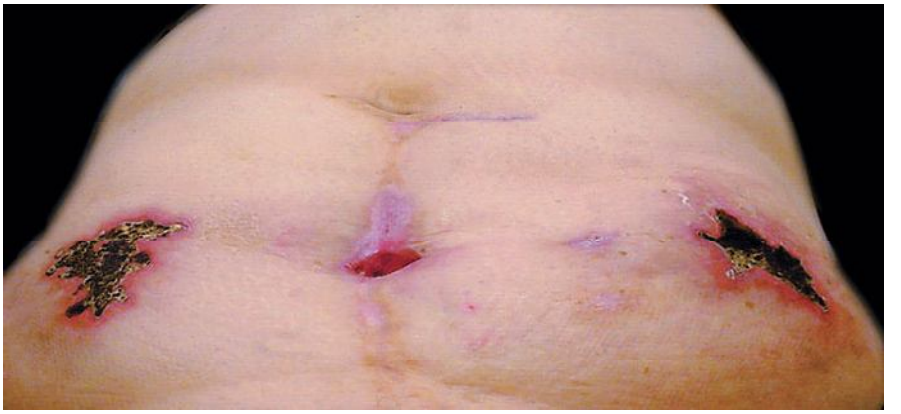
▲ **FIGURE 152-13** Papules of cutaneous calcinosis are arranged in a linear array in the skin overlying the mandible.

Box 152-2

Differential Diagnosis of Hypercalcemia

- Increased parathyroid hormone
  - Solitary adenoma
  - Multiple adenomas (i.e., multiple endocrine neoplasia type 1)
  - Tertiary hyperparathyroidism with renal failure
- Increased parathyroid hormone-related peptide
  - Squamous cell carcinoma
  - Renal carcinoma
  - Bladder carcinoma
  - Human T-cell leukemia virus type 1
  - Breast cancer
  - Lymphoma
- Increased 1,25-vitamin D
  - Sarcoidosis
  - Excess ingestion
- Increased bone resorption of calcium
  - Myeloma
  - Lymphoma
  - Breast cancer
- Renal failure
  - Secondary hyperparathyroidism
  - Tertiary hyperparathyroidism
  - Vitamin D intoxication
  - Milk-alkali syndrome (susceptibility to hypercalcemia with ingestion of calcium-based antacids and milk)

with hyperparathyroidism. Calciphylaxis occurs most often in the setting of chronic renal failure and secondary hyperparathyroidism, although there are reports of calciphylaxis associated with primary hyperparathyroidism and normal renal function. Although the name may falsely imply an immune etiology, calciphylaxis actually results from calcium deposition in the walls of small- to medium-sized vessels, resulting in vascular occlusion and skin necrosis. Clinically, patients present initially with violaceous patches that may exhibit a mottled or reticular pattern. Subsequently, involved areas can become indurated and painful, with eventual ulceration and eschar formation that proceeds to tissue gangrene (Fig. 152-14; see Fig. 151-13). Both the trunk and extremities can be involved. A calcium-phosphate product (serum calcium × serum phosphate) of greater than 70 mg/dL has often been cited as a predisposing risk factor. The histologic finding of calcium deposits in vessel walls coupled with compatible clinical findings is diagnostic. Calciphylaxis has a very poor prognosis, with reported mortality rates up to 80 percent, usually from infection. Parathyroidectomy and aggressive management of wounds and infections has been successful in treating some cases. There is not compelling evidence to support the use of hyperbaric oxygen, but there are small case series reporting successful treatment of calciphylaxis using hyperbaric oxygen, suggesting use for this often life-threatening condition.[144,145]



▲ **FIGURE 152-14** Calciphylaxis in a patient with chronic renal failure. Note the stellate-shaped necrotic plaques on the abdomen and the scars from peritoneal dialysis. Often the thighs and buttocks are also involved. A deep biopsy that includes subcutaneous fat can help make the diagnosis if it demonstrates the characteristic findings of calcification in the media of small- and medium-sized vessels. Histologically, subcutaneous calcium deposits and fat necrosis can also be seen.

Hypoparathyroidism is associated with scaly, hyperkeratotic, and edematous puffy skin (Table 152-10). Paresthesias secondary to hypocalcemia can be seen. Patchy alopecia and generalized thinning of the hair have been reported. Nails can be brittle with transverse ridging. Hypoparathyroidism has been associated with psoriatic flares, which is interesting in light of the response of psoriasis to calcipotriene.[146] These skin abnormalities often resolve with normalization of serum calcium levels, suggesting that they are due to changes in calcium homeostasis rather than deficiency of PTH.

Hypoparathyroidism in the setting of familial autoimmune polyglandular syndrome type 1 has been associated with chronic mucocutaneous candidiasis (CMC) and adrenal failure.[147] The CMC can precede the diagnosis of hypoparathyroidism, although the CMC does not improve significantly with treatment of the hypoparathyroidism with calcium and vitamin D. Other findings in these patients include dental enamel hypoplasia, vitiligo, and the cutaneous manifestations of adrenal failure (see under Addison Disease).

Hypoparathyroidism in the setting of elevated serum PTH is known as *pseudohypoparathyroidism* or *PTH-resistant hypoparathyroidism*. Although several variants of pseudohypoparathyroidism have been described, perhaps the best-characterized is Albright's hereditary osteodystrophy.[148] These patients present with a constellation of findings that include short stature, obesity, rounded facies, dental hypoplasia, and shortened bones of the hands and feet. Characteristic shortening of the fourth metacarpal leads to a dimpling of the fourth knuckle, known as *Albright's sign*. These patients can also have subcutaneous ossifications and calcifications.

Laboratory Tests

The diagnosis of parathyroid disease can be made with measurements of se-

TABLE 152-10
Approach to the Patient with Suspected Hypoparathyroidism

Cutaneous findings
• Scaly, hyperkeratotic, puffy skin
• Patchy alopecia with hair thinning
• Brittle nails with transverse ridging
Related findings
• Paresthesias
• Neuromuscular irritability
• Bronchospasm or laryngospasm
• Electrocardiogram changes
Diagnosis
• Serum calcium and serum parathyroid hormone
• Serum magnesium levels to rule out hypomagnesemia
• Electrocardiogram to rule out QT elongation
Management
• Vitamin D or vitamin D metabolites (i.e., calcitriol at 0.2–1.0 μg/day)
• Calcium supplementation at 2–3 g of elemental calcium per day
• Magnesium supplementation when appropriate

rum calcium levels and serum levels of PTH. In the case of hypercalcemia related to malignancy, measurement of PTHrP may also be useful in the workup.

Treatment

The main treatment for hyperparathyroidism is partial or total parathyroidectomy (see Table 152-9). For hypoparathyroidism, treatment focuses on correction of serum calcium and phosphate (see Table 152-10). In the setting of acute hypercalcemia, aggressive fluid and electrolyte management are essential, because cardiorespiratory failure may result from dehydration.

DISORDERS OF THE ADRENAL GLAND

Cushing Syndrome

Excessive production of endogenous cortisol manifests clinically as Cushing syndrome. Similar findings are seen from chronic exogenous administration of glucocorticoids (see Chap. 225). In the normal physiology of the hypothalamic-pituitary-adrenal axis, corticotropin-releasing hormone is secreted from the hypothalamus and stimulates the production of corticotropin, also known as *ACTH*, by the anterior pituitary. ACTH is synthesized as part of a larger precursor molecule, proopiomelanocortin (POMC). This relationship of POMC to ACTH is important in diseases of the adrenal gland and the resulting skin manifestations. POMC is processed into several peptides, including melanocyte-stimulating hormone (MSH) and ACTH, which stimulates the production of cortisol from the adrenal cortex. In a classic negative feedback manner, cortisol inhibits corticotropin-releasing hormone and ACTH production.

EPIDEMIOLOGY, ETIOLOGY, AND PATHOGENESIS The overall incidence of Cushing syndrome is about 10 persons per million per year, with a female predominance.[149] Cushing syndrome is divided into two categories. The first is caused by inappropriately high secretion of ACTH, usually from a pituitary microadenoma. It is given the unique name of *Cushing disease*. The excess ACTH drives glucocorticoid production in the adrenals. Rarely ectopic, or non-pituitary, production of ACTH results in Cushing syndrome. This clinical presentation is most often associated with a pulmonary carcinoid tumor, although numerous other tumor types have been reported.[150] The second category of Cushing syndrome results from excess cortisol produced by the adrenal cortex independent of regulation by the pituitary or hypothalamus. This is usually due to an adrenal adenoma, which may be benign or malignant, or is the result of generalized hyperplasia of the adrenal gland. Cushing syndrome can be seen in the McCune-Albright syndrome[151] and in association with primary pigmented nodular adrenocortical disease in the Carney complex.[152]

CLINICAL FINDINGS: CUTANEOUS LESIONS The clinical presentation of Cushing syndrome may be subtle (Table 152-11). Skin findings may be present, and if careful attention is paid to the relationship of skin findings and systemic complaints, one may consider the diagnosis early in the clinical course. Common skin complaints are easy bruisability and skin thinning. Mild hypertrichosis often of the lanugo type and acne may occur. Frank hirsutism and severe acne raise the possibility of a concurrent androgen-secreting tumor. The development of multiple violaceous striae wider than 1 cm on the abdomen or proximal extremities is highly suggestive of Cushing syndrome (Fig. 152-15). The width and color of these striae differentiate them from the commonly seen striae in pregnancy or with weight gain. Relatively dramatic changes in fat distribution often occur along with a generalized gain in weight. There is an increase in central obesity and concurrent thinning of the arms and legs with loss of muscle mass. Increased facial fat results in a rounded appearance of the face, often with increased redness and telangi-

ADRENAL GLANDS AND THE SKIN AT A GLANCE

- Excessive production of cortisol manifests as Cushing syndrome and results from pituitary oversecretion of corticotropin or excess production of cortisol by the adrenal cortex.
- Destruction of the adrenal gland with loss of glucocorticoids, mineralocorticoids, and adrenal androgens is known as Addison disease.
- Although many etiologies of Addison disease are described, the most common cause is autoimmune destruction with detectable circulating autoantibodies.

TABLE 152-11
Approach to the Patient with Cushing Syndrome

Cutaneous findings in Cushing syndrome
- Increased central adiposity (moon facies and buffalo hump) with thinning of the extremities
- Skin thinning and easy bruisability
- Violaceous striae
- Acanthosis nigricans
- Increased dermatophyte and candidal skin and nail infections
- Rarely, hyperpigmentation

Related features
- Diabetes
- Hypertension
- Osteoporosis
- Irregular menses

Diagnosis
- Measurement of cortisol in serum and urine
- Failure to suppress cortisol production with dexamethasone suppression tests

Management
- Appropriate endocrine and surgical consultation
- Surgical removal of pituitary or adrenal adenoma
- Adrenal enzyme inhibitors
- Radiation therapy

▲ **FIGURE 152-15** Abdominal striae in a patient with Cushing syndrome. Note gynecomastia. This patient has psoriasis and was treated with corticosteroids.

ectasias. This appearance has been referred to as a moon facies. In addition to truncal obesity, there is an increase in the size of the dorsocervical fat pad, known as a *buffalo hump* and increased fat in the supraclavicular fossae. Men may experience gynecomastia.

Although unusual, hyperpigmentation can occur in cases of Cushing syndrome caused by massive increased ACTH production either from the pituitary or, more commonly, an ectopic source.[153] ACTH itself, in addition to MSH derived from POMC, contributes to increased melanin synthesis. This is similar to the hyperpigmentation more commonly associated with Addison disease. Acanthosis nigricans may be seen because Cushing syndrome contributes to insulin resistance, and, often, patients develop diabetes. The immunosuppressive effects of glucocorticoids result in increased dermatophyte and candidal nail and skin infections. Women may experience irregular menses or amenorrhea. Additional extra-cutaneous signs and symptoms of Cushing syndrome include hypertension, osteoporosis, and decreased muscle mass and strength.[154]

LABORATORY TESTS Diagnostic confirmation of Cushing syndrome requires demonstration of excess cortisol production. Cortisol production varies throughout the day and, as a rule, should be examined in the early morning when it is usually at its highest value. The average daily cortisol level can be measured using a 24-hour urine collection. Any abnormal test should be repeated two or three times for confirmation. If the urine or serum levels are elevated, failure to suppress the 8 A.M. serum cortisol level or 24-hour urine cortisol with a low-dose dexamethasone suppression test is confirmatory. Additional testing, including a high-dose dexamethasone suppression test, can be useful to determine if the source of the excess cortisol production is from the pituitary or elsewhere. Hypercortisolism may be present in patients without true Cushing syndrome. This is known as *pseudo-Cushing syndrome* and can be caused by obesity, major depressive disorders, and chronic alcohol abuse. With further testing, these patients can usually be identified.

TREATMENT The primary treatment of Cushing disease is surgical removal of the ectopic focus of ACTH production or adenoma in the pituitary or adrenal gland. Cure is achieved in the majority of patients, but resistant disease requires radiation in the case of pituitary disease or medical therapy with adrenal enzyme inhibitors.[153] Historically, Cushing syndrome was treated with bilateral adrenalectomy. This frequently resulted in Nelson syndrome, which is characterized by unchecked ACTH production from an enlarging pituitary adenoma with resulting hyperpigmentation. Pituitary radiation can be helpful in these cases.[155]

Addison Disease

EPIDEMIOLOGY, ETIOLOGY, AND PATHOGENESIS Destruction of the adrenal glands and the resulting life-threatening deficiency of glucocorticoids, mineralocorticoids, and adrenal androgens is known as *Addison disease*. It occurs at an estimated prevalence rate of 120 per million in Western countries.[156] It is suspected that many more cases remain undiagnosed. Historically, the most common cause was tuberculosis infection, but now autoimmune destruction as part of the autoimmune polyglandular syndromes 1 and 2 is the most common etiology. In autoimmune cases, enzymes of the adrenal cortex, including 21-hydroxylase and 17-hydroxylase, are target autoantigens, and circulating autoantibodies can be detected. Subsequent lymphocytic infiltration of the adrenal gland with damage and scarring results.

Infectious causes of adrenal insufficiency remain the next most common etiology. Tuberculosis is still a major problem in many areas of the world. Atypical mycobacterial infection can also cause adrenal insufficiency. This is seen more commonly in immunosuppressed patients. Addison disease is increasingly recognized in patients with acquired immunodeficiency syndrome and, in these patients, infections with cytomegalovirus is the most recognized cause. Fungal infections have also been associated with Addison disease, including histoplasmosis, blastomycosis, paracoccidioidomycosis, coccidioidomycosis, and cryptococcosis. In the setting of an acute bacterial infection, bilateral adrenal infarction due to adrenal hemorrhage is known as the *Waterhouse-Friderichsen syndrome*. Classically this is due to meningococcal infection, although other infections have been reported.[157] Other rare causes of Addison disease include drugs, congenital adrenal hypoplasia, and infiltrative disorders, including amyloidosis, sarcoidosis, and metastatic carcinomas. The surgical treatment of Cushing syndrome can be an additional cause of adrenal insufficiency.

TABLE 152-12
Approach to the Patient with Addison Disease

Cutaneous findings in Addison disease
• Hyperpigmentation of skin and mucous membranes
• Longitudinal pigmented bands in the nails
• Vitiligo
• Decreased axillary and pubic hair in women
• Calcification of auricular cartilages in men
Related features
• Abdominal pain
• Electrolyte abnormalities (hyponatremia and hyperkalemia)
• Postural hypotension
• Anorexia and weight loss
• Shock, coma, and death, if untreated
Diagnosis
• Failure to respond adequately to corticotropin stimulation test
Management
• Lifelong replacement therapy of glucocorticoids and mineralocorticoids

CLINICAL FINDINGS: CUTANEOUS LESIONS (Table 152-12) The clinical and cutaneous manifestations of adrenal insufficiency are not usually present until 90 percent of the gland function is destroyed.[156] The most recognized cutaneous manifestation is the hyperpigmentation of skin and mucous membranes. This occurs after long-standing adrenal insufficiency and would not be present in an acute presentation of adrenal crisis unless it is superimposed on a history of chronic adrenal insufficiency. The skin pigmentation is accentuated in sun-exposed areas, flexural folds, and skin creases, including the creases on the palms (Fig. 152-16). Pigment may develop in scars and longitudinal pigmented bands may appear in the nails. These pigment changes are a consequence of low cortisol levels and the resulting loss of negative regulatory feedback on the hypothalamus and pituitary. This results in unchecked production of POMC, ACTH, and MSH, which increase melanogenesis. As mentioned previously (see Epidemiology, Etiology, and Pathogenesis under Addison Disease), the disease is often associated with autoimmunity, and vitiligo can be seen in 10 percent to 20 percent of patients.[158] Axillary and pubic hair may be sparse in women, due to the loss of adrenal androgens. This does not occur in men because adequate androgen levels are maintained by the testes. Unique to men is the reported calcification of the auricular cartilages.[159] Extra-

▲ **FIGURE 152-16** **A.** This patient with Addison disease demonstrates the characteristic hyperpigmentation of the skin with accentuation in sun-exposed areas. **B.** Palmar creases are also hyperpigmented compared to a normal hand.

cutaneous symptoms include weakness, anorexia, weight loss, abdominal pain, and postural hypotension due to electrolyte abnormalities.

LABORATORY TESTS Acute adrenal crisis can occur in the setting of chronic adrenal insufficiency and can be life threatening. The primary treatment is glucocorticoid replacement and, in an acute crisis, a blood sample should be obtained for measurement of cortisol, but therapy with 100 mg IV hydrocortisone should be instituted immediately. In chronic adrenal insufficiency, the diagnosis is confirmed using the cosyntropin stimulation test. This involves the IV administration of synthetic corticotropin (ACTH) and the measurement of stimulated cortisol in the blood 30 minutes later. Inability to produce adequate cortisol is diagnostic. Chronic replacement therapy is necessary and may require adjustments for illness or severe stress. With treatment, there is a gradual improvement in the skin changes.

ESTROGEN AND PROGESTERONE

Epidemiology

The most commonly encountered cause of estrogen excess is the pharmacologic use of estrogens for birth control, treatment of dysfunctional uterine bleeding, and as post-menopausal hormone replacement. Up to one-third of childbearing age women in the United States use oral contraceptives.[160] Ovarian, testicular, or hypothalamic tumors can also cause estrogen excess. Estrogen deficiency occurs most commonly as a result of menopause, which occurs on average at about 50 years of age. Other less common causes of estrogen deficiency include pituitary or gonadal failure. Exercise-induced amenorrhea is also associated with a concomitant estrogen deficiency.

Etiology and Pathogenesis

Estrogen receptors are found throughout the skin, including on keratinocytes, sebaceous glands, eccrine and apocrine glands, in hair follicles, in dermal fibroblasts, and in melanocytes. Estrogens bind to cytosolic receptors that subsequently translocate to the nucleus and activate gene transcription. Estrogen receptors are found in greater numbers in women compared with men. The main observations regarding the effects of estrogen on skin come from studies of post-menopausal women, in whom estrogen deprivation leads to skin wrinkling, xerosis, and atrophy. Increased epidermal and dermal thickness, increased water-holding capacity, changes in lipid composition of the stratum corneum, and improvement in skin laxity all occur with estrogen replacement, highlighting the important effects of this hormone throughout the skin.[161] Estrogen deprivation has also been reported to hinder wound healing, which subsequently improves with estrogen replacement. Estrogens have also been reported to suppress sebaceous gland function and also tend to inhibit hair growth.

The most potent naturally occurring estrogen is estradiol, which is the principal estrogen secreted by the ovary. Estrone, another estrogen secreted by the ovaries, is synthesized primarily in peripheral tissues from the conversion of androstenedione. In the menstrual cycle, estradiol levels peak at mid-cycle immediately preceding ovulation, and then again near the end of the cycle around day 24 before falling to baseline

ESTROGEN AND SKIN AT A GLANCE

- Exogenous estrogen, either through oral contraceptives or hormone replacement, is the most common cause of estrogen excess.
- Wrinkling, xerosis, and atrophy are signs of estrogen deficiency.
- Triple-ingredient preparations are first-line therapy for treating melasma if patients are not content with covering cosmetics.

before menses. During pregnancy, the main estrogen is estriol, which is synthesized by the placenta. Progesterone is the main hormone secreted by the corpus luteum, and peak levels are seen after ovulation, remaining elevated until just before menses. Gonadal hormones are not entirely specific, and progesterone is able to cross-react by binding to androgen receptors to exert androgenic or anti-androgenic effects.

Clinical Findings and Diagnosis: Cutaneous Manifestations of Estrogen Excess and Deficiency

Estrogen can have both beneficial and undesired effects. Estrogen replacement therapy in post-menopausal women can reverse epidermal atrophy and restore cutaneous collagen. The inhibitory actions of estrogen on sebum production can lead to improvement of acne with oral contraceptive therapy, particularly with the use of estrogen-dominant preparations. Despite circulating estriol during pregnancy, the relative androgen excess due to elevated progesterone can actually exacerbate acne in some patients. Telogen effluvium characterized by diffuse loss of scalp or body hair can occur after delivery or discontinuation of oral contraceptives. Both pregnant women and patients taking synthetic estrogen can be more prone to certain side effects of estrogen, including telangiectasias, palmar erythema, spider angiomas, and pigmentary changes.

Melanocytic lesions, including preexisting nevi and malignant melanoma, can darken during pregnancy. Hyperpigmentation of the nipples, linea nigra, and genitalia can be seen. Melasma, sometimes referred to as the *mask of pregnancy*, presents as irregularly shaped, hyperpigmented patches on the forehead, cheeks, nose, upper lip, chin, and neck (Fig. 152-17). Although melasma may improve after delivery, it can reoccur with subsequent pregnancies. When caused by oral contraceptives, melasma can still persist even after discontinuation of the medication.

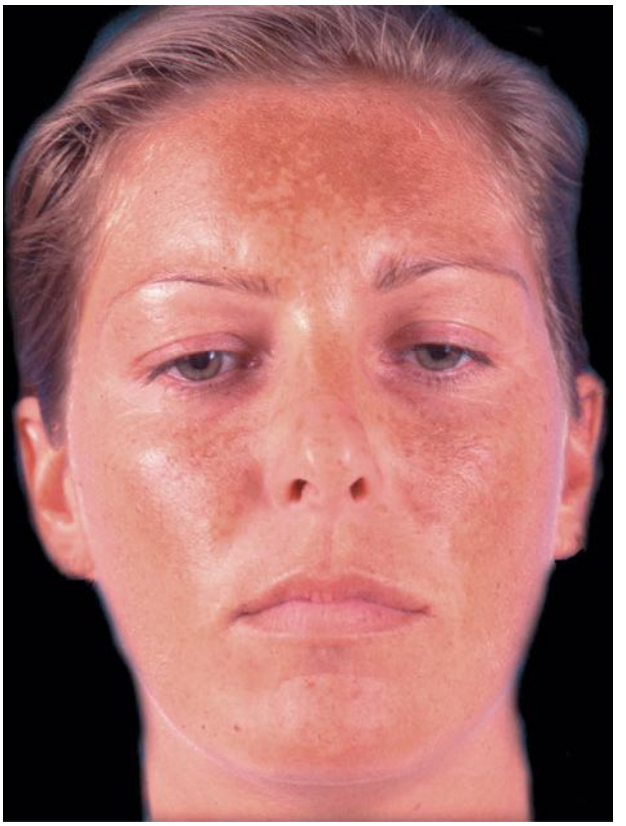
Acanthosis nigricans can be associated with estrogen excess. In clinical states characterized by elevated estrogen levels, including pregnancy and the use of oral contraceptives, increased hair growth over the face, breasts, and extremities can be seen. This phenomenon may be a result of the complex interplay of estrogens and androgenic hormones rather than a direct effect of increased estrogen levels on the hair follicles themselves. Estrogen and progesterone dermatitis has been described in the literature and is characterized by a polymorphous eruption marked by cyclical pre-menstrual flares that may include pruritus. The diagnosis may be made by separate subcutaneous injection of both estrogen and progesterone in the skin of the forearm, checking within 15 to 60 minutes for reactions ranging from erythema to a wheal.[162] Oral contraceptives have been implicated as a cause of erythema nodosum.

Estrogen deficiency from either menopause or pituitary failure can result in hot flashes, epithelial atrophy of the genitalia, and decreased breast size. Certain medications, such as danazol, leuprolide, and clomiphene citrate, can induce a pharmacologic menopause that presents with flushing. Flushing episodes accompanied by uncomfortable heat lasting several minutes can occur in younger women immediately before or during their period when estrogen levels are at their lowest.

Treatment

The Pigmentary Disorders Academy generated a consensus statement on the treatment of melasma and recommended the use of fixed "triple-ingredient" combinations as first-line therapy.[163] Topical retinoids, corticosteroids, azelaic acid, and hydroquinone-based bleaching creams have been used in various combinations to treat melasma. Kligman's formula, first developed in 1975, is the classic triple-ingredient melasma preparation consisting of 5 percent hydroquinone, 0.1 percent tretinoin, and 0.1 percent dexamethasone in a hydrophilic ointment. Dual ingredient combinations or single agents are reasonable alternatives. For refractory cases, chemical peels (i.e., glycolic acid or trichloroacetic acid) in combination with topical therapy can be tried. Lasers can also be considered but seem to be of limited usefulness. Given the exacerbation of hyperpigmentation with sun exposure, the consistent use of broad-spectrum sunscreens is also important for melasma treatment.

Although estrogen therapy can reverse some of the epithelial atrophy seen during menopause, the risks and benefits of hormone replacement therapy must be weighed on an individual basis. Low-dose clonidine has been reported as an effective treatment for menopause-related flushing. There has been controversy regarding the use of estrogen therapies in patients with systemic lupus erythematosus, although two recent, well-designed trials suggest that these therapies can be used safely in most patients with systemic lupus erythematosus whose disease is stable.[164,165]



◀ **FIGURE 152-17** Melasma is demonstrated in a symmetric pattern on the face of a young woman. The upper lip is also a common site of involvement.

ANDROGENIC HORMONES

Epidemiology

In males, cutaneous manifestations of androgen excess occur most commonly with either the onset of sexual maturation or with androgen replacement therapy. Androgen-secreting tumors are a less common cause of androgen excess. In women, androgen excess can occur due to congenital adrenal hyperplasia (CAH) secondary to deficiency of enzymes in adrenal enzymes such as 21-hydroxylase (also called *CYP21*), which accounts for almost 90 percent of CAH in the United States.[166] Deficiency of CYP21 is inherited as an autosomal recessive trait and results in accu-

ANDROGENS AND SKIN AT A GLANCE

- The peripheral conversion of testosterone to 5 α-dihydrotestosterone is important for the pathophysiology of androgenic alopecia.
- Hirsutism secondary to androgen excess has a characteristic distribution that includes the beard area, chest, back, and suprapubic region.

mulation of 17-hydroxyprogesterone. Although progestins in oral contraceptives are listed as potential causes of hirsutism due to their chemical similarity to testosterone, they likely do not cause androgenic effects at clinically used doses based on data from animal studies. PCOS occurs in about 5 percent of pre-menopausal women in the United States and is characterized by insulin resistance, polycystic ovaries, and the presence of androgenic cutaneous findings, including acne, hirsutism, and androgenic alopecia. PCOS is also associated with the metabolic syndrome, which is characterized by lipid abnormalities, diabetic predisposition, and heart disease. Androgenic alopecia affects approximately one-half of men older than age 40 years, and potentially as many women as well, with most patients showing signs of alopecia by age 30 (see Chap. 86).

Etiology and Pathogenesis

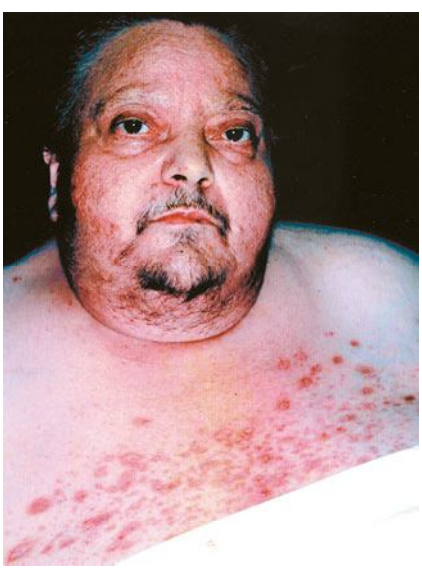
Like estrogen receptors, androgen receptors are also present throughout the skin. In men, androgens are synthesized in the testis and adrenals, whereas in women androgens are secreted by the ovaries and adrenals. In addition to testosterone, progesterone, dehydroepiandrosterone (DHEA), and DHEA sulfate (DHEA-S) are all natural androgens that can lead to cutaneous findings when they are present in excess.[167] Testosterone is subsequently converted in peripheral target tissues to the active metabolite 5 α-dihydrotestosterone (5α-DHT) by the enzyme 5α-reductase. Unlike testosterone, which can be aromatized to form estrogen, 5α-DHT cannot be aromatized and thus retains purely androgenic properties. In addition, 5α-DHT binds the androgen receptor with greater affinity than testosterone.

Androgens are significant regulators of hair growth and sebaceous gland function. Androgens have also been implicated in wound healing, epidermal differentiation, and the regulation of dermal fibroblasts. Androgen receptors have a trophic distribution throughout the body that is most evident with the appearance of "male pattern" hair growth on the face, chest, and back, as well as areas of hair loss on the scalp. Both estrogens and androgens can be bound by sex hormone binding globulin (SHBG, also called *TEBG* for *t*estosterone-*e*strogen-*b*inding *g*lobulin). SHBG levels are decreased by synthetic progestins found in oral contraceptives (i.e., norgestrel, norethindrone, norgestimate, desogestrel), as well as in obesity, acromegaly, hypothyroidism, and hyperinsulinemia. The decreased SHBG results in higher levels of circulating androgens and accounts, in part, for why androgenic findings can be associated with these conditions.

Clinical Findings and Diagnosis: Cutaneous Manifestations of Androgen Excess

Androgen-related skin conditions are commonly seen in dermatology practice. Although our knowledge regarding acne pathogenesis is still incomplete, at least part of acne's pathophysiology involves the response of sebaceous glands to androgens. In most males and females, acne tends to subside after adolescence (see Chap. 78). Cases of persistent acne should elicit a differential diagnosis that includes causes of persistent androgen excess, including CAH, PCOS in women, or an androgen-secreting tumor (Fig. 152-18), in addition to rosacea and chemically induced acne. In the appropriate clinical setting, laboratory studies may be helpful in determining the source of androgen excess (see Table 152-13). Performance-enhancing anabolic steroids are derivatives of testosterone, and the resulting androgen excess can manifest as acne.

There is some genetic variation underlying the response of hair follicles to androgens as evidenced by the varying degrees of hirsutism seen among women with different ethnic backgrounds but similar serum androgen levels. Hirsutism secondary to androgen excess occurs in a characteristic distribution involving the beard region of the face, the chest, the upper back, and the suprapubic area.



▲ **FIGURE 152-18** Hyperandrogenism manifests clinically in this woman with an androgen-secreting adrenal tumor. Note the characteristic facial hair, the receding hairline, and the acneiform eruption on the chest.

TABLE 152-13
Approach to the Female Patient with Suspected Hyperandrogenism

History and physical findings concerning for hyperandrogenism
- Sudden onset of acne
- Severe acne refractory to conventional treatments
- Irregular menstrual periods
- Hirsutism

Laboratory evaluation (most accurate when patient is off oral contraceptives for 4–6 weeks and if tests are drawn before menses)
- Dehydroepiandrosterone sulfate: screens for adrenal androgen source
  - > 8000 ng/mL may suggest adrenal tumor
  - 4000–8000 ng/mL may suggest congenital adrenal hyperplasia
- Testosterone: screens for ovarian source
  - 150–200 ng/dL can occur in polycystic ovarian syndrome
  - Some adrenal tumors can also secrete testosterone
- Luteinizing hormone–follicle stimulating hormone ratio
  - > 2–3 can be consistent with polycystic ovarian syndrome

Adapted from Thiboutot D: Acne: Hormonal concepts and therapy. *Clin Dermatol* **22**:419, 2004.

Ironically, although androgens can cause hair excess, they are also responsible for male-pattern alopecia as well. Scalp hairs are eventually converted first to indeterminate hairs and then to vellus hairs. Clinically, scalp hairs become thinner until they are replaced by nonpigmented vellus hairs. In men, the pattern is characteristic and consists of symmetric recession of the hairline and the temples along with hair loss on the vertex. In women, the hairline is usually preserved, and the pattern is mostly diffuse thinning without an area of frank baldness. Although androgenetic alopecia can be acquired in patients with androgen excess, it is most commonly an incompletely characterized genetic disorder that appears to be inherited in an autosomal dominant manner (see Chap. 86).

Treatment

In women whose acne appears to be hormonally related, the use of anti-andro-

gens, including the diuretic spironolactone or the oral contraceptive drospirenone, may prove more effective than conventional topical and oral acne medications. These drugs act as competitive inhibitors of DHT binding to androgen receptors. Specific 5α-reductase inhibitors, such as finasteride, can be used to treat androgenetic alopecia, although this medication is contraindicated in women of child-bearing age due to possible effects on development of genitalia and gonads in the male fetus.

When patients have an excess of adrenal androgens such as DHEA-S, the use of low-dose glucocorticosteroids (such as prednisone, 2.5 to 5.0 mg/day) can be used for suppressive therapy, and the efficacy of therapy can be monitored by measuring serum DHEA-S levels. Cyproterone acetate is an antiandrogen that is not available in the United States, although it has shown promise in the treatment of acne when used in other countries in oral contraceptive preparations. Flutamide is a nonsteroidal androgen receptor antagonist that is rarely used due to the risk of fatal hepatitis as well as concerns about effects on fetal development in women of child-bearing age.[168]

DISORDERS OF GROWTH HORMONE

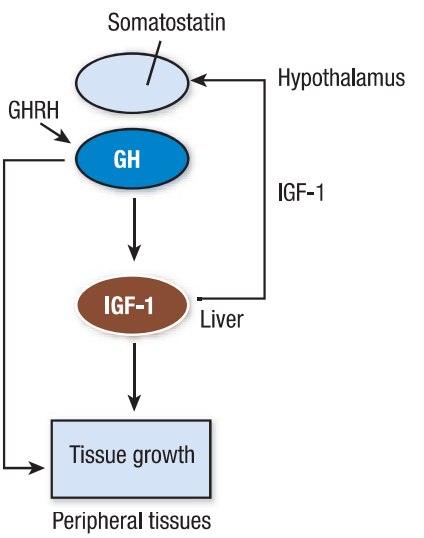
Acromegaly

Growth hormone (GH) is secreted by the pituitary in a pulsatile fashion and reaches its maximum rate during puberty and then declines over time. The pulsatile pattern of secretion is equally important to the amount of hormone for normal function. Secretion of GH is primarily regulated by GH-releasing hormone (GHRH) and somatostatin.[169] Recently, the natural GH secretagogue ghrelin, produced in the stomach, has been discovered to have potent GH-releasing properties and may be involved in a separate pathway of GH regulation.[169,170] GHRH stimulates the release of GH, whereas somatostatin has an inhibitory effect. The target of these regulatory factors is the GHRH receptor in the pituitary. The peripheral effects of GH are largely indirectly mediated through production of IGF-1 in the liver and stimulation of the IGF-1 receptor. GH contributes significantly to linear growth in children, increases protein synthesis, mobilizes stored triglycerides, and antagonizes the action of insulin (Fig. 152-19).

ETIOLOGY AND PATHOGENESIS Excessive production of GH is almost always due to a pituitary adenoma. In children, this results in pituitary gigantism, whereas in adults, excessive GH manifests as the clinical syndrome acromegaly. This syndrome is diagnosed in about 3 to 4 people per million every year.[171] Very rarely, acromegaly is caused by a GH-producing tumor in the hypothalamus or by an ectopic non-endocrine tumor such as small cell lung cancer or carcinoid tumor.[172] GH-producing adenomas are present in 8 percent of patients with Carney complex, an inherited disorder with multiple lentigines and multiple endocrine abnormalities.[173]

GROWTH HORMONE AT A GLANCE

- Growth hormone plays a central role in longitudinal growth.
- In children, deficiency manifests as short stature while gigantism occurs from oversecretion of growth hormone before puberty, when the growth plates in long bones are still open.
- The disease acromegaly occurs in adults after the growth plates have closed.
- Acromegaly results from oversecretion of growth hormone, usually due to a pituitary adenoma.



▲ **FIGURE 152-19** Effects and regulation of growth hormone (GH). GHRH = growth hormone releasing hormone; IGF-1 = insulin-like growth factor-1.

TABLE 152-14
Approach to the Patient with Acromegaly

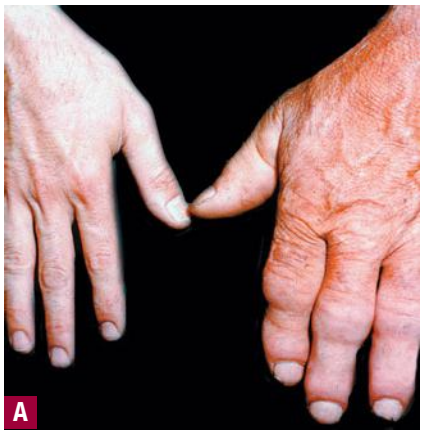
Cutaneous findings in acromegaly
- Enlargement of hands and feet with a doughy texture
- Increased ring, glove, shoe, and hat size
- Jaw enlargement with separation of teeth (prognathism)
- Macroglossia
- Cutis vertices gyri
- Acanthosis nigricans
- Hirsutism
- Hyperhidrosis
- Brittle thick nails

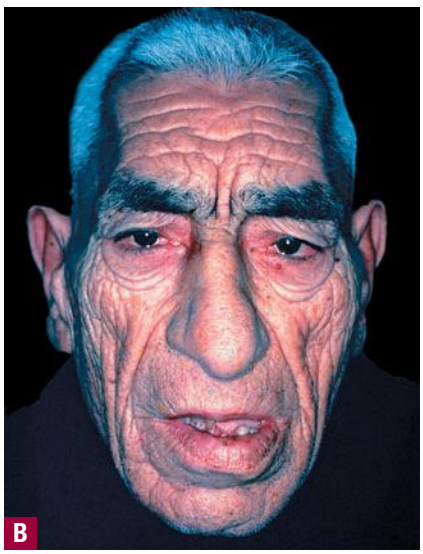
Related features
- Diabetes
- Hypertension
- Hyperlipidemia

Diagnosis
- Elevated serum insulin-like growth factor-1 levels
- Failure to suppress growth hormone levels by oral glucose-tolerance test

Management
- Appropriate endocrine and surgical consultation
- Surgical removal of adenoma by transphenoidal resection
- Somatostatin analogues or growth hormone receptor antagonists for residual disease
- Radiation therapy is an option for resistant cases

CLINICAL FINDINGS: CUTANEOUS LESIONS (Table 152-14) The clinical manifestations of acromegaly include the overgrowth of bone and connective tissue, metabolic effects, and localized tumor mass effects. The onset is insidious, and the average age at the time of diagnosis is 40 to 45 years old, but often the condition has been present for many years before the diagnosis.[174] The metabolic effects include diabetes, hypertension, and hyperlipidemia. There is a gradual coarsening of the features and increased head, hand, and foot size. This acral pattern of overgrowth may be noticed as increasing shoe, ring, glove, or hat size (Fig. 152-20A). Macroglossia can be seen. The skin becomes thickened, almost doughy, with deep grooves prominent on the forehead and around the nasolabial folds (Fig. 152-20B). On the scalp, cutis verticis gyrata may develop. Heel pads and the pads of the digits become thickened. Nails are thickened and brittle, and some patients develop hirsutism. Hyperhidrosis and malodor are common complaints. Many patients de-





▲ **FIGURE 152-20** **A.** Acral enlargement is a prominent feature of acromegaly and is easily demonstrated in comparison with a normal hand. **B.** Patients develop deep grooves on the forehead and around the nasolabial folds. When jaw enlargement is present, spaces between the teeth can be seen. (Reprinted from Braverman I, Saunders WB: *Skin Signs of Systemic Disease*, 3rd ed, 1997, with permission.)

velop acanthosis nigricans and multiple acrochordons with or without frank diabetes. Retinal angioid streaks can be seen in acromegaly (as well as in osteogenesis imperfecta and pseudoxanthoma elasticum) (see Chap. 139). Histologically, there is a dense deposition of GAGs in the papillary and superficial reticular dermis. Often, coarse collagen bundles with normal elastin and increased numbers of fibroblasts are seen in the dermis.

LABORATORY TESTS Measurement of the serum GH level is highly variable and unreliable diagnostically because of the pulsatile pattern of secretion. Plasma IGF-1 levels are very much dependent on GH and fairly stable during any 24-hour period. Serum IGF-1 can be used as a surrogate measurement of GH. As a screening test for acromegaly, IGF-1 levels will be elevated. Further workup with assistance from a consulting endocrinologist may include an oral glucose tolerance test. In the proper clinical setting failure to suppress the GH level to < 1 ng/mL within 1 or 2 hours after 75 to 100 g of oral glucose is diagnostic for acromegaly.[175]

TREATMENT Because most cases of GH excess are due to a pituitary adenoma, surgical removal is the primary therapy. This is most commonly accomplished through a selective transsphenoidal resection.[176] Residual disease after surgery is more common in larger adenomas and may be higher than 30 percent for tumors larger than 1 cm. The inhibitory effect of somatostatin on GH secretion is harnessed for therapy. Somatostatin analogues, including octreotide, are used for the medical treatment of residual disease after surgery and are increasingly being considered as potential primary therapy. The somatostatin analogues alone have demonstrated the ability to reduce the size of tumors and to control IGF-1 levels in select patients. In resistant cases, radiation therapy can be considered.

Growth Hormone Deficiency and Panhypopituitarism

GH deficiency can occur in children or adults and be inherited or acquired. The primary clinical manifestation of this deficiency occurs in children as abnormal short stature. This can be corrected by the administration of GH. The clinical presentation of GH deficiency in adults includes decreased lean body mass, decreased strength and exercise capacity in part due to decreased sweating, and a loss of general vitality. Replacement therapy in adults is a complex discussion and beyond the scope of this chapter. Recently, practice guidelines have been established by the Endocrine Society for the assessment and treatment of GH deficiency in adults.[177] In the setting of panhypopituitarism, there is total loss of all pituitary function, including GH (Table 152-15). These patients usually present with a combination of symptoms either due to a space-occupying lesion in the pituitary or to hormone dysregulation. These symptoms may be a manifestation of any number of endocrine systems that are regulated at the level of the pituitary including features of hypothyroidism. Skin findings that have been described in these patients include fine wrinkling of the skin, decreased pigmentation, and decreased to absent pubic and axillary hair (Fig. 152-21).

TABLE 152-15
Causes of Hypopituitarism

- Mass lesions: nonfunctioning pituitary adenoma, cyst, craniopharyngioma, metastasis
- Infectious causes: tuberculosis, histoplasmosis
- Pituitary infarction: known as *Sheehan syndrome* when occurs with childbirth
- Pituitary apoplexy: sudden hemorrhage into the pituitary
- Lymphocytic hypophysitis
- Infiltrative disorders: hemochromatosis, sarcoidosis, Langerhans cell histiocytosis
- Head trauma
- Surgery or radiation

▲ **FIGURE 152-21** In this patient with panhypopituitarism, fine wrinkling and pale skin can be seen as well as other features suggestive of hypothyroidism. Her decreased pigmentation is contrasted by that of her nurse on the right. Patients with panhypopituitarism often present with findings of multiple endocrine disorders.

CHAPTER 153

Sarcoidosis

Richard M. Marchell
Bruce Thiers
Marc A. Judson

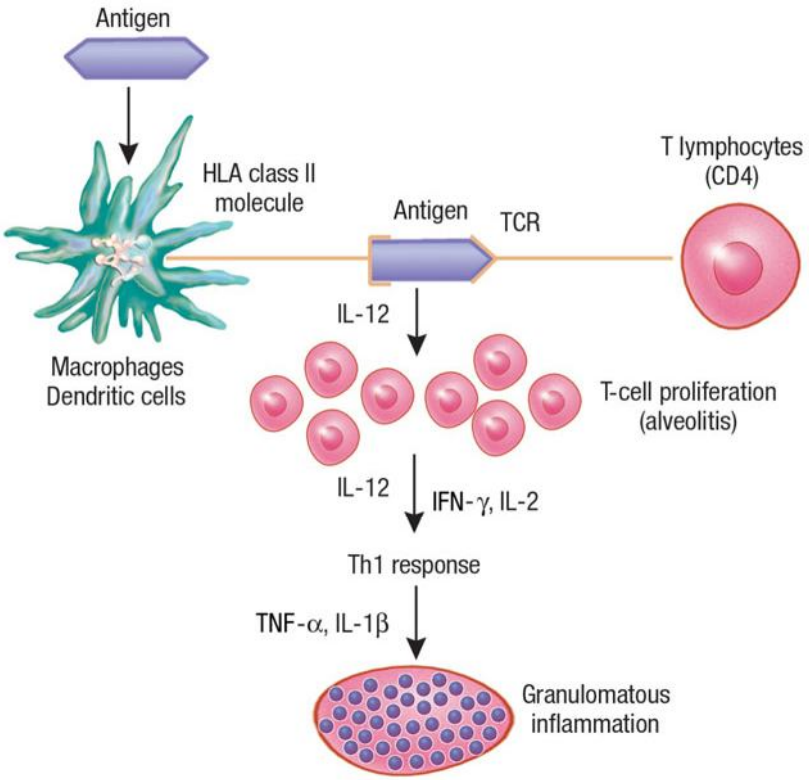
Sarcoidosis is a multisystem granulomatous disease of unknown cause. The lung is the most commonly affected organ, but the skin is frequently involved.[1] The first descriptions of sarcoidosis in the late 1800s were limited to its skin manifestations.[1] The term *sarcoidosis* is derived from Caesar Boeck's 1899 report of what he described as "multiple benign sarkoid of the skin," because he believed the lesions resembled sarcomas but were benign.[2]

EPIDEMIOLOGY

Sarcoidosis occurs worldwide and affects all ages and races. Disease onset is most often in the third decade of life, although a smaller second peak occurs in people older than 50 years.[1] The prevalence rate is slightly higher in women.[1] Sarcoidosis is more frequent away from the equator. The highest prevalence of sarcoidosis is found in Denmark, Sweden, and, in the United States, in persons of African descent.[1] In the United States, the lifetime risk of sarcoidosis is 2.4 percent in African Americans and 0.85 percent in Caucasians.[3] The age-adjusted annual incidence rate of sarcoidosis in the United States is 35.5 per 100,000 for African Americans and 10.9 per 100,000 for Caucasians.[3] The

SARCOIDOSIS AT A GLANCE

- Sarcoidosis is a systemic granulomatous disease of unknown cause that primarily affects the lungs, but often involves the skin.
- The highest prevalence of sarcoidosis is in Denmark and Sweden; in the United States, it is higher in persons of African descent.
- The most common sites of cutaneous sarcoidosis are the head and neck. Scar tissue at all sites can be affected.
- The most common cutaneous form of sarcoidosis, the papular form, is characterized by translucent yellow-red papules with an "apple jelly" appearance on diascopy.
- Noncaseating, "naked" granulomas on biopsy are quite suggestive, but not specific for the diagnosis.
- Erythema nodosum is the main nonspecific cutaneous manifestation of sarcoidosis, and heralds a good prognosis.



▲ **FIGURE 153-1** Proposed immunopathogenesis of sarcoidosis. An antigen, presently unknown, is engulfed and processed by an antigen-presenting cell (macrophage or dendritic cell). The processed antigen is presented to a T-cell receptor (TCR) of a T lymphocyte via an HLA class II molecule. Once the HLA receptor and TCR have bound the processed antigen, numerous lymphokines and cytokines of the T helper 1 (Th1) class are released that lead to T-cell proliferation, recruitment of monocytes, and eventual granuloma formation. A few of these lymphokines and cytokines are shown, with those released by the antigen-presenting cells on the left and those released by lymphocytes on the right. IFN = interferon; IL = interleukin; TNF = tumor necrosis factor.

frequency and severity of the disease also vary between different ethnicities and races. African Americans tend to have more severe disease, whereas Caucasians are more likely to present with asymptomatic disease.[4,5] African Americans are also more likely to have extrapulmonary disease,[6] require treatment,[7] develop new organ involvement,[8] and have a lower rate of clinical recovery than Caucasians.[5,8] The disease is more common in life-long nonsmokers.[9]

ETIOLOGY AND PATHOGENESIS

The current understanding is that the development of sarcoidosis requires at least three major events: (1) exposure to antigen(s), (2) acquired cellular immunity directed against the antigen and mediated through antigen-presenting cells and antigen-specific T lymphocytes, and (3) the appearance of immune effector cells that promote a nonspecific inflammatory response.[10] The identity of the putative antigen(s) of sarcoidosis is unknown.

Presumably, antigen-presenting cells such as macrophages recognize, process, and present the processed antigen to $CD4^+$ T cells of the T helper 1 type. The processed antigen is presented to these lymphocytes via HLA (major histocompatibility complex)-class II molecules on the antigen-presenting cells that have undergone enhanced expression from exposure to the sarcoidosis antigen and possibly interferon-γ (IFN-γ).[10,11] These activated macrophages produce interleukin (IL)-12, which induces lymphocytes to shift toward a T helper 1 profile and causes T lymphocytes to secrete IFN-γ. These activated T cells release IL-2 and chemotactic factors that recruit monocytes and macrophages to the site of disease activity. IL-2 and other cytokines also expand various T-cell clones. IFN-γ further activates macrophages and transforms them into giant cells.[11] Tumor necrosis factor (TNF), IL-2, and other cytokines may also be important in stimulating macrophages.[12] Fig. 153-1 displays the major features of the presumed immunopathogenesis of sarcoidosis.

A variety of candidate antigens have been suggested as provocative agents for the cascade of immunologic events that eventuate in sarcoidosis. Infectious agents such as mycobacteria,[13] *Propionibacterium acnes*,[14] and *Chlamydia*[15] have been associated with sarcoidosis. Mineral dusts, such as silica, iron,[16] and titanium,[17] also have been associated with sarcoidosis as have combustible wood products because the disease has been found more commonly in individuals who use wood stoves.[18] Interestingly, firefighters have been found to be at greater risk of developing sarcoidosis.[19]

Genetics play a major role in determining susceptibility to sarcoidosis, as it is more common in relatives of an affected person than in individuals in the general population.[20] Genes coding for HLA class II antigens are thought to be prime candidates for a role in the development of the disease because these molecules present exogenous peptides to $CD4^+$ T-cell receptors. Numerous studies in various ethnic groups have shown a relationship of HLA antigens to the development of disease, protection from disease, good prognosis, poor prognosis, acute disease, chronic disease, and various phenotypic expressions of sarcoidosis.[21]

The interplay of antigenic and genetic factors suggests that there may be multiple causes of sarcoidosis. Patients may have to experience a specific interaction between one or several exposures and be genetically programmed to one or several abnormal immunologic responses. Each putative antigen may be associated with a specific HLA class II molecule and T-cell receptor.

CLINICAL FINDINGS

History

The diagnosis of sarcoidosis is often delayed for months to years because symptoms are non-specific and can relate to involvement of any organ.[22]

Thirty to sixty percent of patients with pulmonary sarcoidosis are asymptomatic.[23] Other than the lung, the skin, eye, liver, and peripheral lymph nodes are commonly involved. Consequently, sarcoidosis should be considered in a patient with skin lesions and concomitant pulmonary symptoms, eye complaints, right upper quadrant abdominal pain, or peripheral lymphadenopathy. In addition, the cytokines associated with the granulomatous inflammation of sarcoidosis may cause constitutional symptoms such as fever, night sweats, malaise, and weight loss.

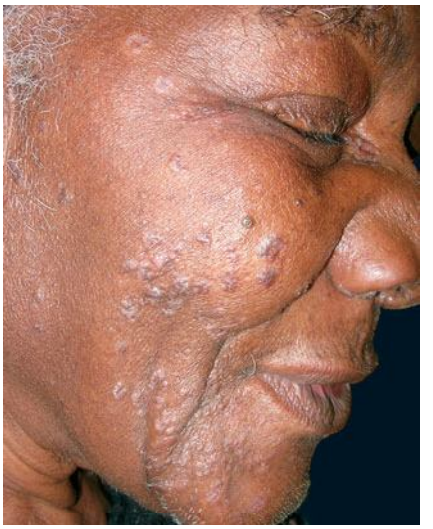
Cutaneous lesions of sarcoidosis may occur before, coincident with, or after systemic involvement. Specific cutaneous lesions are usually asymptomatic. Pruritus and pain are rare. Cosmetic disfigurement is the most common complaint. Erythema nodosum associated with sarcoidosis is indistinguishable from erythema nodosum unassociated with sarcoidosis (see Chap. 68).

Cutaneous Lesions

Classically, lesions are divided into two categories: specific and non-specific. Specific lesions have granulomas on biopsy. Non-specific skin findings are reactive and do not exhibit sarcoidal granulomas.

SPECIFIC LESIONS ***Skin.*** Specific sarcoidal lesions most often are found on the head and neck (Figs. 153-2, 153-3, and 153-4) but may occur symmetrically or asymmetrically on any part of the skin and mucosa. Almost all morphologies have been reported, including macules, papules, patches, plaques, and nodules. Alopecia occurs with scalp involvement, and nail changes also occur. Specific lesions of sarcoidosis may be scaly, telangiectatic, or atrophic. Despite the diversity in appearance, there are several clinical presentations that are classically associated with cutaneous sarcoidosis.

The most common presentation is the papular form (see Figs. 153-2, 153-3, and 153-4). These firm, 2- to 5-mm papules often have a translucent red-brown or yellow-brown appearance. The yellow-brown color has been likened to "apple jelly" and is accentuated with diascopy (Fig. 153-5). In addition to the color change, the underlying granulomas have a nodular quality that can also be appreciated with diascopy. The apple jelly appearance and nodules are not pathognomonic for sarcoidosis, as other granulatomous skin conditions, such as lupus vulgaris (see Chap. 184), may exhibit similar diascopic properties. Epidermal changes may or may not be present, but often the lesions have a waxy appearance, which reflects mild epidermal atrophy. Papular lesions occur most commonly on the face and neck, with a predilection for periorbital skin (see eFig. 153-5.1 in on-line edition). Annular plaques (Fig. 153-6), non-annular plaques (Fig. 153-7 and see eFig. 153-7.1 in on-line edition), and nodules (Fig. 153-8) may develop from these papular lesions and may or may not retain the classic translucent quality of the papules.

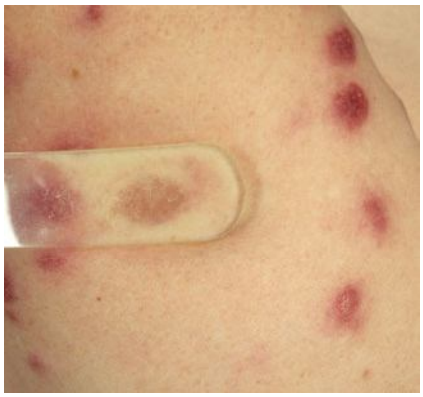


▲ **FIGURE 153-4** Cutaneous sarcoidosis of the face. Symmetric papules on cheeks.

Lupus pernio describes the relatively symmetric, violaceous, indurated plaques and nodules that occur on the nose, earlobes, cheeks, and digits (Figs. 153-9, 153-10, and 153-11). This clinical variant of sarcoidosis is distinctive and has been associated with systemic involvement. Lupus pernio is associated with a higher prevalence of upper respiratory tract disease.[24] Lupus pernio lesions may directly extend into the nasal sinus,

▲ **FIGURE 153-2** Cutaneous sarcoidosis of the face. Micropapular form.

▲ **FIGURE 153-3** Cutaneous sarcoidosis of the face. Papular form. Some of the papules have enlarged to small plaques.



▲ **FIGURE 153-5** Diascopy highlights the "apple jelly" coloration of cutaneous sarcoidosis.

leading to epistaxis, nasal crusting, and sinus bone involvement.

Angiolupoid lesions are pink papules and plaques with prominent telangiectasias that usually occur on the face (see eFig. 153-11.1 in on-line edition) and may be a variant of lupus pernio, as both lesions usually appear on the face and can be violaceous.[25,26] However, angiolupoid lesions tend to be less numerous than the papular and lupus pernio forms.[26]

Rarely, sarcoidosis can present as persistent subcutaneous nodules (Darier-Roussy sarcoid).[27] The nodules may be tender or painless and preferentially occur on the extremities.

Scars. Cutaneous sarcoidosis occurs preferentially within scar tissue, at traumatized skin sites, and around embedded foreign material such as silica. Scars become inflamed and infiltrated with sarcoidal granulomas (Fig. 153-12). Inflammation of old scars (see eFig. 153-12.1 in on-line edition) may parallel or precede systemic disease activity. Infiltrated scars may be tender or pruritic. Scar sarcoidosis may be the only cutaneous finding in a patient with systemic sarcoidosis; therefore, it is important to closely examine scar tissue in patients suspected of having the disease. The presence of sarcoidal granulomas surrounding foreign material does not establish the diagnosis of sarcoidosis, nor does foreign material in the presence of granulomas exclude the diagnosis.[28] Other signs of systemic or cutaneous involvement are required to confirm the diagnosis.

▲ **FIGURE 153-7** Plaques of cutaneous sarcoidosis on the neck and upper back.

Scalp. Alopecia occurs with involvement of the scalp and may be scarring or non-scarring (see eFig. 153-12.2 in on-line edition).[29–32] Biopsy shows noncaseating granulomas. Its reversibility is dependent on the degree of destruction of hair follicles.

Nails. Sarcoidosis may cause nail plate deformation and discoloration, but the incidence is very low.[33] There may be clubbing, subungual hyperkeratosis, and even nail plate destruction. Nail manifestations may result from granulomas in the nail matrix or from involvement of adjacent bone.

▲ **FIGURE 153-8** Nodular sarcoidosis in the face. In Caucasians, lesions of sarcoidosis are often red or purple.

Mucous Membranes. Sarcoidal granulomas may cause papules and plaques of the mucosal surfaces and tongue. Sarcoidosis is one cause of Mikulicz syndrome, the bilateral enlargement of the lacrimal (see eFig. 153-12.3 in on-line edition), parotid, sublingual, and submandibular glands.

Additional Presentations. A myriad of additional clinical presentations have also been reported. These include ichthyosis,[34] erythroderma,[29] ulcerations (see eFig. 153-12.4 in on-line edition),[35] morpheaform plaques,[36] lichen niditus–like papules,[37] folliculitis-like lesions,[38] psoriasiform plaques,[39] hypopigmented areas,[40] gyrate erythema,[41] verrucous lesions,[38] faint erythema, penile (see eFig. 153-12.5

▲ **FIGURE 153-6** Cutaneous sarcoidosis with an annular configuration.

▲ **FIGURE 153-9** Lupus pernio along the nasal rim.

▲ **FIGURE 153-10** Violaceous lupus pernio lesions on cheek and nose.

in on-line edition) and vulvar lesions,[42,43] palmar erythema,[44] discoid lupus–like plaques,[45] lower extremity edema,[46] lesions mimicking polymorphous light eruption,[38] and pustular lesions.[38]

NON-SPECIFIC LESIONS Erythema nodosum (see Chap. 68) is the main non-specific cutaneous manifestation of sarcoidosis (prevalence of approximately 17 percent). Erythema nodosum with bilateral hilar adenopathy, arthralgias, and fever is frequently the initial manifestation of sarcoidosis and is called *Löfgren syndrome*. These patients tend to have an acute form of sarcoidosis with eventual resolution.

Other non-specific cutaneous manifestations of sarcoidosis are much less common. Non-specific erythematous eruptions resembling viral exanthems or drug reactions without histologic evidence of granulomatous inflammation occur rarely with acute sarcoidosis. Additionally, patients with sarcoidosis may have pruritus

▲ **FIGURE 153-11** Violaceous lupus pernio on distal fingers.

▲ **FIGURE 153-12** Sarcoidosis arising in old facial scars sustained after car accident.

without granulomatous infiltration, leading to prurigo nodules.[25] Erythema multiforme had been regularly cited as a non-specific cutaneous manifestation of sarcoidosis,[38] but reports of histologically proven erythema multiforme with interface dermatitis associated with sarcoidosis are virtually nonexistent in the literature,[25,38,47,48] and any association is probably coincidental. Erythroderma and lower extremity swelling have been described as both specific and non-specific lesions of sarcoidosis.[25,46,49,50]

Related Clinical Findings

LUNGS The lung is the most common organ involved with sarcoidosis. Findings on pulmonary examination are usually absent. Patients with pulmonary sarcoidosis are often asymptomatic, with the disease detected on a screening chest radiograph. Common symptoms include dyspnea, cough, chest pain, and wheezing. The chest radiograph is abnormal in more than 90 percent of patients with sarcoidosis. Bilateral hilar adenopathy is noted in 50 percent to 85 percent of cases (see eFig. 153-12.6 in on-line edition). Pulmonary parenchymal infiltrates are seen in 25 to 60 percent of cases.

Chest computed tomography (CT) reveals more thoracic disease than can be appreciated on the chest radiograph. CT is superior to the chest radiograph in detecting thoracic involvement with sarcoidosis, but there is insufficient evidence that CT has a clinical role in the management of pulmonary sarcoidosis.[51]

In sarcoidosis patients with normal lung parenchyma on chest radiograph, pulmonary function tests are abnormal in 20 to 40 percent of cases. When the chest radiograph is abnormal, pulmonary function tests are abnormal in 50 to 70 percent of cases.

EYES The eyes are involved in one-fourth to three-fourths of sarcoidosis patients.[52] Eye involvement with sarcoidosis is potentially vision-threatening, and the patient may be asymptomatic. For this reason, every patient diagnosed with sarcoidosis requires an ophthalmologic examination.[52] Redness, burning, itching, or dryness are the most common ocular symptoms when present. Any portion of the eye may be involved, and eye involvement may be the first manifestation of the disease.[52] Uveitis is the most common ocular manifestation and can lead to cataracts and glaucoma. Other ocular manifestations include conjunctivitis, lacrimal gland involvement causing keratoconjunctivitis sicca (dry eyes), and optic neuritis, which may rapidly lead to loss of vision. Heerfordt syndrome includes fever, parotid gland enlargement, facial palsy, and anterior uveitis.[1]

LIVER Hepatic involvement is common at disease onset but usually does not cause signs or symptoms.[53] Although histologic evidence of hepatic sarcoidosis is present in more than one-half of sarcoidosis patients,[54] signs of organ dysfunction due to hepatic sarcoidosis are far less common.[53] Hepatomegaly, abdominal pain, and pruritus are present in only 15 to 25 percent of patients with hepatic sarcoidosis. An increased serum alkaline phosphatase level occurs in approximately one-third of patients,[55] but it is rarely associated with permanent hepatic dysfunction and therefore does not mandate treatment.[53,55] Treatment is required in the rare patient with significant symptoms, evidence of synthetic dysfunction, or hyperbilirubinemia. Rarely, hepatic sarcoidosis may lead to a primary biliary cirrhosis–type picture, and portal hypertension may develop.[56]

HEART Clinical evidence of cardiac involvement is found in only 5 percent of sarcoidosis patients,[57] although myocardial granulomas have been found in approximately 25 percent of patients at autopsy.[58] Most clinical problems are related to cardiac arrhythmias or left ventricular dysfunction.[59] Sudden death may occur. Congestive heart failure may result when the myocardium is massively infiltrated with granulomas. Because of the potential lethal nature of heart involvement with sarcoidosis, an electrocardiogram is recommended for every patient diagnosed with the disease.[1]

NERVOUS SYSTEM Any portion of the central nervous system or peripheral nervous system may be affected by sarcoidosis. Neurosarcoidosis has a predilection for the base of the brain, and cranial neuropathies are the most common manifestation.[60] The facial nerve is the cranial nerve most frequently involved.[60] In fact, it is common for Bell palsy to be the first manifestation of sarcoidosis and resolve completely before other manifestations of the disease occur. Mass lesions may develop in the brain or spinal cord. Aseptic meningitis and peripheral neuropathy are other neurologic manifestations of sarcoidosis.[61]

OTHER ORGANS The sinuses and upper airway are commonly involved with sarcoidosis, a condition known as *SURT*: *s*arcoidosis of the *u*pper *r*espiratory *t*ract.[62] Nasal SURT is often associated with lupus pernio skin lesions and may cause epistaxis and severe nasal crusting. Sarcoidosis of the spleen is not rare.[63] Sarcoidosis may also cause a disorder in calcium metabolism that results from activated sarcoidal macrophages demonstrating an increase in 1-α hydroxylase activity. This enzyme converts 25-hydroxyvitamin D to 1,25-dihydroxyvitamin D, the active form of the vitamin, an increase of which may result in hypercalcemia, hypercalciuria, and nephrolithiasis.[64] Sarcoidosis may be associated with a reduction in any blood cell line. Leukopenia may result from bone marrow involvement or from splenic sequestration. Thrombocytopenia may result from bone marrow involvement, splenic sequestration, or from an idiopathic thrombocytopenic purpura–like syndrome related to the hypergammaglobulinemia often seen in patients with sarcoidosis.[65]

LABORATORY TESTS

Table 153-1 lists clinical, imaging, and laboratory tests recommended when a diagnosis of sarcoidosis is entertained. These tests screen for involvement of various organs. A careful history and physical examination should be performed to detect signs and symptoms of organ involvement as well as to obtain a history suggesting another granulomatous disease (e.g., exposure to tuberculosis, endemic fungi, beryllium exposure).

Additional laboratory tests that assess disease activity are listed in the following sections. Although controversial, these tests are not routinely recommended because active granulomatous inflammation in sarcoidosis may remit spontaneously and therefore does not mandate treatment.

TABLE 153-1
Recommended Initial Evaluation of Patients with Sarcoidosis

1. History (occupational and environmental exposure, symptoms)
2. Physical examination
3. Posteroanterior chest x-ray
4. Pulmonary function tests: Spirometry, DL_{CO}, and KL_{CO}
5. Peripheral blood counts: White blood cells, red blood cells, platelets
6. Serum chemistries: Calcium, liver enzymes (alanine aminotransferase, aspartate aminotransferase, alkaline phosphatase), creatinine, blood urea nitrogen
7. Urine analysis
8. Electrocardiogram
9. Routine ophthalmologic examination
10. Tuberculin skin test

DL_{CO} = diffusing capacity of lung for carbon monoxide; KL_{CO} = diffusing capacity per liter alveolar volume.

Angiotensin-Converting Enzyme

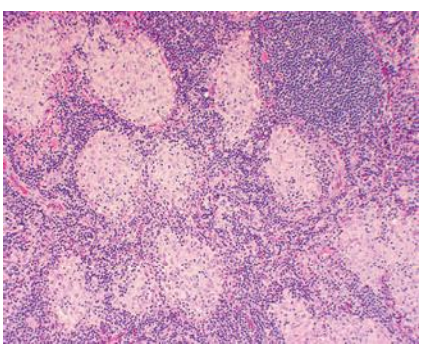
The epithelioid cell of the sarcoidal granuloma secretes angiotensin-converting enzyme[66]; therefore, serum angiotensin-converting enzyme (SACE) levels reflect the total granuloma burden in sarcoidosis. Clinical data concerning SACE in sarcoidosis suggest that an elevated SACE level is insufficiently specific for the diagnosis of sarcoidosis to rest on it alone and insufficiently sensitive to exclude the diagnosis.[67] However, SACE may be useful as an adjunct in the diagnosis of the disease. Because SACE reflects the total body granuloma burden, SACE levels may be useful to monitor the course of sarcoidosis. Initial SACE levels are not different between patients who deteriorate and those who improve[68]; thus, SACE levels should not be used as a basis for treatment decisions.

Gallium Scan

The mechanism of gallium-67 uptake in sarcoidosis is not completely understood. It is thought that inflammatory processes cause hyperemia and increased capillary permeability of gallium. Gallium also accumulates in macrophages and, to a lesser extent, in T lymphocytes, which are major participants in the granulomatous inflammation of sarcoidosis. Sarcoidosis may cause gallium uptake in thoracic and extrathoracic sites, although typically not in areas of skin involvement. Gallium scanning has not been found to be useful for monitoring the clinical course of sarcoidosis, but it may have a role in identifying organs with sarcoid involvement (see discussion of panda and lambda sign under Diagnosis section).

PATHOLOGY

The epithelioid granuloma of sarcoidosis usually contains a compact collection of mononuclear phagocytes. The granulomas typically are surrounded by a paucity of lymphocytes ("naked granulomas"), but varying degrees of lymphocytic inflammation may be present (Fig. 153-13 and see eFig.153-13.1 in on-line edition).[66] Epithelioid cells, which are themselves transformed monocytes, are commonly present within the sarcoidal granuloma. Multinucleated giant cells of the Langhans type result from the fusion of epithelioid cells. Although central fibrinoid necrosis is not uncommon, gross necrosis is not a characteristic feature of sarcoid granulomas and suggests an alternative diagnosis, such as tuberculosis, fungal infection, or vasculitis.[66] Mycobacterial and fungal diseases must always be considered as alternative diagnoses; therefore, stains and cultures for mycobacteria and fungi should be routinely performed on biopsy specimens. Table 153-2 lists the major pathologic differential diagnoses of sarcoidosis on skin biopsy.



▲ **FIGURE 153-13** Histologic specimen of sarcoidosis demonstrating noncaseating granulomatous inflammation with multinucleated giant cells and a surrounding zone of lymphocytes.

Adapted from American Thoracic Society/European Respiratory Society: Statement on sarcoidosis. Joint Statement of the American Thoracic Society (ATS), the European Respiratory Society (RS) and the World Association of Sarcoidosis and Other Granulomatous Diseases (WASOG) adopted by the ATS Board of Directors and the ERS Executive Committee, February 1999. *Am J Respir Crit Care Med* **160**:736, 1999, with permission.

A clinically important aspect of the pathology of sarcoidosis involves the development of fibrosis. Dense bands of fibroblasts may encase the ball-like granulomas. This fibrotic response can produce tissue destruction and organ dysfunction that is often irreversible.[10] Currently available chemotherapeutic agents for sarcoidosis can effectively treat the granulomatous inflammatory response but not the fibrotic reaction.

DIAGNOSIS

The diagnosis of sarcoidosis requires a compatible clinical picture, histologic demonstration of noncaseating granulomas, and exclusion of other diseases capable of producing similar histology or clinical features.[1] Because sarcoidosis is a diagnosis of exclusion, the diagnosis can never be confirmed with 100 percent certainty.

Normally, the diagnosis of sarcoidosis requires a compatible clinical picture, histologic demonstration of noncaseating granulomas, and exclusion of other diseases capable of producing similar histology or clinical features (Fig. 153-14). Alternatively, the diagnosis can be assumed without biopsy when the clinical presentation is typical for the disease and is not explained by an alternative cause

The presence of noncaseating granulomas in a single organ does not conclusively establish the diagnosis of sarcoidosis because sarcoidosis is, by definition, a systemic disease that should involve multiple organs.[70] Isolated skin granulomas should not be assumed to represent sarcoidosis, and efforts must be made to exclude alternative diagnoses (see Table 153-2). Although a confirmed diagnosis of sarcoidosis requires proof of granulomatous involvement in at least two separate organs, histologic confirmation is usually not required in the second organ.[71]

Certain disease presentations are so specific for the diagnosis of sarcoidosis (e.g., Löfgren syndrome,[72] Heerfordt syndrome, and asymptomatic bilateral hilar adenopathy) that the diagnosis may be accepted without a tissue biopsy.

Asymptomatic Bilateral Hilar Adenopathy

Asymptomatic hilar adenopathy on chest radiograph almost always represents sarcoidosis.[73] It has been suggested that histologic confirmation of sarcoidosis may not be required in asymptomatic patients with bilateral hilar adenopathy, provided the physical examination, complete blood cell count, and routine blood tests are all normal and there is no prior history of malignancy.[23] In such cases, chest radiographs should be monitored at 3- to 6-month intervals, and a biopsy should be performed if there is significant change in the chest radiograph.[23]

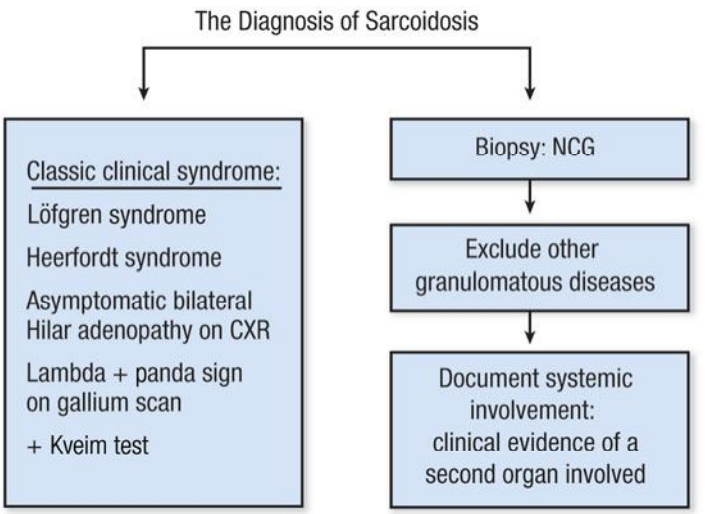
Panda and Lambda Sign on Gallium-67 Scan

The presence of panda sign (bilateral lacrimal and parotid gland uptake) and lambda sign (bilateral hilar and right paratracheal uptake) on gallium-67 scanning is highly specific for sarcoidosis and may obviate the need for invasive diagnostic procedures. However, these signs are both positive in only a small percentage of sarcoidosis patients.

NATURAL HISTORY AND PROGNOSIS

The granulomatous inflammation of sarcoidosis can remit spontaneously or with therapy. Therefore, the general prognosis of sarcoidosis is good.[70] Pulmonary sarcoidosis resolves, improves, or stabilizes in 60 to 90 percent of patients even without treatment.[75] Remissions often occur within the first 6 months after diagnosis, although it may take 2 to 5 years.[76] The prognosis is generally favorable for liver and peripheral lymph node sarcoidosis as well. The skin lesions may resolve with or without scarring or pigmentary changes.

Almost all severe impairment from sarcoidosis is the result of the development of fibrosis. As mentioned previously, this is probably the result of hyalinization of granulomatous inflammation. Presently it is unclear if this is the result of inadequate treatment or a host propensity for a brisk fibrotic response. Such cutaneous fibrosis may result in permanent scarring and disfigurement. Rarely, cutaneous lesions may ulcerate or destroy nearby bone or cartilage; this most commonly occurs in patients with lupus pernio.



▲ **FIGURE 153-14** Approach to patient with sarcoidosis. Diagnostic algorithm. Usually the diagnosis is made by following the pathway on the right: A tissue biopsy demonstrates noncaseating granulomatous inflammation with a compatible clinical picture, alternative causes of granulomatous inflammation are excluded (including tuberculosis), and there is clinical evidence of systemic (multiorgan) granulomatous inflammation. On occasion, the diagnosis can be assumed without biopsy confirmation if the clinical presentation is very specific for sarcoidosis. These clinical presentations are listed on the left side of the pathway. CXR = chest x-ray; NCG = noncaseating granulomas.

TABLE 153-3
Prognosis for Sarcoidosis

	Good	Poor
Erythema nodosum	+

CXR = chest x-ray; FVC = forced vital capacity. Adapted from Judson MA et al: Sarcoidosis, in *Diffuse Lung Disease, A Practical Approach*, edited by Baughman RP, DuBois RM, Lynch JP. London, Arnold Publishers, 2004, p 109, with permission.

Because sarcoidosis is a systemic disease, the prognosis is not solely related to pulmonary involvement. In the United States, three-fourths of sarcoidosis deaths result from pulmonary involvement. Sarcoidosis of the heart and central nervous system accounts for most of the remaining deaths.[77]

There is no current laboratory or radiologic test that can predict the outcome of sarcoidosis. Skin lesions are not a reliable indicator of prognosis, but several useful associations have been documented. Patients with cutaneous lesions are more likely to have chronic systemic sarcoidosis than sarcoidosis patients without skin involvement.[78] Erythema nodosum with fever and arthralgias portends a good prognosis.[79] Patients with Löfgren syndrome have a more than 80 percent rate of spontaneous remission, generally within 4 to 6 weeks.[1] Lupus pernio indicates chronic disease and is associated with upper respiratory tract involvement, pulmonary fibrosis, and bony cysts.[1] Table 153-3 reviews various clinical features that are associated with the prognosis of sarcoidosis.

TREATMENT

Because sarcoidosis often spontaneously remits and therapy may be associated with significant side effects, it is not mandatory to treat the disease.[80] Treatment is indicated when there is evidence of progressive organ damage.[80] Table 153-4 shows suggested indications for treatment of various organs with sarcoidosis involvement. Tests of disease activity that are discussed in preceding sections are rarely used to determine the need for therapy. This is because the presence of active granulomatous inflammation from sarcoidosis does not imply that the disease will be progressive or lead to significant fibrosis and permanent organ damage.

Topical/Intralesional Therapy

Cutaneous sarcoidosis, including lupus pernio, may be improved with prolonged application (longer than 8 weeks) of class I topical steroids, but intralesional injections of triamcinolone are generally more effective. Topical tacrolimus reportedly has been effective for skin disease in several cases as well.[81–83]

Systemic Corticosteroids

In general, corticosteroids are the drug of choice for the treatment of sarcoidosis. The recommended initial dose for pulmonary sarcoidosis is 20 to 40 mg of prednisone equivalent/day.[1,80] Cardiac and neurologic sarcoidosis may require higher initial doses, up to 60 to 80 mg of prednisone equivalent/day.[1] The corticosteroid dose can often be tapered to 0.1 to 0.2 mg/kg of prednisone equivalent/day over a few months.[1,80] It is unusual for patients with pulmonary sarcoidosis to require a maintenance corticosteroid dose of more than 15 mg of prednisone equivalent/day, although more may be required for sarcoidosis of the skin, heart, or nervous system. An attempt should be made to taper the corticosteroid dose within 9 to 12 months of the initiation of therapy.[80] Cardiac sarcoidosis may be an exception to this rule if the patient has had previous life-threatening manifestations of cardiac involvement. If life-threatening arrhythmias have occurred, placement of an internal defibrillator is indicated.[59,84,85]

Immunosuppressive Medications

If the patient cannot be successfully weaned from corticosteroids, adjunctive immunosuppressive medications can be used.[80] Most of these are inadequate as monotherapy but are effective as corticosteroid-sparing agents. The appropriate doses for sarcoidosis are listed in Table 153-5 and discussed in the following sections.

METHOTREXATE After corticosteroids, methotrexate is the next most studied agent for sarcoidosis. It is usually corticosteroid-sparing, and corticosteroids can be discontinued in one-fourth of cases.[86] The drug requires careful monitoring of liver function tests and blood cell counts. Folic acid may be given in conjunction

Other manifestations		X

TABLE 153-5
Sarcoidosis Chemotherapy

AGENT	DOSE/COMMENT
Corticosteroids	
Topical	Localized skin lesions: Ultrapotent topical steroids or intralesional injections Anterior uveitis: Eyedrops
Prednisone equivalent	20–40 mg/day, then taper Consider higher dose for cardiac, neurologic involvement
Methotrexate	10–25 mg/wk. Monitor LFTs, CBC. Consider adjunctive folate.
Hydroxychloroquine	200–400 mg/day. Check glucose-6 phosphodiesterase. Monitor ophthalmology examinations.
Chloroquine	250–1000 mg/day. Check glucose-6 phosphodiesterase. Monitor ophthalmology examinations.
Tetracyclines	Minocycline: 200 mg/day Doxycycline: 200 mg/day Primarily for non-lupus pernio skin disease
Pentoxifylline	400 mg tid
Thalidomide	50–200 mg/day. Very sedating; give qhs. Peripheral neuropathy common
Leflunomide	100 mg/day for 3 days loading, then 10 mg/day. Can increase to 20 mg/day. Monitor CBC and LFTs
Infliximab	5 mg/kg IV q6wk. Need pre-treatment purified protein derivative skin test and close monitoring for tuberculosis.
Cyclophosphamide	500–1000 mg IV q3–4wk. Monitor CBC and urinalysis. Stop if hematuria develops. Patients must be informed of carcinogenicity. Only for severe life-threatening disease (e.g., neurosarcoidosis).

CBC = complete blood cell count; LFTs = liver function tests.

with methotrexate. Approximately 10 percent of sarcoidosis patients taking methotrexate develop cirrhosis, even if their liver function tests are normal.[87] Therefore routine liver biopsies should be considered after 2 g of total therapy (usually after 2 years).[87] Low-dose methotrexate, 10 mg to 25 mg a week, is used for the treatment of cutaneous sarcoidosis.[88] Cutaneous improvement may be noted within 1 month, but maximal therapeutic benefit often does not occur until at least 6 months after the initiation of treatment.

HYDROXYCHLOROQUINE/CHLOROQUINE Antimalarial drugs are useful for skin and joint sarcoidosis, and hypercalcemia.[89,90] Antimalarial agents are not highly effective for pulmonary disease, often take several months to be effective, and cannot be used in patients with glucose-6 phosphodiesterase deficiency. Either drug, especially chloroquine, can cause retinal damage.[91] Patients taking antimalarial agents must therefore have regular ophthalmologic examinations.

CYCLOPHOSPHAMIDE Cyclophosphamide is effective for many forms of sarcoidosis. However, because of its significant side-effect profile, including its carcinogenic potential, it is usually only used for severe or potentially life-threatening disease.

TETRACYCLINE DERIVATIVES Minocycline and doxycycline have been reported to improve skin sarcoidosis in case series. These drugs may take more than 2 years to be effective.[92] Although the efficacy of these drugs suggests that sarcoidosis may be caused by an infectious agent, the tetracyclines also modify the immune response by suppressing activity of macrophages and T lymphocytes.[93]

TUMOR NECROSIS FACTOR ANTAGONISTS TNF is a cytokine that is secreted in macrophages associated with sarcoidal granulomas.[9] Antagonists of TNF have been shown to be useful for the treatment of sarcoidosis. Pentoxifylline,[94] thalidomide,[95] and infliximab[96] have been the most studied. Infliximab appears to be particularly useful for the treatment of lupus pernio, and it may be superior to other TNF antagonists, as a study of etanercept failed to show benefit for sarcoidal uveitis.[97] A tuberculin skin test is required before the use of TNF antagonists, and patients taking the drugs must be monitored closely for the development of tuberculosis. Adalimumab has also been reported to treat sarcoidosis effectively.[98]

OTHER AGENTS Azathioprine,[99] mycophenolate mofetil,[100] leflunomide,[101] and cyclosporine[102] have been reported to be useful for the treatment of systemic sarcoidosis in case reports or small case series. Allopurinol,[103] isotretinoin,[104] and fumaric acid esters[105] have been reported to be effective for sarcoidal skin disease. Resolution of sarcoidal skin manifestations after phototherapy and photodynamic therapy has also been described.[106]

Surgical Treatment

Electrodesiccation, pulse dye laser therapy, carbon dioxide laser therapy, and reconstructive surgical procedures have all been used successfully to improve the cosmetic disfigurement of cutaneous sarcoidosis, but these interventions do not have any effect on disease progression.

PREVENTION

As the cause of sarcoidosis remains unknown, prevention is currently impossible.

ACKNOWLEDGMENT

CHAPTER 154

Cutaneous Manifestations of Internal Malignant Disease: Cutaneous Paraneoplastic Syndromes

Christine A. DeWitt
Lucinda S. Buescher
Stephen P. Stone

PARANEOPLASTIC DERMATOSES

Some cutaneous manifestations of cancer are paraneoplastic syndromes [i.e., dermatoses (often unique)] secondary to the cancer. There is an evolving consensus of what constitutes a true paraneoplastic syndrome.[1] There are two essential criteria: (1) the dermatosis must develop only after the development of the malignant tumor, even though some tumors may be asymptomatic and occult, and (2) both the dermatosis and the malignant tumor follow a parallel course in that complete removal of the cancer results in clearing of the dermatosis, and recurrence of the cancer causes relapse of the dermatosis. A suggested classification of clinicopathologic categories is included in Table 154-1.

Epidemiology

Changes of the skin can be markers of an internal malignancy, but the exact prevalence is unknown. This is in part due to the complexity of disease variation in some cases and the rarity of occurrence in others. Age, sex, and risk factors for developing a paraneoplastic dermatosis correlate with the overall risk for the respective internal malignancy.

The specific relationship of the cancer with the marker can be variable. For instance, hypertrichosis lanuginosa acquisita can be a marker for many different malignant neoplasms, whereas necrolytic migratory erythema (NME) is nearly specific for a glucagon-producing tumor of the pancreas. The specific correlations with internal malignancies for each paraneoplastic dermatosis are listed in Table 154-1.

Etiology and Pathogenesis

These manifestations are grouped by their major clinical manifestations. Unfortunately, our lack of knowledge prevents a more pathophysiologic approach.

Proven association of the cutaneous eruption with a tumor can be more easily made when the supposed manifestation is very rare, and the tumor is also very uncommon. It becomes a major problem, however, when the manifestation is very common, such as the seborrheic keratoses in Leser-Trélat sign, and the presumed association is with a wide spectrum of commonly occurring neoplasms. In this situation, anecdotal reports abound.

HYPERKERATOTIC DERMATOSES

Acanthosis Nigricans (See Chap. 152)

The term *acanthosis nigricans* was originally proposed by Unna, although the first cases were malignancy-associated and described independently by Pollitzer and by Janovsky in 1890. Curth clinically classified acanthosis nigricans into malignant, benign, syndromic acanthosis nigricans, or pseudoacanthosis nigricans (obesity-related).[2]

EPIDEMIOLOGY The majority (80 percent) of acanthosis nigricans occurs idiopathically or in benign conditions such as endocrinopathies and/or heritable diseases.[3] Malignancy-associated acanthosis nigricans is rare. It was present in 1 of 35 patients with intrathoracic or intra-abdominal malignancies,[4] and in 2 of 12,000 cancer patients. Although reported in all age groups, at least 80 percent of malignancy-related acanthosis nigricans occurs in individuals over the age of 40 years.[3]

PARANEOPLASTIC DERMATOSES AT A GLANCE

- Skin can be a marker for internal malignancy:
  - Epi-phenomenon
  - Familial cancer syndromes
  - Direct tumor extension
- Paraneoplastic dermatoses follow a parallel course with the malignancy and allow early diagnosis and monitoring.
- Dermatoses with high associations with internal malignancy include tripe palms, Bazex syndrome, paraneoplastic pemphigus, erythema gyratum repens, necrolytic migratory erythema, and hypertrichosis lanuginosa acquisita.
- Weakly associated with internal malignancy are acanthosis nigricans, acquired ichthyosis, and multiple seborrheic keratoses.
- Management of the dermatosis is the treatment of the malignancy.

ACANTHOSIS NIGRICANS AT A GLANCE

- Acanthosis nigricans is a cutaneous marker, most commonly of insulin resistance and less frequently of genetic disorders and malignancy.
- Characterized by symmetric hyperpigmented, hyperkeratotic, verrucous plaques that bestow a velvety texture on intertriginous skin and occasionally mucocutaneous areas.
- Darker skin pigmentation, insulin resistance, and obesity are more commonly associated with benign acanthosis nigricans.
- Malignant acanthosis nigricans often appears rapidly in older individuals and can involve atypical sites such as mucosal surfaces.

ETIOLOGY AND PATHOGENESIS Although the precise etiology of benign acanthosis nigricans remains unclear, there is evidence that insulin plays a significant role. The pathogenesis of malignancy-associated acanthosis nigricans is even less clear. A humoral factor produced by the tumor is likely, given cases in which the skin disorder improved or resolved following treatment of the malignancy. Elevated urinary transforming growth factor-α (TGF-α) and increased expression of epidermal growth factor (EGF) receptors in lesional skin were noted in a patient with acanthosis nigricans, acrochordons, Leser-Trélat sign, and melanoma. The enhanced expression of this cytokine and its receptor normalized after removal of the melanoma, and the acanthosis nigricans, acrochordons, and seborrheic keratoses improved postoperatively.[5] A separate case, with gastric cancer, was also shown to express TGF-α and EGF receptors.[6]

More recently, a pathogenic role has been proposed for a tyrosine kinase receptor expressed on the basal cells of the epidermis. In several inherited human skeletal dysplasias associated with acanthosis nigricans, such as craniosynostoses and dwarfing chondrodysplasias, activating mutations in the fibroblast growth factor receptor 3 (FGFR3) can be observed, whereby FGFR3 has an inhibitory affect on bone formation.[7] In other studies, FGFR3 has oncogenic affects in such malignancies as multiple myeloma, bladder, and cervical carcinoma. With respect to the role of FGFR3 on the epidermis, animal models with activating mutations develop benign epidermal tumors resembling acanthosis nigricans and seborrheic keratoses.[8]

CLINICAL FINDINGS (See Chap. 152) The clinical hallmark of acanthosis nigricans is development of gray-brown, velvety plaques that may start as a dirty appearance. The hyperpigmentation is later accompanied by hypertrophy, increased skin markings, and papillomatosis. Pruritus can be a problem in some patients. The most commonly involved locations are the axillae, neck, external genitalia, groin, face, inner thighs, antecubital and popliteal fossae, umbilicus, and perianal area. Acrochordons may develop, superimposed on the acanthosis nigricans or on other locations (see Fig. 152-2).

TABLE 154-1
Clinical Characteristics of the Paraneoplastic Dermatoses

Paraneoplastic Dermatosis	Major Internal Malignancy	% with Cancer	Approach to the Patient	Unique Features
Hyperkeratotic diseases				
Acanthosis nigricans[a]	Adenocarcinomas: intra-abdominal; gastric (50%–60%)	Unknown	CBC, CMP, fasting blood glucose; upper endoscopy or CT scan of abdomen if history supports	Later age, rapid course, and oral involvement more common in malignancy-associated. Usually with insulin resistance.
Acquired ichthyosis[a]	Hodgkin lymphoma (70%–80%)	Unknown	CBC, CXR; consider CT of abdomen to rule out lymphoma	Spares flexures, palms, soles; up to 30% of cases may occur in patients with acquired immunodeficiency syndrome
Tripe palms	Lung CA most common; gastric CA second	> 90%	CBC, CMP, CT of chest and abdomen	Co-exists with acanthosis nigricans in 75%
Leser-Trélat sign	Adenocarcinomas: GI (47%); lymphoproliferative (20%)	Unknown	CBC, imaging of GI tract	Early onset, eruptive nature, and pruritus are paraneoplastic features; co-exists with acanthosis nigricans in 20%
Bazex syndrome[a]	SCC of upper aerodigestive tract	Nearly 100%	ENT examination; CXR; thoracoabdominal CT	Acral papulosquamous lesions (ears, nose), paronychia, onychodystrophy
Collagen-vascular diseases				
Dermatomyositis[a]	Women: ovarian and breast CA; Men: GI and respiratory tract CA	25%–30%	CBC, CMP, CXR; up to date cancer screenings, bimanual exam in women; abdominal CT to rule out ovarian CA in selected cases	Patients older than in idiopathic form; males predominate; refractory or flaring of previously well-controlled disease may signal malignancy
Progressive systemic sclerosis	Lung; SCC of the tongue (25× increased risk)	3%	Annual oral examination; pulmonary function test	Decreased pulmonary CO diffusion (< 70%) risk factor for lung CA
Reactive erythemas				
Erythema gyratum repens[a]	Bronchial CA (32%)	82%	CXR, upper GI evaluation, mammogram	"Wood-grain" patterned erythema

(continued)

TABLE 154-1
Clinical Characteristics of the Paraneoplastic Dermatoses (Continued)

Paraneoplastic Dermatosis	Major Internal Malignancy	% with Cancer	Approach to the Patient	Unique Features
Necrolytic migratory erythema	Pancreatic α-cell tumor	Nearly 100%	Abdominal CT	Not parallel to malignancy
Neutrophilic dermatoses				
Sweet syndrome[a]	AML and lymphoma (85%)	20%	CBC with differential bone marrow bx if multiple abnormalities seen; skin bx for histology and culture	Neutrophilia and fever may not be present in patients with hematologic malignancy; presentation often more severe in this form
Pyoderma gangrenosum	AML most frequent; multiple myeloma second	7%	Same as Sweet syndrome; SPEP/UPEP	Atypical presentation more common with malignancy; may be on a continuum with Sweet syndrome; IgA paraproteinemia 10%–18%
Dermal proliferative diseases				
Multicentric reticulohistiocytosis	No specific cancer type or location	28%	CBC, CMP, CXR	Not parallel to malignancy
Necrobiotic xanthogranuloma	IgG paraproteinemia with 10 percent progressing to multiple myeloma	80% (gammopathy)	CBC, CMP, SPEP/UPEP	Periorbital involvement especially with necrosis
Disorders with dermal deposition				
Scleromyxedema	Monoclonal gammopathy of undetermined significance; rare multiple myeloma	80% (gammopathy)	CBC, CMP, ECG, CXR; thyroid studies; SPEP/UPEP	Most have IgG-λ monoclonal gammopathy; only rarely convert to multiple myeloma but poor prognosis if it occurs
Systemic amyloidosis	Multiple myeloma, thyroid or multiple endocrine neoplasia	13%–26% (multiple myeloma)	Bx of clinically involved skin, rectal or abdominal fat tissue; SPEP/UPEP	Macroglossia, pinch purpura, carpal tunnel clue to systemic amyloidosis; 1-yr mean survival in patients with multiple myeloma
Bullous disorders				
Paraneoplastic pemphigus	Lymphoproliferative (75%): non-Hodgkin (42%), CLL (29%)	Nearly 100%	CBC, CMP, CXR, CT abdomen	Parallels benign, but not malignant tumors
Dermatitis herpetiformis	GI (78%) and non-Hodgkin lymphoma	4%	Colonoscopy with mucosal bx	Occurs significantly more in patients who do not follow a gluten-free diet
Other changes				
Hypertrichosis lanuginosa acquisita	Men: lung, colorectal; women: colorectal, lung, or breast	Nearly 100%	CXR, colonoscopy, mammogram	Excessive downy hair initially concentrated on face, spreading caudally
Trousseau syndrome (migratory thrombophlebitis)	Lung and pancreatic carcinoma	50%	CBC, CXR, CT of abdomen	Responds best to low-molecular-weight heparin

AML = acute myelogenous leukemia; bx = biopsy; CA = cancer; CBC = complete blood count; CLL = chronic lymphocytic leukemia; CMP = complete metabolic panel; CT = computed tomography; CXR = chest x-ray; ECG = electrocardiogram; ENT = ear, nose, and throat; GI = gastrointestinal; Ig = immunoglobulin; SCC = squamous cell carcinoma; SPEP = serum protein electrophoresis; UPEP = urine protein electrophoresis.
[a]Dermatoses established to closely parallel course of malignancy.

Several inherited syndromes have acanthosis nigricans described as a feature of the disease. Those that have been reported are listed in Table 154-2.

The lesions of malignant and benign acanthosis nigricans are indistinguishable. However, there are subtle differences regarding the age of onset, distribution, and speed of onset that may assist in recognizing the paraneoplastic form. The benign form typically presents at a younger age and has a gradual progression of flexural surfaces (see Chap. 152). Concerns for malignancy-associated acanthosis nigrans should arise when a rapid appearance of the lesions in an older individual along with atypical sites such as the oral mucosa is involved (Fig. 154-1).

Many consider tripe palms and Leser-Trélat sign (see sections Tripe Palms and Leser-Trélat Sign) to be along a spectrum of malignant acanthosis nigricans given the high degree of co-occurrence and histologic similarities. Florid cutaneous papillomatosis is also a part of this same spectrum. It presents as a rapid appearance of verrucous papillomas that are identical in appearance to typical viral warts. This phenomenon occurs with malignant acanthosis nigricans and, in a large series, had a 100 percent correlation with an internal malignancy, most commonly gastric adenocarcinoma.[9]

Many types of malignancies have been reported in association with malignant acanthosis nigricans. A review of the literature has shown up to 90 percent of patients have an associated intra-abdominal adenocarcinoma, of which approximately 60 percent are gastric.[10]

Histopathology of acanthosis nigricans classically shows hyperkeratosis

TABLE 154–2
Syndromes Associated with Acanthosis Nigricans

- Acromegaly
- Addison disease
- Alström syndrome[a]
- Ataxia-telangiectasia
- Bartter syndrome
- Beare-Stevenson syndrome
- Benign encephalopathy
- Bloom syndrome
- Capozucca syndrome
- Chondrodystrophy with dwarfism
- Costello syndrome
- Crouzon syndrome
- Cushing syndrome
- Dermatomyositis
- Diabetes insipidus
- Donohue syndrome (leprechaunism)[a]
- Down syndrome
- Edwards syndrome[a]
- Gigantism
- HAIR-AN syndrome (hyperandrogenism, insulin resistance, and acanthosis nigricans)[a]
- Hashimoto thyroiditis
- Hepatic cirrhosis
- Hirschowitz syndrome
- Hypothyroidism
- Laurence-Moon-Bardet-Biedl syndrome
- Lawrence-Seip syndrome (congenital lipodystrophy)[a]
- Lipoatrophic diabetes[a]
- Lupoid hepatitis
- Lupus erythematosus
- MORFAN syndrome (mental retardation, overgrowth, remarkable facies, and acanthosis nigricans)
- Phenylketonuria
- Pituitary hypogonadism
- Pituitary tumors
- Prader-Willi syndrome
- Pseudoacromegaly[a]
- Pyramidal tract degeneration
- Rabson-Mendenhall syndrome[a]
- Rud syndrome[a]
- Scleroderma
- Stein-Leventhal syndrome (polycystic ovarian disease)[a]
- Streak gonads
- Type A syndrome of insulin resistance[a]
- Type B syndrome of insulin resistance[a]
- Werner syndrome
- Wilson disease (hepatolenticular degeneration)

[a]Associated with insulin resistance.

and epidermal papillomatosis. There is only slight acanthosis and, in some places, atrophy can be seen. Other features that can be observed include pseudocyst formation and increased melanin pigmentation. The dermis is usually devoid of inflammatory cells with the exception of mucosal acanthosis nigricans, which may have a mixed infiltrate of lymphocytes, plasma cells, and occasional neutrophils. The pathologic differential diagnosis includes confluent and reticulated papillomatosis of Gougerot and Carteaud, seborrheic keratosis, and epidermal nevus.

DIFFERENTIAL DIAGNOSIS

COMPLICATIONS The cutaneous complications of acanthosis nigricans are most often of cosmetic concern. With time, severe papillomatosis and acrochordon formation can lead to frictional irritation and can be quite problematic. Of most concern with these patients, however, is an undiagnosed endocrinopathy or malignancy.

PROGNOSIS AND CLINICAL COURSE The malignant form may also parallel the course of the underlying malignancy. Unfortunately, most associated malignancies present at an advanced stage, and thus the median survival rate for those with malignant acanthosis nigricans has been reported to be from 10 to 24 months.[11]

TREATMENT Management of any co-occurring disease or malignancy often improves and may even resolve acanthosis nigricans. Topical keratolytics, including the retinoids, and oral retinoids can reduce the appearance of acanthosis nigricans. Other oral medications reported to show improvement include dietary fish oil, metformin, and cyproheptadine, possibly by inhibition of tumor-secreted growth factors in the case of the latter.[2]

PREVENTION Unfortunately for those with acanthosis nigricans associated with inherited conditions and malignancy, there is no effective prevention.

Acquired Ichthyosis (See Chap. 47)

The sudden onset of ichthyosis in an adult may indicate an occult malignant tumor, most often Hodgkin lymphoma. However, patients with acquired immunodeficiency syndrome can represent up to 30 percent of patients with acquired ichthyosis.[12] Diffuse rhomboidal scaling is observed on extensor surfaces and typically spares skin folds, palms, and soles. Erythema is often present in the ichthyotic fissures. Although the ichthyosis usually occurs as a late manifestation of a lymphoma, it may precede the diagnosis by several years and typically parallels the course of the malignancy.

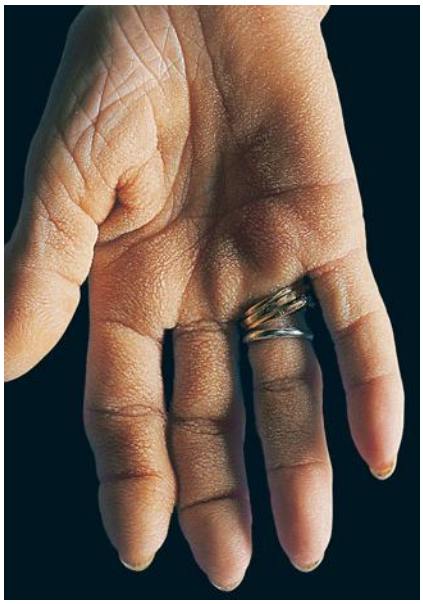
Tripe Palms

EPIDEMIOLOGY Tripe palms is a rare paraneoplastic dermatosis with approximately 100 cases reported in the literature. The association with malignancy is high, with a greater than 90 percent occurrence.

ETIOLOGY AND PATHOGENESIS Specific mechanisms of development have not been fully elucidated. Similar to acanthosis nigricans, there is limited evidence for the role of TGF-α in the pathogenesis of tripe palms, and that normalization of this cytokine results in clinical improvement.[13]

Other investigations have shown melanocortin-1 and EGFs to be upregulated in malignancy-associated tripe palm.[14,15] However, there is evidence that these are not uniformly present.[16]

CLINICAL FINDINGS The name originated from the description in the first reported case in 1963 whereby the patient suggested his hands looked similar to the rugose surface of the bovine stomach (Fig. 154-2).[17] Based on clinical similarities and frequency of co-occurrence, many consider this to be a form of palmar acanthosis nigricans. Indeed, tripe palms have also been called "*acanthosis nigricans of the palms*" and "*acanthosis palmaris*." The honeycombed and corrugated thickening of the palms may be associated with periungual tender-



▲ **FIGURE 154-2** Tripe palm. The palmar ridges show maximal accentuation, thus mimicking the mucosa of the stomach of a ruminant.

ness. Normal dermatoglyphic ridges are accentuated.

Histopathology of tripe palms includes hyperkeratosis, acanthosis, and papillomatosis. These features closely resemble those pathologic findings observed in acanthosis nigricans and seborrheic keratoses.

The majority (75 percent) of patients will have concomitant acanthosis nigricans. In patients with only tripe palms, pulmonary carcinoma (53 percent) is the most frequent malignancy. In patients with both tripe palms and acanthosis nigricans, gastric carcinoma (35 percent) is the most common, followed by lung carcinoma (11 percent).[18]

DIFFERENTIAL DIAGNOSIS

COMPLICATIONS This is often a complication itself of underlying malignancy.

PROGNOSIS AND CLINICAL COURSE A complete malignancy workup should be performed in patients with tripe palms due to the high association and because it is the initial presenting sign in 40 percent of patients that have an undiagnosed malignancy.

TREATMENT There is no specific therapy for tripe palms. Similar to acanthosis nigricans, there are anecdotal reports of improvement with oral retinoids alone and in combination with metformin.[19] It has been reported that approximately 30 percent will resolve with treatment of the underlying tumor.[20] However, there are many cases whereby a remission of the cancer has had no effect.

PREVENTION There is no way to prevent the development of tripe palms. Patients should be up to date with standard cancer screenings. An expanded cancer investigation is warranted if no co-existence of malignancy is noted at the time of diagnosis.

Leser-Trélat Sign

EPIDEMIOLOGY Leser-Trélat sign is a rare paraneoplastic dermatosis that occurs with equal frequency between men and women and among different races. Similar to the occurrence of malignancy, this sign is more common in older individuals.

Controversy has surrounded this as a true diagnosis due to the extremely common nature of benign seborrheic keratoses and furthermore, occurring in the age group most susceptible to malignancy. In a large population based study of 1752 consecutive cases of seborrheic keratoses, there was no statistical evidence of an increased incidence of internal malignancy compared to the general population. Subanalysis of those presenting with eruptive seborrheic keratoses also failed to demonstrate an increased risk of internal malignancy.[21] In another study of 82 patients with seborrheic keratoses and a recent solid tumor, a comparison with age- and sex-matched controls did not demonstrate a difference in either the clinical features or numbers of seborrheic keratoses.[22] As such, large epidemiologic studies have not provided the evidence needed to conclusively define this sign as a true paraneoplastic dermatosis.

Although large studies have not shown a statistical difference, there exists evidence to demonstrate that this sign may signify an internal malignancy. First, there are cases of eruptive seborrheic keratoses in patients in their 20s, an age group that rarely exhibits these lesions. Further workup in both cases led to a diagnosis of an internal malignancy.[23,24] Clinically, Leser-Trélat sign often co-exists with malignant acanthosis nigricans, a more established paraneoplastic phenomenon. Additionally, alterations in growth factor expression differ from control patients. Together, this provides evidence that the Leser-Trélat sign is a legitimate but extremely uncommon paraneoplastic dermatosis.

LESER-TRÉLAT SIGN AT A GLANCE

- Rapid and eruptive increase in numbers and size of seborrheic keratoses.
- Pruritus common.
- Often with malignant acanthosis nigricans.
- Adenocarcinomas of the gastrointestinal tract are most common malignancy, followed by lymphoproliferative malignancies.
- Differential diagnosis includes seborrheic keratoses, verruca vulgaris, dermatosis papulosa nigra, melanocytic nevi, and warty dyskeratomas.

ETIOLOGY AND PATHOGENESIS Similar to the other hyperkeratotic paraneoplastic dermatoses, an exact pathogenesis has yet to be elucidated. However, similar to acanthosis nigricans, evidence also exists with the Leser-Trélat sign that an alteration in growth factor homeostasis is contributory. In several instances, a state of increased growth factor expression has been observed with increased urinary levels of the growth factors EGF and TGF-α detected in patients with an underlying malignancy and eruptive seborrheic keratoses. Subsequently, growth factor levels decreased following primary tumor resection.[25]

It is not known if the tumors are the primary source or are inducing a secondary secretion of such growth factors as TGF-α and EGF. In an analysis of a patient with pancreatic carcinoma and Leser-Trélat sign, the tumor cells expressed low levels of EGF while the hyperkeratotic lesions of seborrheic keratoses expressed increased EGF.[26] In a comparison of Leser-Trélat lesional skin and that of control seborrheic keratoses, increased levels of the growth factor homologs EGF and human EGF receptor 2/neu were detected in the downward branching epithelial strands.[27] In addition to increased levels of growth factor expression, lesional skin in paraneoplastic acanthosis nigricans and seborrheic keratoses has alterations in the extracellular matrix.[28] It is unknown what the

direct impact of growth factor signaling has on the skin. Proposed ideas include either inducing a hyperproliferative state primarily or by altering the surrounding environment such as via the extracellular matrix. These similar mechanisms further support the idea of a continuum between acanthosis nigricans and the Leser-Trélat sign.

CLINICAL FINDINGS Clinical features signifying a paraneoplastic phenomenon include patients with widespread eruptive seborrheic keratoses. Pruritus is a significant feature occurring in 43 percent.[3] Co-occurrence with other hyperkeratotic paraneoplastic dermatoses is common, with 20 percent having acanthosis nigricans, including a report of oral acanthosis nigricans, the Leser-Trélat sign, and tripe palms co-existing in the same patient.[10,29] The rapid occurrence of pruritic eruptive seborrheic keratoses, especially in a setting of acanthosis nigricans, should alert the clinician to a potential internal malignancy.

Adenocarcinomas account for the majority of malignancies described with the Leser-Trélat sign; 47.7 percent involve the gastrointestinal tract.[26] The second most common malignancy is lymphoproliferative disorders and includes leukemias, lymphomas, Sézary syndrome and mycosis fungoides. Involvement of other organs such as the pancreas, kidneys, and lungs has been reported in several cases as well. In a series of 44 patients with lung cancer, the Leser-Trélat sign was observed in 2.27 percent.[30]

Typically defined by a concurrent malignancy, the Leser-Trélat sign has also been reported in non-neoplastic tumors, human immunodeficiency virus, conditions of erythroderma, and in association with the chemotherapeutic drug cytarabine.[31–34] The term *pseudo-sign of Leser-Trélat* has been used to designate non-malignancy–associated eruptive seborrheic keratoses that presents identically to its paraneoplastic counterpart. Unfortunately, these examples do not help to further define an already confusing and controversial clinical entity.

DIFFERENTIAL DIAGNOSIS

COMPLICATIONS As with many paraneoplastic dermatoses, sudden reappearance may herald tumor recurrence, although this particular sign only occasionally parallels the malignancy.

PROGNOSIS AND CLINICAL COURSE This sign can develop from 5 months before to 9.8 months after the diagnosis of malignancy and, once diagnosed, the prognosis is poor, with an average survival time of 10.6 months.[35] This eruption parallels the course of the underlying malignancy in some cases, but not as a general rule.

TREATMENT Treatment should be directed towards the underlying tumor. If the lesions are symptomatic or cosmetically concerning to the patient, other options for treatment include standard therapies for seborrheic keratoses such as α hydroxy acids, retinoids, trichloroacetic acid, cryosurgery with or without curettage, dermabrasion, laser, and shave excision.

PREVENTION There is no effective prevention other than keeping up with age-appropriate cancer screenings.

Paraneoplastic Acrokeratosis of Bazex

EPIDEMIOLOGY Bazex established an association between this uniquely distributed papulosquamous eruption and underlying malignancy. In fact, he considered the characteristic cutaneous presentation a pathognomonic sign of internal malignancy.[36] There have been more than 100 cases reported in the medical literature. Patients are typically men over the age of 40 years old. Acrokeratosis paraneoplastica is unrelated to Bazex-Dupre-Christol, which is a genodermatosis characterized by congenital hypotrichosis, follicular atrophoderma, and basal cell carcinomas arising at an early age.

ETIOLOGY AND PATHOGENESIS The mechanism by which this characteristic eruption occurs is still speculative. One theory proposes that antibodies mounted against the tumor cross-react with keratinocyte or basement membrane antigens (similar to those found in paraneoplastic bullous pemphigoid).[37] Other theories include a T-cell mediated immune response to tumor-like antigens in the epidermis or excessive expression of autocrine growth factors from the tumor resulting in epidermal hyperplasia.[38–40]

CLINICAL FINDINGS The name, *acrokeratosis paraneoplastica*, is aptly descriptive because characteristic lesions are located acrally and exhibit hyperkeratosis. The plaques are usually erythematous to violaceous with overlying scale. Almost all patients have lesions affecting the ears and nails during the disease. Nearly two-thirds will demonstrate involvement of the nose and fingers, and over one-half have lesions on the hands and feet, especially volar surfaces.[41] Other clinical findings include hyperpigmentation and bullae. Bullae, when present, are most common on the hands and feet.

Three stages of skin lesions parallel the growth and dissemination of the underlying tumor. In the first stage, the helices, nose, fingers, and toes are usually affected in a symmetric fashion. Early lesions are macular and not clearly demarcated, simulating a non-specific dermatitis. They may exhibit crust in addition to scale. The eruption is classically asymptomatic, but pruritus may be a problem. Paronychia is the first sign of nail involvement (Fig. 154-3). In most cases, the responsible tumor is occult at this stage and remains so for an average of 11 months.[41]

During the second stage, the tumor exhibits symptoms, due to local extension or metastatic spread, and the skin eruption becomes more extensive. The cheeks display the typical red to purple scaly or crusted plaques. The palms and soles develop a keratoderma that often spares the central volar surfaces but may lead to painful fissures (Fig. 154-4). Nail plate changes include yellowing, thickening, onycholysis, and ridging, both horizontal and vertical.

The final stage is observed when the tumor goes untreated or fails to respond

ACROKERATOSIS PARANEOPLASTICA OF BAZEX AT A GLANCE

- Distribution of cutaneous lesions is symmetric and characteristically involves the helices, nose, cheeks, digits, nails.
- Lesions evolve from non-specific dermatitis and paronychia to inflammatory plaques, acral keratoderma, and nail plate changes.
- Skin lesions often pre-date detection of internal malignancy.
- Upper aerodigestive tract malignancy most common.

◀ **FIGURE 154-3** Distal edema of toes, painful generalized paronychia, and distal subungual hyperkeratosis in early acrokeratosis paraneoplastica.

to treatment. All of the above signs and symptoms persist while the papulosquamous lesions begin to appear on the trunk, elbows, knees, and dorsal hands and feet. Rarely, vesicles and bullae may be present, most commonly on the fingers, hands, and feet. Nail changes can be quite variable, ranging from the typical thickening to nail atrophy and loss.

The main differentiation to be made in diagnosis is psoriasis, especially acral variants. The distinguishing clinical feature, which is nearly always present in acrokeratosis paraneoplastica, is involvement of the helices of the ears (Fig. 154-5) and the tip of the nose. Knees and elbows may develop plaques but it occurs late in the disease. Typically, Bazex is treatment resistant unlike other diseases considered in the differential.

Mucosal squamous cell carcinoma of the head and neck is the most frequently associated malignancy in acrokeratosis paraneoplastica and is markedly over-represented when compared with the cancer statistics in the general population. Tumors in the oropharynx or larynx and cervical squamous cell lymph node metastases of an occult primary malignancy make up more than 60 percent of cancers associated with Bazex syndrome but only 7 percent of cancer patients without Bazex. The lung[42] and esophagus were the next most frequent site of tumors (15 percent and 10 percent, respectively), though not always squamous cell carcinomas.[41]

Histologically, some psoriasiform features are present, including hyperkeratosis, parakeratosis, and a superficial lymphohistiocytic infiltrate, but other nonpsoriasiform changes also exist. These include vacuolar degeneration with melanin-containing macrophages in the dermis and dyskeratotic keratinocytes.[41]

DIFFERENTIAL DIAGNOSIS (Box 154-1)

COMPLICATIONS The keratoderma affecting volar surfaces may develop fissures. On the feet, this can lead to painful ambulation. Secondary infection occurs. Paronychia is usually painful and may be debilitating.

▲ **FIGURE 154-4** Keratoderma characteristically spares central aspects of plantar (and palmar) surfaces in acrokeratosis paraneoplastica.

▲ **FIGURE 154-5** Characteristic helical inflammation with scale in acrokeratosis paraneoplastica.[45] (Used with permission from Peter Karl Kohl.)

Box 154-1

Differential Diagnosis of Acrokeratosis Paraneoplastica

Most Likely
- Psoriasis
- Dermatitis (seborrheic, eczematous, or contact)
- Dermatophytosis/onychomycosis

Consider
- Mycosis fungoides
- Drug eruption
- Cutaneous lupus erythematosus
- Keratoderma blenorrhagicum (reactive arthritis)
- Arsenical keratoses

Always Rule Out
- Internal malignancy
- Dermatophyte infection

PROGNOSIS AND CLINICAL COURSE The skin eruption is expected to resolve with treatment of the underlying malignancy and can reappear with tumor recurrence. For some patients the cutaneous lesions, but more commonly the nail dystrophy (ridging and subungual hyperkeratosis), may persist despite (presumed) successful tumor eradication.

TREATMENT Adequate treatment of the underlying malignancy usually results in improvement of acrokeratosis paraneoplastica and recurrence of the eruption heralds tumor recurrence. The skin lesions are typically resistant to standard therapies for hyperkeratotic conditions, and few treatments specific for the cutaneous component of acrokeratosis paraneoplastica have been reported. Retinoids have been used with variable success.[43] Isolated reports suggest benefit from oral psoralen and ultraviolet A phototherapy, topical salicylic acid, and corticosteroids.[44]

PREVENTION There is no effective prevention other than keeping up with age-appropriate cancer screenings.

COLLAGEN-VASCULAR DISEASE

Dermatomyositis (See Chap. 157)

Dermatomyositis can be a marker for internal neoplasia, and the development of the dermatomyositis can predate the diagnosis of the cancer. The clinical manifestations of dermatomyositis appear to be the same with and without a malignant tumor, although Basset-Sequin et al.[45] noted that cutaneous necrosis and an elevated erythrocyte sedimentation rate appeared to be markers for those

▲ **FIGURE 154-6** **A.** Serpiginous parallel bands on axilla and arm. (Used with permission from Michael Adler.) **B.** "Wood-grained" pattern of erythema and slight scale in a woman with breast cancer. (Used with permission from Barbara Resnick.)

with cancer and a reduced survival. Men over the age of 50 years old have an elevated risk of malignancy.[46] The most common cancers are ovarian, lung, pancreatic, stomach, colorectal, and lymphoma.[47] Although dermatomyositis in an adult is strongly associated with concurrent cancer, polymyositis alone is much less strongly associated.[48]

The cancers are usually identifiable by history and physical examination. Adults with dermatomyositis should be examined thoroughly for evidence of an associated malignant tumor, including all recommended cancer screenings. The diagnosis of malignancy is usually made within 1 year, but can be several years later. In children, dermatomyositis is not statistically linked to malignancy.

Progressive Systemic Sclerosis (See Chap. 158)

Systemic scleroderma is not commonly associated with internal malignancy. In a Japanese review of 8327 patients with systemic sclerosis, the frequency of malignancy was 5.4 percent in men and 2.8 percent in women (overall, 3.1 percent).[49] Several population-based studies have been performed to determine the incidence of malignancy with mixed results. Some have detected no increase in overall malignancy incidence as compared with the general population, although others have detected a small, but statistically significant increased risk.[50] In a nested cohort comparing patients diagnosed with systemic sclerosis before the age of 60 years and after the age of 75 years, not surprisingly, there was an increased frequency of all malignancies in the older age, but especially esophageal and oropharyngeal cancer.[51,52]

Lung cancer has been the most often associated malignancy, but there is also a nearly 25-fold increased risk of squamous cell carcinoma of the tongue.[53] Almost all patients with associated lung tumors have very advanced systemic scleroderma, particularly older patients with advanced interstitial lung disease. Evidence suggests the association is most likely one of a lung tumor developing secondary to the chronic pulmonary fibrosis.

REACTIVE ERYTHEMAS

Erythema Gyratum Repens (See Chap. 42)

This particular annular ("gyratum" is Latin for circle) erythema is nearly always indicative of internal malignancy and is one of the most dramatic skin diseases in both its appearance and evolution. Affected individuals are often Caucasian men (2:1) in their 60s. Numerous serpiginous bands are arranged in a parallel configuration of concentric red swirls over most of the body. This presentation is occasionally referred to as a "wood-grained" appearance (Fig. 154-6A). Even more striking is the relatively rapid rate at which lesions migrate ("repens" is Latin for creeping), estimated at 1 cm per day.[54] A slight scale may be found along the trailing edge of erythema (see Fig. 154-6B). The hands, feet, and face are commonly spared, except for occasional volar hyperkeratosis. Ichthyosis is present in many cases. Pruritus is universal and may be severe.

An underlying malignancy is associated with erythema gyratum repens more than 80 percent of the time. This distinctive migratory eruption appears 4 to 9 months before the diagnosis of malignancy in approximately 80 percent of cases. Approximately one-third of patients will manifest a lung cancer, whereas 8 percent have esophageal cancer, and 6 percent have breast cancer. Individual case reports of many other types of associated tumors are published, as well as 6 percent of cases with an unknown primary. In those individuals with erythema gyratum repens who did not have a detectible underlying malignancy, concurrent conditions included tuberculosis, pregnancy, and bullous dermatoses, among others.[54]

The exact etiology of erythema gyratum repens is unknown, but it has been suggested that the tumor may induce a chemical alteration of the normal components of the surrounding tissue. Molecular mimicry ensues as the inflammatory response directed against the tumor cross-reacts with benign cutaneous proteins. This theory is supported by documentation of immunoglobulin G (IgG) and C3 deposition at the basement membrane of affected skin and bronchial basement membrane in one case associated with lung cancer.[54] Migration characterizes all of the figurate erythemas, but is notably rapid in erythema gyratum repens, and the mechanism for this is not clear, although recent studies have focused on fibroblast activity. Inflammatory cells and/or fibroblasts may mediate ground substance alterations which may localize the inflammation that orchestrates the movement of the infiltrate in a patterned mode.[55,56]

◀ **FIGURE 154-7** The glucagonoma syndrome, necrolytic migratory erythema. Flaccid and papulovesicular lesions (**A**) with erosions, crusting, and fissures around the orifices, and (**B**) appearing as geographic, circinate "necrolytic migratory erythema" in the groin. (**A** and **B** are not the same patient.)

The treatment for erythema gyratum repens is to locate and treat the primary malignancy. With adequate control of the cancer, the rash usually abates, but this may not be possible in cases that are widely metastatic at the time of diagnosis. Unfortunately, the eruption is often treatment resistant, although variable results occur with systemic steroids.[57] Topical steroids, vitamin A, and azathioprine have not been beneficial.[58–60] The eruption has been known to resolve immediately before death, possibly due to generalized ante mortem immunosuppression.[55]

Necrolytic Migratory Erythema

EPIDEMIOLOGY NME is virtually pathognomonic for pancreatic glucagonoma and is present in more than two-thirds of patients at the time of tumor diagnosis.[61] When the characteristic eruption occurs without underlying pancreatic malignancy, the condition is referred to as *pseudoglucagonoma syndrome*. Glucagonomas are rare, with an estimated 400 cases cited in the literature.[62] There is no sexual predilection, and it most commonly affects people in their sixth decade.[63]

ETIOLOGY AND PATHOGENESIS Most of the signs and symptoms can be attributed to the metabolic effects of excess glucagon. Amino acid levels are depressed due to glucagon stimulating consumption of amino acid substrates for gluconeogenesis and increasing amino acid oxidation.[64] With insufficient amino acids, epidermal protein deficiency and necrolysis ensue. Reduced amino acid levels (histidine, tryptophan) can cause painful, erythematous eroded skin, especially in intertriginous areas in several nutritional disorders. Glucagon also increases cutaneous levels of arachidonic acid, which likely increases downstream inflammatory mediators (prostaglandins and leukotrienes).

CLINICAL FINDINGS The skin lesions of NME are polymorphous, but erosions and crusts are usually apparent. Primary lesions are erythematous patches that eventuate into plaques that develop central bullae. The blisters erode rapidly, form crust, and eventually resolve. The erythematous and eroded annular patches and plaques coalesce into large geographic areas. The eruption disappears and reappears spontaneously over the course of weeks. Pruritus and pain are common symptoms. The distribution of NME is characteristic and includes intertriginous areas (groin, perineum, buttocks, lower abdomen), the central face (especially perioral) and distal extremities (Fig. 154-7). Mucosal involvement manifests as angular cheilitis, atrophic glossitis and stomatitis. Dystrophic nails may accompany the syndrome.

NECROLYTIC MIGRATORY ERYTHEMA AT A GLANCE

- Painful, eroded, crusted intertriginous and facial skin eruption.
- Highly suggestive of pancreatic malignancy (glucagonoma).
- Half of tumors are metastatic at the time of diagnosis.
- Pseudoglucagonoma syndrome occurs in absence of glucagonoma.
- Skin improves with treatment of underlying nutritional aberrations.

The features of glucagonoma syndrome are weight loss, sore mouth, diarrhea, weakness, mental status changes, and diabetes mellitus.[62] Weight loss is the most common presenting sign. Laboratory abnormalities include a dramatically elevated serum glucagon, usually well over 1000 pg/mL (normal range 50 to 150 pg/mL). Most patients have hyperglycemia and a normochromic normocytic anemia. Abnormal liver function is present, and serum levels of amino acids, total protein, albumin, and cholesterol are low. Occasionally, zinc levels are deficient.

Pseudoglucagonoma syndrome presents identically, but the α-cell pancreatic tumor is not present, which may explain why the serum glucagon levels are not elevated to the same degree. Underlying diseases identified in patients with the pseudo-syndrome are liver disease, pancreatitis, celiac sprue, inflammatory bowel disease, acrodermatitis enteropathica, pellagra, and non-pancreatic malignancies.[62]

The histology of NME is characteristic. Acute lesions demonstrate a striking degree of epidermal necrosis in the upper layers of the stratum spinosum. Neutrophils may be abundant in the necrotic layer, and frank separation from the underlying intact epidermis may occur. Chronic lesions also show a psoriasiform dermatitis with parakeratosis and loss of the granular layer. The constellation of hyperkeratosis, architectural disorder, and scattered degenerating keratinocytes may be seen in other nutritional deficiencies, graft-versus-host disease, connective tissue disorders, and phototoxic drug eruptions.[65]

DIFFERENTIAL DIAGNOSIS (Box 154-2)

COMPLICATIONS Nearly all patients suffer from weight loss; malaise and anemia are a result of the catabolic effects of glucagon. Gastrointestinal symptoms, such as abdominal pain, diarrhea, and anorexia, may be debilitating. Neuro-psychiatric

Box 154-2

Differential Diagnosis of Necrolytic Migratory Erythema

Most Likely

- Dermatitis (seborrheic, eczematous, or contact)
- Drug eruption

Consider

- Pemphigus (foliaceus, erythematosus)
- Acrodermatitis enteropathica
- Essential fatty acid deficiency
- Vitamin deficiency (especially B_2, B_3, B_6)
- Amino acid deficiency (histidine, tryptophan)
- Cutaneous lupus erythematosus

Always Rule Out

- Glucagonoma (abdominal computed tomography)
- Liver disease
- Pancreatitis
- Nutritional deficiencies (zinc, vitamin, amino and fatty acids)
- Malabsorption
- Inflammatory bowel disease

features occur in approximately 20 percent of patients and may present as depression, dementia, psychosis, agitation, ataxia, and decreased cognitive function.[66] Venous thrombosis occurs in up to 30 percent of patients with glucagonoma.[67]

PROGNOSIS AND CLINICAL COURSE If the glucagonoma is not metastatic and can be completely resected at the time of diagnosis, symptoms of the syndrome will resolve. Unfortunately, by the time of diagnosis, tumors are frequently large and metastatic in most cases. Fortunately, the tumors are slow-growing, and patients may experience symptom improvement with surgically decreasing the tumor burden, although survival may not be affected by the procedure. Chemotherapy has been disappointingly ineffective.[62]

TREATMENT The underlying cause for hyperglucagonemia must be addressed to eradicate the painful skin disease. For patients with glucagonoma, resection of the tumor is important for symptom relief. Measures to correct nutritional deficiencies and glucagon levels have provided relief for many patients. Intravenous somatostatin (a glucagon antagonist) has been shown to improve the cutaneous symptoms of the syndrome.[68] Supplementation to correct zinc, amino acid, or fatty acid deficiencies has been shown to be beneficial in some cases.

PREVENTION None known.

NEUTROPHILIC DERMATOSES

Sweet Syndrome (See Chap. 31)

Many authors have suggested that the neutrophilic dermatoses, Sweet syndrome and pyoderma gangrenosum, represent a continuum when associated with an underlying malignancy. In approximately 40 percent of patients with malignancy-associated Sweet syndrome, a diagnosis of cancer is made within 1 month of the dermatoses.[69] Two-thirds of the time, cutaneous manifestations occur before the diagnosis of malignancy and is seen most commonly with acute myelocytic leukemia but also may be associated with other leukemias, myelodysplastic syndrome, multiple myeloma, and lymphoma.[70] Of note, patients with an underlying hematologic malignancy may have a normal neutrophil count that is, in actuality, a relative neutrophilia.

Much less commonly, associations have also been reported with solid tumors such as cancers of the genitourinary tract, embryonal carcinoma of the testes, ovarian carcinoma, gastric carcinoma, and adenocarcinoma of the breast, prostate, and rectum.[71] Unlike many of the other paraneoplastic dermatoses, the neutrophilic dermatoses respond to systemic corticosteroids and other standard treatments regardless of the course of the underlying malignancy.

Pyoderma Gangrenosum (See Chap. 32)

Overall, there is a low incidence of malignancy in patients with pyoderma gangrenosum but the incidence increases up to 27 percent in those presenting with atypical features such as hemorrhagic bullae, superficial and/or rapid appearance, involvement of the upper extremities/hands, and scarring. Similar to Sweet syndrome, the most common underlying malignancy is hematologic with acute myelogenous leukemia the most common followed by multiple myeloma.[72]

Another unexplained co-occurrence in patients with pyoderma gangrenosum is an IgA paraproteinemia, occurring in 10 percent to 18 percent of patients. By itself, this is not a malignancy. However, studies of individuals with monoclonal gammopathy of undetermined significance show an increased risk of malignant transformation occurring at a rate of approximately 1 percent, and can be as high as 40 percent at 25 years. Those with IgA gammopathies have a higher probability of malignant transformation.[73,74] Therefore, careful monitoring is warranted in these patients as well. A parallel course to the underlying malignancy has not been well established with this paraneoplastic dermatosis.

DERMAL PROLIFERATIVE DISORDERS

Multicentric Reticulohistiocytosis (See Chap. 149)

Though malignancy has been diagnosed in many patients with multicentric reticulohistiocytosis, no one malignancy predominates. Neoplasms that have been reported most commonly include melanoma, hematologic malignancies, and carcinomas of the breast, colon, ovaries, cervix, and stomach.[12] The natural course of the disease is generally one of spontaneous remission after several years of activity that resides with permanent joint destruction. While active though, treatment options for multicentric reticulohistiocytosis have only been partially effective, and the course of the disease does not consistently parallel the activity of the underlying malignancy.

Necrobiotic Xanthogranuloma (See Chap. 149)

This non-Langerhans cell histiocytosis is a rare disease that has a high association with hematologic abnormalities. In the majority (80 percent) of patients with necrobiotic xanthogranuloma, an IgG paraproteinemia can be detected with an approximate 10 percent conversion to multiple myeloma. Periorbital involvement is seen in 85 percent of patients and ulceration is more common in this particular xanthoma.[75] Other malignant associations include chronic lymphocytic leukemia, Hodgkin lymphoma, and non-Hodgkin lymphoma.[3]

DERMAL DEPOSITION

Scleromyxedema (See Chap. 159)

Scleromyxedema is the generalized form of papular mucinosis (lichen myxedematosus) and is more severe than its localized counterpart with particular predilection for face, arm, and hand involvement. Systemic organ involvement is more common, and the majority (80 percent) of patients with scleromyxedema has an IgG-λ light chain monoclonal gammopathy of undetermined significance. Serum protein electrophoresis should be performed in conjunction with thyroid studies to rule out thyroid dysfunction and myxedema. Fortunately, the paraproteinemia only rarely

converts to multiple myeloma, but when it occurs, it portends a poor prognosis. Other rare malignancies to co-occur include Waldenström macroglobulinemia, leukemia, or Hodgkin or non-Hodgkin lymphoma.[3] It is uncertain if treatment of scleromyxedema with agents such as melphalan triggers malignant transformation.[76] The course of the disease is usually progressive with major cardiac and pulmonary involvement, and there is no established marker for those most likely to progress to malignancy.

Systemic Amyloidosis (See Chap. 133)

The amyloid sub-type in primary systemic amyloidosis most commonly associated with internal malignancy is the amyloid light chain.

Multiple myeloma is the most common malignancy, seen in 13 percent to 26 percent of patients and, once diagnosed, has an extremely poor prognosis, with a mean survival of 1 year. Other malignancies reported include Hodgkin lymphoma and gastric, breast, and renal cell carcinoma.[12,77,78] The purely cutaneous variants of amyloidosis are not significantly associated with malignancy but familial cutaneous lichenoid amyloidosis has been reported in association with multiple endocrine neoplasia type 2A.[79] All patients with skin lesions of systemic amyloidosis should have a serum and urine electrophoresis performed.

BULLOUS DISORDERS

Paraneoplastic Pemphigus (See Chap. 53)

The signature clinical finding is the early onset of severe refractory oral mucosal involvement. Other sites of involvement can include the ocular, respiratory, and gastrointestinal epithelium. Because nearly every patient with paraneoplastic pemphigus has an associated malignancy, if there is no diagnosed malignancy at the time of presentation, an extensive workup is required. There are occasional instances whereby the association is with a benign tumor. The most common malignancy associated is non-Hodgkin lymphoma. The next most common in frequency are chronic lymphocytic leukemia, Castleman disease, and thymoma.

Dermatitis Herpetiformis (See Chap. 59)

Dermatitis herpetiformis and celiac disease are independent risk factors for gastrointestinal lymphoma. There is no indication that there is a greater than expected number of patients with dermatitis herpetiformis developing tumors other than intestinal lymphoma.[80] The incidence of lymphoma has been reported as between 1 percent and 4 percent developing 2 to 31 years after the diagnosis.[81,82] Interestingly, the increased risk is observed only in adults and the incidence ratio decreases with every calendar year after diagnosis, ultimately reaching null.[83]

The most commonly associated malignancy is enteropathy-associated T-cell lymphoma of the gastrointestinal tract but patients are also at risk to develop B-cell lymphoma both in and out of the gastrointestinal tract and non-Hodgkin lymphoma.[81,84] The relative risk of non-Hodgkin lymphoma associated with dermatitis herpetiformis is 5.4 (95 percent, CI 2.2 to 11.1) in males, less in females.[84] It is often observed that affected patients with lymphoma are less compliant with a gluten-free diet as compared to those without malignancy.[81]

Bullous Pemphigoid (See Chap. 54)

Case-control studies have failed to show a significant increased risk of a malignant tumor in patients with bullous pemphigoid other than that associated with the age of the patient.[85] However, a Japanese cohort of patients with bullous pemphigoid had a 5.8 percent prevalence of neoplasia versus 0.61 percent of controls.[86] In younger patients, bullous pemphigoid under the age of 60 years old was observed in 9.5 percent of patients in a retrospective review of 74 patients, and there are anecdotal reports of patients clearing when the concomitant tumor is treated.[87]

MISCELLANEOUS

Hypertrichosis Lanuginosa Acquisita

Acquired hypertrichosis lanuginosa (described by Fretzin[88] as *malignant down*) is a rare condition characterized by the relatively sudden appearance of long, fine, non-pigmented lanugo (Latin for "down") hairs. The lanugo most frequently appears on the face and ears early in the course (Fig. 154-8). The hairs may grow to an extraordinary length; eyebrows and eyelashes may grow to inches long. The long fine hairs may also be seen on the trunk and limbs, including the axillae. Epithelial proliferation of the oral mucosa may cause glossodynia, hypertrophy of the papillae of the tongue, mucosal pigmentation, and disturbances of taste or smell.[89,90] Symptoms in the mouth are similar to those seen in various vitamin deficiencies, and one case has been reported with decreased vitamins A and B_1 and niacinamide levels.[91]

▲ **FIGURE 154-8** Hypertrichosis lanuginosa acquisita in a 19-year-old woman with pancreatic carcinoma.

This condition is frequently paraneoplastic and nearly always pre-dates the diagnosis of malignancy. The most commonly associated malignancies are located in the lung and colon. Breast and uterine adenocarcinomas, lymphoma, and urinary bladder transitional carcinomas have also been found in patients with acquired hypertrichosis lanuginosa as have other malignancies.[89,90] Unfortunately, tumors are usually widespread by the time hypertrichosis manifests and, thus, this paraneoplastic condition portends a poor prognosis.

Hypertrichosis lanuginosa may also be seen in other disorders. These include acquired immunodeficiency syndrome (most characteristically hypertrichosis and trichomegaly of the eyelashes),[92] anorexia nervosa, thyrotoxicosis, and porphyria cutanea tarda. The condition may be a consequence of medications such as cyclosporin, phenytoin, penicillin, spironolactone, corticosteroids, or minoxidil.[90]

Trousseau Syndrome

In general, malignancy predisposes to alterations in the clotting cascade, resulting in a combined state of hemorrhage and

hypercoagubility. Approximately 11 percent of all cancer patients will develop migratory thrombophlebitis during the course of their disease, and up to 23 percent will have evidence at autopsy.[93,94] Trousseau syndrome is an acquired coagulopathy presenting as migratory thrombophlebitis often in a setting of underlying malignancy. Both the arterial and venous vasculature can be affected and can lead to devastating complications such as pulmonary embolism, stroke, limb necrosis, and organ ischemia.

The human oncogene MET induces increased production of plasminogen activator inhibitor type 1 and cyclooxygenase 2 in some models and may be part of the mechanism linking the hypercoagulable and hemorrhagic state with malignancy.[95]

The most common malignancy reported with Trousseau syndrome is lung carcinoma. However, this most likely reflects the frequency with which it occurs in the general population. The less common pancreatic cancer has a more striking association, with 42 percent having evidence of pulmonary embolism. Furthermore, certain characteristics of tumors have been shown to correlate with an increased risk for the development of Trousseau syndrome. These features include adenocarcinoma, metastatic progression, and involvement of the gallbladder, gastrointestinal, and/or pulmonary systems.[94]

Treatment is best achieved with eradication of the underlying malignancy. To manage the embolic sequelae in Trousseau syndrome, anticoagulation can be achieved with the use of heparin. Low-molecular weight heparin is the treatment of choice, as unfractionated heparin exhibits strong neutralization in the presence of tumor cells.[96]

FAMILIAL CANCER SYNDROMES

It is important for clinicians to recognize cutaneous features of genetic conditions that predispose to internal malignancy. In several cases, cutaneous features predate the development of malignancy and increased surveillance may improve the survivability in these patients.

For malignancies associated with a genodermatosis, there may be an increased risk for family members to develop cancer. Appropriate genetic testing may elicit the carrier state of each relative in question and can assist with genetic counseling of the patient and the patient's family.

The characteristic cutaneous findings and the major associated internal malignancy for the genodermatoses with cancer susceptibility are listed in Table 154-3.[97–103,106]

TABLE 154–3
Genetic Conditions Involving the Skin and Associated with Malignancy

Syndrome	Cutaneous Findings	Major Associated Internal Malignancy	Minor Associated Internal Malignancy
Autosomal dominant			
Birt-Hogg-Dubé syndrome[98]	Fibrofolliculomas, trichodiscomas, acrochordons	Renal carcinoma (12%)	—
Bloom syndrome	Short stature, poikiloderma, CALMs	Acute leukemias/lymphoma[a] Gastrointestinal carcinoma[a]	Wilms' tumor, medulloblastoma, osteogenic sarcoma
Carney complex[106]	Mucocutaneous myxomas, nevi, ephelides, blue nevi	Myxomas (cardiac, 53%; skin, 33%) Sertoli cell testicular cancer (33% males) Primary pigmented nodular adrenocortical disease (26%; benign, causes Cushing syndrome)	Other testicular cancers, breast and thyroid tumors, and melanotic schwannomas
Cowden disease[97]	Trichilemmomas, acral keratoses, oral papillomas, sclerotic fibromas	Breast cancer (22%) Hamartomatous intestinal polyps (60%) Thyroid abnormalities (62%; includes follicular thyroid carcinoma, goiter, and adenoma)	Transitional cell and renal cell carcinomas, glioblastoma multiforme, liposarcoma; lung, hepatocellular, pancreatic, uterine, and ovarian cancer
Gardner syndrome[97]	Epidermoid cysts, fibromas, pilomatricomas	Intestinal polyposis and colorectal adenocarcinoma (near 100%)	Follicular or papillary thyroid cancer, adrenal adenomas and adenocarcinomas, and hepatoblastoma
Gorlin syndrome[97]	Multiple basal cell carcinomas, epidermoid cysts, milia, palmar and plantar pits	Medulloblastoma (10%) Meningiomas (5%)	Ovarian fibromas, fibrosarcomas, cardiac fibromas, ovarian desmoids
Howel-Evans syndrome[100]	Palmoplantar keratoderma	Esophageal carcinoma (up to 90%)	
Maffucci syndrome	Venous malformations	Chondrosarcoma (20%)	Angio- and lymphangiosarcoma, fibrosarcoma, osteosarcoma
MEN1 syndrome[97,99]	Angiofibromas, collagenomas, CALMs, lipomas, hypopigmented macules, gingival papules, necrolytic migratory erythema	Parathyroid adenomas (90%) Gastrinomas (54%; includes Zollinger-Ellison syndrome) Anterior pituitary tumors (10%–30%)	Insulinomas, glucagonomas, foregut carcinoids, pheochromocytoma
MEN2a syndrome[97,99]	Scapular macular or lichen amyloidosis	Medullary thyroid carcinoma (90%) Pheochromocytomas (50%) Parathyroid tumors (20%–30%)	
MEN2b/3 syndrome[97,99]	Mucosal neuromas, CALMs, marfanoid habitus, mucosal/intestinal ganglioneuromas	Medullary thyroid carcinoma (90%) Pheochromocytoma (50%)	

(continued)

TABLE 154–3
Genetic Conditions Involving the Skin and Associated with Malignancy (Continued)

Syndrome	Cutaneous Findings	Major Associated Internal Malignancy	Minor Associated Internal Malignancy
Muir-Torre syndrome[97]	Sebaceous tumors, keratoacanthomas	Colorectal carcinomas (51%) Genitourinary cancers (25%)	Breast, head and neck, and small intestine carcinomas, hematologic malignancies
Neurofibromatosis type 1[97]	CALMs, neurofibroma, plexiform neurofibroma, axillary freckling, Lisch nodules	Optic gliomas (66%) Neurofibrosarcoma (3.5%) Chronic myelomonocytic leukemia (if associated with juvenile xanthogranuloma; 221× increased risk)	Astrocytomas, non-Hodgkin lymphoma, acute lymphoblastic leukemia, pheochromocytoma, carcinoid
Neurofibromatosis type 2[97]	Schwannomas, neurofibroma, CALMs, plexiform neurofibroma	Bilateral vestibular schwannomas (near 100%) Spinal tumors (90%; usually schwannomas) Meningiomas (50%)	Gliomas, astrocytomas, intramedullary ependymomas
Peutz-Jeghers syndrome[97]	Perioral and mucosal lentigines	Polyps (near 100%) Gastrointestinal carcinoma (13%)	Variety of solid tumors
Reed syndrome[101]	Cutaneous leiomyomas	Uterine leiomyoma (98%) Renal carcinoma (type II papillary renal cell)	
Tuberous sclerosis	Ash leaf macules, shagreen patches, facial angiofibromas, periungual fibromas	Intracranial cortical/subcortical tubers (near 100%) Cardiac rhabdomyomas (50%) Renal angiomyolipomas (49%)	Wilms' tumor, pancreatic carcinoma, parathyroid adenoma
Autosomal recessive			
Ataxia-telangiectasia	Telangiectasias	Leukemia/lymphomas (38%) Breast cancer (increased risk in heterozygotes)	
Bloom syndrome[97,102]	Short stature, CALMs, poikiloderma	Acute leukemia[a] Lymphoma[a] Gastrointestinal adenocarcinoma[a]	Wilms' tumor, medulloblastoma, osteogenic sarcoma
Chédiak-Higashi syndrome[102]	Silver hair, slate-gray skin, ecchymoses	Lymphoma-like accelerated phase (85%)	
Fanconi anemia[103]	Short stature, CALMs microcephaly, thumb and/or radial ray anomalies	Acute myeloid leukemia (9%)	Myelodysplastic syndrome, gynecologic malignancies
Griscelli syndrome	Silver hair, pigmentary dilution	Lymphoma-like accelerated phase (in the majority)[a]	
Rothmund-Thompson syndrome[97]	Poikiloderma, nail dystrophy, photosensitivity hypotrichosis	Osteogenic sarcomas[a]	
Werner syndrome[97,102]	Premature aging, short stature, bird-like facies	Sarcomas (10%; soft tissue, bone) Thyroid cancer[a]	Meningiomas, adenocarcinomas; acrolentiginous melanoma in Japan
Xeroderma pigmentosum[97]	Photosensitivity, actinic keratoses, squamous cell carcinoma, basal cell carcinoma, melanoma, lentigines, dermatoheliosis	Ocular cancers Lung and gastric carcinomas (10–20× increased risk)	Sarcomas, leukemia
X-linked recessive			
Dyskeratosis congenita	Leukoplakia, alopecia, reticulate pigmentation, nail dystrophy	Mucosal squamous cell carcinoma[a]	
Wiskott-Aldrich syndrome	Eczema, petechiae	Lymphoreticular malignancy (20%; non-Hodgkin lymphoma)	
X-linked icthyosis[102]	Adherent brown scales	Testicular cancer (from associated cryptorchidism)	
Miscellaneous			
Beckwith-Wiedemann syndrome	Capillary malformation, macroglossia, earlobe creases	Wilms' tumor[a] Hepatoblastoma[a]	Adrenal cortical carcinoma, rhabdomyosarcoma
Epidermal nevus syndrome	Epidermal nevi, hemangiomas, CALMs, capillary malformation	Wide variety (usually ecto- and mesoderm derived)	
Familial melanoma (dysplastic nevus syndrome)[97]	Multiple dysplastic nevi, melanomas	Pancreatic cancer (22× increased risk)	Lung, laryngeal, and breast carcinomas

CALMs = café-au-lait macules; MEN = multiple endocrine neoplasia.
[a]Frequency unable to be reported due to rarity of the genodermatoses and/or a specific malignancy.

DIRECT TUMOR INVOLVEMENT OF THE SKIN

Cutaneous Metastases

Direct involvement of the skin by metastatic spread from a distant primary tumor is perhaps the most unquestioned sign of internal malignancy. The overall incidence of cutaneous involvement is approximately 5 percent.[104] In a review of over 100,000 cancer patients, skin involvement was the first sign of internal malignancy in 7.8 percent.[105] The most common malignancies to metastases to the skin in women are breast, colon, and melanoma. In men, the most common are lungs, colon, and melanoma.

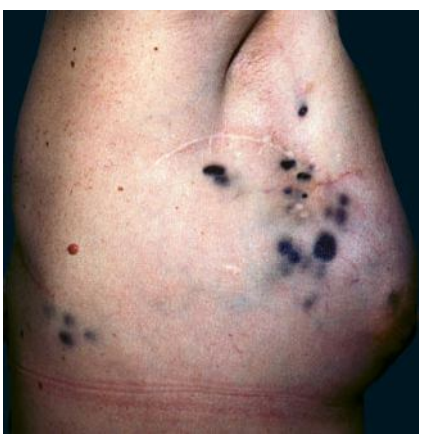
Several clinical and pathologic features can aid in determining the source of the metastasis. Metastatic breast cancer can present as an erysipelas-like eruption known as *carcinoma erysipelatoides* (Fig. 154-9A). Usually asymptomatic, this type of breast cancer can be painful. Another clinical variant is the leather-like skin change of sclerosing metastatic breast cancer known as *carcinoma en cuirasse*, which may later present as nodules and ulceration (see Fig. 154-9B). Carcinoma en cuirasse can be progressive for many years, even decades, in the absence of any apparent systemic involvement.

Metastases from malignant melanoma are usually pigmented (Fig. 154-10). Often there is a bluish tint to the lesion, even if it is deep in the skin. However, even if the primary tumor was pigmented, the metastases can be amelanotic. The reverse is also true.

Other tumors that commonly metastasize to skin include tumors of the lung (Fig. 154-11), stomach, kidney, and ovary. The scalp is quite commonly involved by metastases from lung, kidney, and breast tumors. Alopecia may result. The face and neck may be involved by metastases from oropharyngeal carcinomas. Metastases from renal and thyroid carcinoma may be pulsatile and may have a bruit.

A proposed diagnostic truncated immunohistochemical battery includes cytokeratin 7, cytokeratin 20, and S-100. When administered to a cohort of patients with lung, colorectal, bladder, renal cell carcinoma, and melanoma, there was an overall diagnostic accuracy of 83.3 percent. Other useful markers include antithyroid transcription factor (lung), human melanoma black-45 (melanoma), prostate-specific antigen (prostate), estrogen/progesterone receptors (breast), and mucicarmine (salivary gland).[105]

Generally cutaneous metastases herald a poor prognosis because evidence of systemic spread to other sites is usually quickly apparent. The average survival time of patients with cutaneous metastases is approximately 7.5 months.[105]



▲ **FIGURE 154-10** Deeply pigmented cutaneous metastases from melanoma.

Leukemia and Lymphoma Cutis (See Chaps. 145 and 146)

Involvement of the skin with lymphoma cells is quite common, particularly in the case of a T-cell lymphoma. T-cell leukemias frequently have skin involvement, and this involvement may manifest itself as a diffuse erythroderma, as is seen in Sézary syndrome.

B-cell lymphomas also can involve the skin, with Hodgkin lymphoma being the most common. B-cell lymphoma involvement of the skin is usually manifested by the development of one or more papules or nodules that may be ulcerated and form arcuate lesions. Alopecia also can be caused by lymphoma. Alopecia mucinosa is involvement of

▲ **FIGURE 154-11** Metastatic lung cancer presenting as a forehead nodule.

the hair follicles by lymphoma, with associated mucin deposition.

Aside from the erythroderma seen in T-cell leukemia, other lymphocytic, myeloid, and myelomonocytic leukemias can have cutaneous manifestations. The most common of these are the infiltrations of the skin produced by monocytic or myelomonocytic leukemia, which can produce a leonine facies in addition to other infiltrative plaques. Involvement of the skin can be a presenting feature in myelomonocytic leukemia, although it generally occurs late in the course of the disease.

When assessing a solitary nodule that is histologically lymphoma but in the absence of any definable systemic disease, it is important to consider benign cutaneous lymphoid infiltrates in the differential diagnosis.

Paget and Extramammary Paget Disease (See Chap. 121)

Paget disease of the nipple is an erythematous scaling eruption indicating ductal carcinoma of the underlying breast. Extramammary Paget disease, which can occur in the anogenital skin, similarly may be associated with an underlying adenocarcinoma. The underlying carcinoma may be of apocrine or eccrine sweat gland origin, or can be from the rectum or urethra.

SECTION 27

THE SKIN IN VASCULAR AND CONNECTIVE TISSUE AND OTHER AUTOIMMUNE DISORDERS

CHAPTER 155

Mechanisms of Autoimmune Disease

Insoo Kang
Joe Craft

Autoimmune diseases, including rheumatoid arthritis (RA) and systemic lupus erythematosus (SLE), are relatively common disorders.[1] Although the underlying etiologies of these illnesses are still elusive, they arise in the context of a break in the immune tolerance to self.[2,3] The mechanisms for abrogation of immune self-tolerance appear to be multifactorial, including genetic and environmental, that work in concert to initiate the eventual hallmarks of disease: unregulated immune activation against self-antigens and subsequent tissue destruction. Immune activation against self-antigens is clinically manifest by the presence of autoantibodies and autoreactive T cells.[1,2] Based on their autoantigenic targets, autoimmune diseases can be classified into organ-specific and systemic autoimmune processes. For example, Graves disease, with its autoantibodies against the thyroid-stimulating hormone receptor, is a typical example of organ-specific autoimmune disease as is type 1 diabetes mellitus (DM) with its autoantibodies and autoreactive T cells directed against components of pancreatic β cells, whereas SLE with its characteristic autoantibodies against ubiquitous nuclear antigens is a good example of a systemic autoimmune disease. Although adaptive immune cells, such as B cells and T cells, recognize self-antigens and, hence, dominate the phenotype of the patient with autoimmunity, other immune components, including antigen-presenting cells (APCs) and complement, are involved in various steps from initiation of the autoimmune response to tissue destruction.[4–6]

GENETICS

Autoimmune Diseases Are Polygenic

Autoimmune diseases are polygenic, involving both major histocompatibility complex (MHC) and non-MHC genes.[7,8] Yet, the concordance rate of autoimmune diseases in monozygotic twins is not 100 percent, ranging from 10 percent to 50 percent, including in RA and SLE,[6,7] indicating a significant role for non-genetic factors in the development of these disorders. Nevertheless, genetic influences are strong. For instance, the contribution of alleles of MHC to the development of autoimmunity has been known for more than 30 years. An increased frequency of HLA (human leukocyte antigen)-DR4 has been observed in some patients with RA.[8] Using more sophisticated molecular techniques, the sequence of genetic alleles encoding HLA loci have been typed, with the resultant demonstration that the *HLA-DRB1* gene is highly polymorphic, and such polymorphisms can affect the binding of peptides to HLA molecules and the contacts between the T-cell receptor (TCR) and the HLA molecule.[8] Thus, the associations between autoimmune diseases and particular HLA molecules can be explained by a model where disease susceptibility is determined by differences in the ability of different HLA alleles to present autoantigenic peptides to autoreactive T cells.[2,8]

Non-Major Histocompatibility Complex Associations with Autoimmune Diseases

The association of non-MHC genes with autoimmune diseases is well established.[1,7] These genes include those involved in autoantigen clearance, apoptosis, cell signaling, cytokine production, and the expression of co-stimulatory molecules.[1,2,7] For instance, complement components are required for proper clearance of immune complexes, and an increased incidence of homozygous C4 deficiency is found in patients with SLE who have immune complex deposits in damaged organs such as the kidneys.[6]

MECHANISMS FOR AUTOIMMUNE DISEASES AT A GLANCE

- Autoimmune diseases are relatively common disorders and can be divided into organ-specific and systemic autoimmune diseases based on the autoantigens targeted by immune cells.
- Although the underlying etiologies of these illnesses are still elusive, they arise in the context of a break in the immune tolerance to self.
- The mechanisms for abrogation of immune self-tolerance appear to be multifactorial, including genetic and environmental, that lead to unregulated immune activation against self-antigens and subsequent tissue destruction.
- B cells and T cells recognize self-antigens and dominate the phenotype of the patient with autoimmunity, although other immune components including antigen-presenting cells and complement are involved in various steps from initiation of the autoimmune response to tissue destruction.

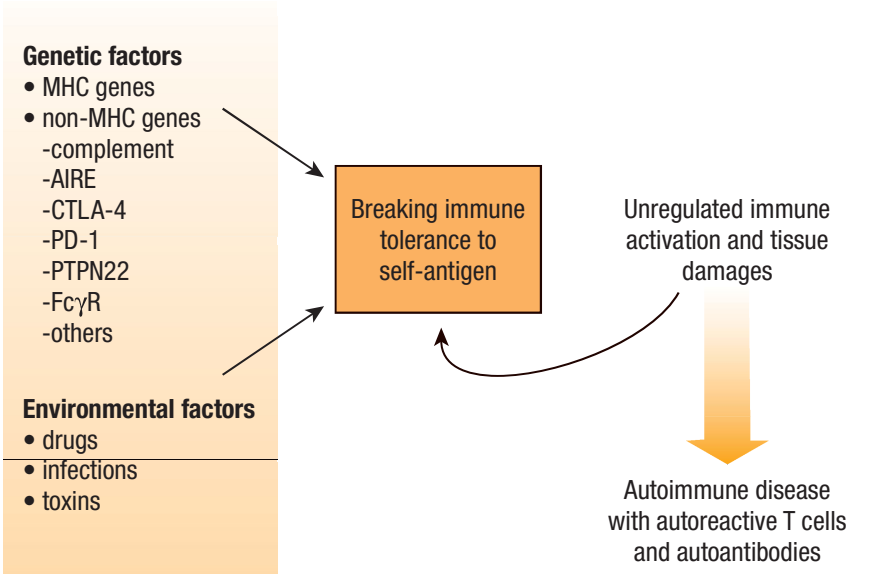
Autoimmune Regulator

A gene called *autoimmune regulator* (*AIRE*) has been identified as a candidate gene responsible for the development of autoimmune diseases.[9,10] AIRE is a transcriptional factor that regulates the ectopic expression of proteins, normally expressed in peripheral tissues, in the thymus, allowing for thymic expression of the latter and subsequent negative selection of self-reactive thymocytes before they migrate as mature T cells to the secondary lymphoid organs such as the spleen and lymph nodes. An alteration in thymic expression of *AIRE* can lead to increased generation of autoreactive T cells due to their impaired negative selection.[11] Indeed, patients with mutations of the *AIRE* gene develop a syndrome called *autoimmune polyendocrinopathy candidiasis ectodermal dystrophy* or *autoimmune polyglandular syndrome 1* (*APS-1*) that is characterized by chronic mucocutaneous candidiasis, hypoparathyroidism, and Addison disease.[12] In addition, patients with this condition often have other organ-specific autoimmune diseases, including type 1 DM, autoimmune thyroid diseases, gonadal failure, vitiligo, alopecia areata, dystrophy of dental enamel and nails, and pernicious anemia.[12]

Cytotoxic T-Lymphocyte Antigen-4

An increased incidence of autoimmune diseases has been reported in individuals with a particular variant of genes that affect T-cell activation. These include cytotoxic T-lymphocyte antigen-4 (CTLA-4) gene and protein tyrosine phosphatase 22 gene (PTPN22; see Protein Tyrosine Phosphatase 22).[1,13] CTLA-4 is a key immunoregulatory molecule that restrains T-cell activation. It is expressed on T cells upon TCR stimulation by antigen on APC and competes with CD28, a positive co-stimulatory molecule also on T cells, for binding to CD80 and CD86 expressed on APC.[14] By contrast to CD28 engagement by CD80 and CD86, binding of CTLA-4 to the latter molecules inhibits T-cell activation. The association of SLE and RA with single nucleotide polymorphisms (SNPs) in the *CTLA-4* promoter and coding region has been reported. These polymorphic sites include –1722 position of the *CTLA-4* promoter and +49 position of exon-1,[15,16] although the functional consequence of such gene polymorphisms is not clear yet. CTLA-4 polymorphisms also have been linked to autoimmune endocrinopathies; for example, a decrease in the alternate splice product of *CTLA-4* that is the soluble form of CTLA-4 is found in individuals with CTLA-4 SNP CT60 G/G, which is linked with increased susceptibility to Graves disease, autoimmune hypothyroidism, and type 1 DM.[17] This finding suggests a possible functional role for CTLA-4 polymorphisms in autoimmune diseases (Fig. 155-1).



▲ **FIGURE 155-1** Mechanisms for development of systemic autoimmune disease. The figure shows potential mechanisms for initiation of systemic autoimmune diseases, in this case, systemic lupus erythematosus, including genetic and environmental factors that work in concert to initiate breaking immune tolerance to self-antigen. Subsequently, unregulated immune activation and tissue damages arise, leading to the development of autoimmune disease with autoreactive T cells and autoantibodies. AIRE = autoimmune regulator; CTLA-4 = cytotoxic T-lymphocyte antigen-4; FcγR = receptor for immunoglobulin G Fc portion; MHC = major histocompatibility complex; PD-1 = programmed cell death 1; PTPN22 = protein tyrosine phosphatase 22. See details in text.

Programmed Cell Death 1

In a manner analogous to CTLA-4, a protein called *programmed cell death 1* (PD-1) is expressed on T cells providing an inhibitory signal upon their activation. This molecule is also expressed on other immune cells including B cells and myeloid cells.[1,18] PD-1 is encoded by the *PDCD1* gene, with a SNP in its fourth intron associated with autoimmunity, including SLE and RA.[19–21] Of interest, this disease-associated SNP impairs the binding of the hematopoietic runt-related transcription factor 1 (RUNX1), presumably leading to aberrant expression of *PDCD1* gene and subsequently uncontrolled T-cell activation.[19] The association of genetic polymorphisms of CTLA-4 and PD-1, molecules involved in regulating T-cell activation, with autoimmune diseases supports the notion that regulation of T-cell activation by these co-stimulatory molecules is a critical checkpoint for the development of autoimmunity.

Protein Tyrosine Phosphatase 22

The *PTPN22* gene is another gene that is associated with autoimmune diseases.[1] A variant of the *PTPN22* gene, which encodes a tryptophan at codon 620 (620W) instead of an arginine (wild-type), has been found to be associated with an increased risk of RA, SLE, type 1 DM, and Graves disease (reviewed in ref. 1). Such a mutation appears to have functional consequences, as the *PTPN22* gene encodes lymphoid tyrosine phosphatase that modulates the activation of Lck and other kinases involved in TCR signaling.[22] Indeed, the *PTPN22* 620W allele appears to potentially increase the inhibition of TCR activation by downregulating Lck activation.[22] Thus, it still needs to be clarified how this allele promotes the development of autoimmunity.

Receptors for Immunoglobulin G Fc Portion

In addition to genes expressed by T cells, those involved in humoral immune responses also appear to be associated with autoimmunity. The receptors for immunoglobulin G (IgG) Fc portion (FcγR) are expressed on B cells, macrophages, monocytes, granulocytes, and dendritic cells (DCs). There are eight genes identified for the human FcγR: *FCGRIA*, *FCGRIB*,

FCGRIC, *FCGRIIA*, *FCGRIIB*, *FCGRIIC*, *FCGRIIIA*, and *FCGRIIIB*.[23] The binding of FcγRs to IgG, except for that to FcγRIIb, results in a broad spectrum of activating cellular responses including phagocytosis, cytolysis, cytokine production, and degranulation that lead to inflammation. By contrast, FcγRIIb physiologically serves as an inhibitory receptor that downregulates the effector function of cells.[23] An increased frequency of some variants of *FCGR* genes has been reported in humans with autoimmune diseases, including SLE and RA (reviewed in ref. 23).[24–27] FcγRIIa with an arginine at position 131 has a higher response to IgG1 than Fc–γRIIa with a histidine at the same position, suggesting that FcγRIIa gene polymorphisms have physiologic relevance.[27] Of interest, FcγRIIa with an arginine has been reported as a susceptibility factor for SLE in some ethnic groups.[23,28] Similarly, a variant of FcγRIIIa with a phenylalanine at position 158 may be a susceptibility factor for SLE and RA.[24,26] In addition, genetic polymorphisms of the inhibitory FcγRIIb have been reported in patients with SLE,[25,29,30] The best known such polymorphism is a substitution of an isoleucine at position 232 (187 by counting from the N-terminus of the mature protein) with a threonine.[25,29,30] The latter genotype is more commonly reported in patients with SLE. Although the biologic implication of such an alteration on the development of SLE is as yet unclear, functioning inhibitory FcγRs are necessary for dampening autoimmunity in murine lupus.[31]

Overall, genetic studies on MHC genes and non-MHC genes support the notion that some patients with autoimmune diseases have an increased genetic risk for the development of autoimmune diseases secondary to genetic alterations affecting immune cell function. However, such alterations are not always observed in patients with autoimmune diseases, and ethnic differences in genetic susceptibility are not uncommon. These findings indicate that autoimmune diseases are polygenetic and that environment factors are also involved in their development.

TOLERANCE AND AUTOIMMUNITY

Central Tolerance

Intact mechanisms of self-tolerance are necessary to prevent the development of autoimmune diseases.[2] Self-tolerance is generated and maintained through the capacity of the immune system to distinguish self-reactive B and T cells from non–self-reactive cells. These processes begin during the development of lymphocytes in the bone marrow and thymus, respectively.[3] Such selective processes are controlled by the binding affinity of antigen receptors to self-antigens during lymphocyte development. B and T cells expressing antigen receptors with affinity for self-antigens are altered, either becoming nonreactive to antigenic stimuli (through a process called *anergy induction*) or changing their antigen receptors so that they no longer bind self-antigens (a process called *receptor editing*, largely operative in self-reactive B cells), or if they bind too strongly to self, they are simply killed via apoptosis. These interventions lead to central tolerance to self-antigens.[3] A defect in central tolerance can cause autoimmune diseases as evidenced by the development of APS-1 in humans with an alteration in the *AIRE* gene (see Genetics) that is involved in negatively selecting autoreactive T cells.[32,33]

Peripheral Tolerance

Despite removing or modifying autoreactive lymphocytes in the thymus and bone marrow by selective processes, some lymphocytes reactive to self-antigens still mature and enter the peripheral immune system; (i.e., negative selection is not perfect, probably because if it were, potentially beneficial T and B cells would never make it past central selection in the thymus and bone marrow, respectively). These autoreactive T and B cells that escape central selection can potentially be activated upon recognition by self-antigens; thus, peripheral tolerance mechanisms need to be available to avoid the development of autoimmunity. Such mechanisms are several, and involve minimizing contacts of autoreactive cells with self-antigens (ignorance of the self-reactive lymphocyte), not providing appropriate signals for their activation, terminating activated autoreactive cells by regulatory molecules such as PD-1 or CTLA-4 and/or actively suppressing autoimmune responses by other T cells.[2] In critical organs like the brain, eyes, and gonads, immunologic ignorance is a principle mechanism for avoidance of autoreactivity via the provision of anatomical barriers separating the tissue and lymphocytes. Activation of the latter can be further prevented by the relative paucity of APCs in these organs and the minimal expression of MHC molecules in these tissues.[34,35] These sites are termed *immunologically privileged sites* because even tissue grafts do not elicit immune responses in these tissues. Immunologically privileged sites have additional mechanisms that prevent immune activation. These include production of transforming growth factor-β (TGF-β), which can suppress immune responses such as in the anterior chamber of the eyes, and constitutive expression of Fas ligand that induces apoptosis of infiltrating activated lymphocytes.[34,35]

Nevertheless, because autoantigens are expressed on some tissues and autoreactive lymphocytes are present in the circulation, there is still a reasonable chance for these cells to recognize autoantigens expressed by MHC molecules on APC. However, such an autoantigenic signal through potentially self-reactive antigen receptors is not enough to activate lymphocytes, as additional signals (second signals) provided by APCs, such as CD80 and CD86, to CD28 on T cells are required for proper activation.[14,26] When proper co-stimulation is not provided by APCs, autoreactive T cells that are only signaled through the TCR undergo apoptosis or become anergized. As CD80 and CD86 upregulation on APCs requires an inflammatory stimulus provided to the APC such as that provided by a pathogen during infection, APC presentation of self-antigens in the absence of inflammation does not lead to autoreactive T-cell activation. By contrast, peptides of pathogens lead to cellular activation as they are presented to the immune system in the appropriate inflammatory context. Of course, this regulatory control on autoimmunity may be bypassed if, in a similar manner, self-antigens are presented at a site of inflammation. Fortunately, this appears to be a relatively unusual event, and autoimmunity invoked by this mechanism is typically avoided.

Autoreactive lymphocytes that manage to become activated in the periphery can be also deleted by apoptosis (programmed cell death) and/or their activation terminated by inhibitory molecules expressed on autoreactive lymphocytes. Fas and Fas ligand expressed on T cells are largely responsible for the former process.[37,38] The latter process can be achieved through CTLA-4 and PD-1 expressed on activated T cells that inhibit and downregulate T-cell activation.[14,18] The potential roles for CTLA-4 and PD-1 in controlling autoimmunity have been demonstrated by mouse studies where these genes have been genetically eliminated, for example, with resultant autoimmunity.[39,40] In addition,

genetic polymorphisms in these molecules have been reported to be associated with autoimmune diseases including SLE and RA (see Genetics). More important, there have been attempts to treat autoimmune diseases by modulating CTLA-4 and PD-1 inhibitory pathways.[41,42] Indeed, abatacept, a recombinant fusion protein comprising the extracellular domain of human CTLA-4 and a fragment of the Fc domain of human IgG1, is available for the treatment of RA.[41] This drug, like CTLA-4, competes with CD28 for CD80 and CD86 binding, blocking T-cell activation and thus selectively modulating T cell activation. The activation of autoreactive lymphocytes is also actively suppressed through other mechanisms. The most appealing such mechanism is immune suppression through subsets of T cells called *regulatory T cells* (*Tregs*), discussed in Regulatory T Cells.

Regulatory T Cells

The concept that certain T cells can regulate immune responses dates back to the early 1970s. These cells, which Gershon initially called *suppressor cells*,[43] remained largely undefined and their mechanism of suppression not identified. After their original discovery, they remained out of vogue until more than a decade later when others, including Sakaguchi, reported modulation of immune responses by $CD4^+$ T cells expressing CD25 [interleukin 2 (IL-2) receptor α chain][44] as well as by T cells producing TGF-β and IL-10.[45–47] Cells with immune regulatory functions are now called *Tregs*. Several subsets of Tregs have been identified thus far, including (1) naturally occurring $CD4^+$ $CD25^+$ Tregs expressing the transcriptional repressor protein forkhead box P3 (Foxp3); (2) $CD4^+$ T cells producing IL-10, called *type 1 Tregs* (*Tr1*); (3) $CD4^+$ T cells producing TGF-β, named *T helper 3 cells* (*Th3*); and (4) $CD8^+$ T cells producing IL-10 or TGF-β (reviewed in refs. 48 and 49).

$CD4^+$ $CD25^+$ Regulatory T Cells

Among the best characterized Tregs are naturally occurring $CD4^+$ $CD25^+$ $Foxp3^+$ cells that are produced in the thymus. The potential role for these Tregs in controlling the development of autoimmunity was initially demonstrated by studies where mouse T-cell suspensions were transferred into congenic athymic nude mice. If the latter animals received such suspensions depleted of $CD4^+$ $CD25^+$ T cells, they developed an autoimmune syndrome including thyroiditis, gastritis, insulitis, sialoadenitis, adrenalitis, oophoritis, glomerulonephritis, and polyarthritis.[44] By contrast, athymic nude mice that received whole T-cell suspensions did not develop autoimmunity, indicating a role for $CD4^+$ $CD25^+$ T cells in preventing autoimmune diseases.[44] Subsequently, the inhibitory effects of $CD4^+$ $CD25^+$ Tregs in different types of animal models of autoimmune diseases, including collagen-induced arthritis and autoimmune diabetes, were documented.[50,51] Yet, not all $CD4^+$ $CD25^+$ T cells have immunoregulatory functions as CD25 is upregulated upon T-cell activation. Thus, the search for other markers that specifically identify these cells has been extensive, and has led to the identification of CD38, CD103, CTLA-4, glucocorticoid-induced tumor necrosis factor (TNF) receptor, lymphocyte activation gene, and Foxp3[52] as potential markers as well as contributors to function. The most promising of this group is Foxp3. Disruption of its gene in mice results in autoimmune diseases,[53,54] whereas overexpression of Foxp3 in T cells induces expansion of $CD4^+$ T cells with immunosuppressive function.[53–55] Furthermore, $CD4^+$ $CD25^-$ T cells transfected with FoxP3 acquire immunosuppressive function.[53,54]

Although the exact mechanism(s) by which naturally occurring $CD4^+$ CD25 Tregs suppress autoreactive T cells is not fully understood, cell-to-cell contact is necessary, and CTLA-4 appears to be required.[56] CTLA-4 expressed on Tregs interacts with CD80 and CD86 expressed on APC as well as on the target T cells[57,58]; although CD80 and CD86, ligands for CTLA-4, are conventionally expressed on APC, as noted above under Cytotoxic T-Lymphocyte Antigen-4, they have also been found on activated $CD4^+$ T cells.[57,58] These molecules likely interact with CTLA-4 expressed on $CD4^+$ $CD25^+$ T cells, providing "outside-in" signaling, leading to immune suppression. This notion is supported by the study of graft-versus-host disease (GVHD), in which $CD4^+$ $CD25^-$ T cells with or without expression of CD80 and CD86 were transferred into lymphopenic recombination-activating gene 2 (RAG2)-deficient mice, together with $CD4^+$ CD25+ T cells.[57,58] Mice that received $CD4^+$ $CD25^+$ T cells as well as $CD4^+$ $CD25^-$ T cells with expression of CD80 and CD86 developed no GVHD. By contrast, mice that received $CD4^+$ $CD25^+$ T cells and $CD4^+$ $CD25^-$ T cells deficient in CD80 and/or CD86 expression developed GVHD. These findings indicate that $CD4^+$ $CD25^+$ Tregs expressing CTLA-4, via interaction with CD80, can modulate activated T cells and CD86 expressed on activated T cells.

By contrast to animal studies, the data on $CD4^+$ $CD25^+$ Tregs in human autoimmune diseases is relatively minimal. In patients with type 1 DM, a typical example of organ-specific autoimmune diseases, the frequency of $CD4^+$ $CD25^+$ Tregs has been shown to be significantly lower than in healthy controls and patients with type 2 DM, suggesting a role for these cells in disease development.[59] However, differences in the frequency of $CD4^+$ $CD25^+$ Tregs has not been reported in patients with type 1 DM compared with healthy controls,[60] although the inhibitory function of such cells was impaired in such patients.[61] Similarly, there was no difference in the frequency of $CD4^+$ $CD25^+$ T cells and their functional markers, including Foxp3, among patients with APS-II characterized by Addison disease, type 1 DM, and autoimmune thyroid disease, as well as control patients with single autoimmune endocrinopathies and normal healthy donors.[62] However, $CD4^+$ $CD25^+$ Tregs from APS-II patients were defective in their suppressive capacity.[62] These findings suggest that patients with autoimmune endocrinopathies, including type 1 DM and APS-II, may have an alteration in the suppressive function of $CD4^+$ $CD25^+$ Tregs.

A role for $CD4^+$ $CD25^+$ Tregs in the development of SLE and RA, typical systemic autoimmune diseases, has also been explored. In pediatric patients with SLE, an inverse correlation between the frequency of $CD4^+$ $CD25^+$ Tregs with disease activity and levels of anti-double-stranded DNA (anti-dsDNA) antibodies has been reported.[63] Similarly, decreased numbers of $CD4^+$ $CD25^+$ Tregs were found in adult patients with SLE, although there was no significant correlation found between the levels of $CD4^+$ $CD25^+$ Tregs and disease activity.[64] These observations suggest a potential role for $CD4^+$ $CD25^+$ Tregs in the development of SLE. In RA, $CD4^+$ $CD25^+$ Tregs from both peripheral blood and synovial fluid have been studied.[65–67] The frequency of $CD25^+$ $CD4^+$ Tregs in the latter fluid was higher than that in peripheral blood,[66,67] although there was no significant difference in the numbers of $CD4^+$ $CD25^+$ Tregs in peripheral blood between patients and controls.[66,67] Of interest, $CD4^+$ $CD25^+$ Treg cells in RA have been shown to have compromised function in the suppression of inflammatory cytokines from $CD4^+$ $CD25^-$

T cells.[68] Furthermore, such impairment was reversed after treating patients with anti–TNF-α therapy. These findings suggest that patients with RA have a functional, but not a numerical, defect in $CD4^+$ $CD25^+$ Tregs.

Other Regulatory T Cells

In contrast to $CD4^+$ $CD25^+$ Tregs that naturally occur, other regulatory T cells can be induced in vivo and in vitro (reviewed in ref. 49). These cells include Tr1, Th3 ($CD4^+$ T cells producing large amounts of TGF-β), $CD28^+$ T cells that develop in the setting of immune stimulation such as that initiated by chronic infections. For instance, humans chronically infected with hepatitis C or Epstein-Barr viruses (EBVs), or with *Mycobacterium tuberculosis* or the nematode *Onchocerca volvulus*, may develop pathogen-specific Tr1 cells that produce large amounts of IL-10 that can suppress antigen-specific or non-specific T-cell responses.[69–72] These cells can also be generated after ingestion of a foreign antigen via the oral route.[45] The immunosuppressive mechanisms employed by Tr1 and Th3 cells are dependent on IL-10 and TGF-β production rather than direct cell-to-cell contact as in natural Tregs.[49]

$CD8^+$ T cells may also have immunosuppressive activity.[48] Mice deficient in $CD8^+$ T cells develop experimental autoimmune encephalomyelitis (EAE), an animal model of multiple sclerosis.[73] However, EAE in the same animals was milder when they received adoptive transfers of $CD8^+$ $CD28^-$ T cells. Moreover, $CD8^+$ $CD28^-$, but not $CD8^+$ $CD28^+$, T cells suppressed in vitro interferon-γ (IFN-γ) production by $CD4^+$ T cells specific for myelin oligodendrocyte glycoprotein, an autoantigen in EAE. Such suppression required cell-to-cell contact and was mediated by inhibition of upregulation of co-stimulatory molecules on APCs that led to decreased co-stimulation of $CD4^+$ T cells. Of interest, $CD8^+$ T cells with suppressor activity have been suggested to have a potential role in improving lupus-like disease in mice.[74] Decreased levels of pathogenic anti-dsDNA antibodies with a resultant increase in survival were found in lupus-prone [New Zealand Black (NZB) x New Zealand White (NZW)]F_1 mice when injected with an artificial peptide called pConsensus that was developed based on T-cell stimulatory V_H sequences found in (NZB x NZW)F1 anti-DNA antibodies. This protection depended in part on the generation of peripheral TGF-β– and Foxp3-expressing inhibitory $CD8^+$ T cells, and suggested that $CD8^+$ T cells with regulatory activity could be a potential way to modulate autoimmune diseases.

INNATE IMMUNITY AND AUTOIMMUNITY: DENDRITIC CELLS AND TOLL-LIKE RECEPTORS

Various cells of the innate immune system appear to be involved in the regulation of autoimmunity, including DCs, natural killer cells, γδ T cells, natural killer T cells, and even mast cells.[75–80] Among the best characterized are DCs, or professional APCs.[81] DCs present antigens to T cells for their activation, but their requirement to provide co-stimulation via CD80 and CD86 limits autoreactive T-cell activation in the absence of inflammatory signals. Interaction of CD80 on DCs and CD28 on T cells polarizes TCR-triggered naive T cells into Th1 cells producing IFN-γ. In addition, activated DCs produce multiple cytokines including IL-12, TNF-α and IL-6 that can promote inflammation. DCs express Toll-like receptors (TLRs), or pattern recognition receptors that recognize various pathogen-associated molecular structures including lipopolysaccharide, double-stranded RNA, single-stranded RNA, and hypomethylated cytosine and guanosine sequence (CpG) DNA.[82] Thus, microorganisms can potentially promote autoimmunity and inflammation through these receptors by activating DCs.[81] Activated DC can also affect $CD4^+$ $CD25^+$ Treg function. Microbial activation of TLRs blocks the suppressive effect of $CD4^+$ $CD25^+$ Treg cells, allowing activation of pathogen-specific adaptive immune responses.[83] This block of suppressor activity is dependent in part on IL-6, which was induced by TLRs upon recognition of microbial products.

DCs and TLRs are also likely involved in the development of SLE. Ronnblom and Alm have demonstrated that immune complexes in lupus serum containing autoantibodies associated with apoptotic fragments of cells including DNA or RNA can stimulate plasmacytoid DCs (pDCs) to produce IFN-α with resultant autoimmune inflammation.[4,5] Such events can be mediated by TLRs,[84,85] pDCs express TLR9 that recognize CpG DNA[82]; thus, immune complexes in lupus serum containing CpG DNA and anti-DNA antibodies can stimulate pDC to produce IFN-α, which promotes autoimmunity (see Interferon-α and Autoimmunity). This notion is supported by two studies showing that murine B-cell hybridomas with specificity to rheumatoid factor or DNA activate B cells by engaging both IG receptors and TLR9.[86,87] A similar concept has been raised by recent studies demonstrating the role of TLR7 and TLR8 in cellular responses to single-strand RNA,[88,89] because antibodies against small nuclear RNA and protein complexes are often found in lupus patients.[84,85]

ENVIRONMENTAL FACTORS AND AUTOIMMUNITY

Drugs and Autoimmunity

Certain drugs can induce autoimmune diseases, with potentially protean clinical manifestations.[90] Among the best-known inducers of autoimmunity are procainamide and hydralazine, which can lead to drug-induced lupus in a minority of patients who take these agents. Although the exact mechanisms that promote procainamide- and hydralazine-induced lupus are not fully understood, recent studies suggest that alterations in DNA methylation, a process critically involved in gene regulation, by these drugs could be responsible for the development of lupus.[91,92] Procainamide and hydralazine can decrease DNA methylation in T cells, resulting in increased expression of genes, such as lymphocyte function-associated antigen, which can potentially promote autoimmunity.[93,94] Evidence from mice also suggests that procainamide may alter central (thymic) tolerance in T-cell selection, leading to escape of autoreactive T cells into the periphery.[95]

Interferon-α and Autoimmunity

Ironically, drugs that modulate the immune system, for example IFN-α, can also induce autoimmunity. In patients treated with IFN-α for hepatitis C or for malignancies, drug-induced lupus with nephritis and antineutrophil cytoplasmic antibodies–associated vasculitis have been reported.[84,85,90] In fact, the potential role of IFN-α in the pathogenesis of lupus was suggested in late 1970s by a study reporting increased serum levels of IFN-α in lupus patients.[96] This notion has been recently revived by several groups that have demonstrated increased expression of IFN-induced genes in peripheral blood cells from lupus patients, using microarray analyses.[97,98]

IFN-α can affect innate and adaptive immune cell function. Although it has antiproliferative effects on T cells,[99] at

the same time, it enhances IG isotype switching by stimulating DCs.[100] IFN-α also induces maturation of DCs and drives monocytes to become more effective in stimulating T cells, including those that are potentially autoreactive.[101–103] The results of studies in mice also provide evidence for a role of this cytokine in the development of lupus. Administration of poly(inosine-cytosine), a synthetic double-stranded RNA and strong IFN-α inducer, accelerated development of disease in lupus-prone (NZB x NZW)F_1 mice.[104] Lupus-prone mice lacking receptors for type I IFN, including IFN-α, had reduced anti-dsDNA antibodies and disease activity.[105]

Toxins and Autoimmunity

Environmental chemicals and toxins also have been reported as a potential cause for autoimmune diseases.[106] Probably the best-known chemical is crystalline silica, which has been reported to be associated with the development of systemic sclerosis.[106] In addition to this condition, there are patients with SLE and RA who were exposed to crystalline silica,[106] although such epidemiologic data is difficult to provide evidence for causation. On the other hand, lupus-prone (NZB x NZW)F_1 mice exposed to silica have increased levels of anti-nuclear antibodies, with decreased survival compared with mice not exposed to this chemical.[107] Although the exact mechanism for the development of autoimmune diseases after crystalline silica exposure is unknown, this chemical could serve as an adjuvant promoting immune responses with an increase in the production of pro-inflammatory cytokines such as TNF-α.[108] Although there are case reports of autoimmune diseases associated with the exposure to toxic chemicals as well as animals with autoimmune diseases aggravated by such chemicals, additional studies are needed to define the causal relationship between chemical exposure and autoimmunity.

Infections and Autoimmunity

Infection has been suggested as a possible causative factor for autoimmunity. Postulated mechanisms include: (1) release of inflammatory cytokines such as IFN-α by APCs that can modulate immune responses, (2) production of cross-reactive antibodies or T cells that can recognize both autoantigens and foreign antigens (molecular mimicry), and (3) polyclonal activation of autoreactive T cells by superantigens.[2] However, these possible mechanisms are not yet proven. Nevertheless, a variety of infectious organisms, including virus and bacteria, have been linked to autoimmune diseases,[109] including EBV as a trigger for SLE. The prevalence of EBV infection as determined by measuring anti-EBV antibodies is higher in patients with SLE compared with healthy controls,[110,111] and patients with SLE have increased EBV viral loads in peripheral blood and altered T-cell immune responses to EBV compared with healthy controls.[112] These findings suggest that the immune control of EBV is altered in SLE, although it is not clear whether such an alteration is the cause or the consequence of SLE. An intriguing question is why only a small fraction of individuals develop autoimmunity even though infections that may be associated with autoimmunity, such as EBV, are very common in the population. One likely answer is diversity in the genetic background among individuals, which can lead to different immune responses to the same infectious organisms and possible development of autoimmune diseases.

PATHOGENESIS OF TISSUE DAMAGE IN AUTOIMMUNITY

The mechanisms involved in tissue damages in autoimmune diseases are similar to those that are used in eradicating invading foreign organisms. Autoantibodies can directly bind to autoantigens that are expressed on cells, which results in destruction of cells (type II antibody-mediated hypersensitivity reaction).[2] Autoimmune hemolytic anemia and autoimmune thrombocytopenia, which can be seen in SLE, are good examples of cell destruction by this mechanism.[113] Some autoantibodies can bind autoantigens and activate the complement cascade, which leads to the recruitment of inflammatory cells and subsequent tissue damage (type III immune complex-mediated hypersensitivity reaction).[113] For instance, autoantibodies against chromatin and ribonucleoproteins appear to have a pathogenic role in lupus.[114] The deposition of immune complexes of these autoantibodies with their respective autoantigens in target organs, such as in the kidney, leads to activation of complement and Fc receptor binding with subsequent tissue injury.[115,116] Although autoreactive T cells are required for the development of autoimmune diseases and autoantibodies,[117,118] it is still unclear whether autoreactive T cells are directly involved in damaging tissues in systemic autoimmune syndromes such as SLE. Whereas, their role in directly promoting tissue injury in organ-specific autoimmune syndromes, such as type 1 DM and multiple sclerosis, are much better established.

Taken together, although the mechanisms for development of autoimmune diseases have not been fully dissected, the key impairment is a break in immune tolerance against self that leads to unregulated immune activation and tissue damages. Both genetic and environmental factors are accountable for this phenomenon by affecting various types of components in the immune system that include innate and adaptive immune cells, cytokines, and complement. A better understanding of the mechanisms that underlie the development of autoimmune diseases will be essential for developing specific treatments by selectively targeting the defect(s) in immune tolerance against self.

CHAPTER 156

Lupus Erythematosus

Melissa I. Costner
Richard D. Sontheimer

LUPUS ERYTHEMATOSUS: A CHALLENGE TO DEFINE AND TREAT

Lupus erythematosus (LE) is the root designation for a diverse array of illnesses that are linked together by the development of autoimmunity directed predominately at the molecular constituents of nucleosomes and ribonucleoproteins. Some patients present with life-threatening manifestations of systemic LE (SLE); whereas others, who are affected with what likely represents the same basic underlying disease process, express little more than discoid LE (DLE) skin lesions throughout their illness. It is convenient to conceptualize LE as a clinical spectrum ranging from mildly affected patients with only localized DLE skin lesions to those at risk of dying from the systemic manifestations of LE such as nephritis, central nervous system disease, or vasculitis. The pattern of skin involvement expressed by an individual patient with LE can provide insight about the position on the spectrum where the patient's illness might best be placed.

The nomenclature and classification system originally devised by James N. Gilliam divides the cutaneous manifestations of LE into those lesions that show characteristic histologic changes of LE (LE-specific skin disease) and those that are not histopathologically distinct for LE and/or may be seen as a feature of another disease process (LE–non-specific skin disease). The term *cutaneous LE* (CLE) is often used synonymously with "LE-specific skin disease" as an umbrella designation for the three major categories of LE-specific skin disease: acute cutaneous LE (ACLE), subacute cutaneous LE (SCLE), and chronic cutaneous LE (CCLE). This will be the framework used in our discussion of the extraordinarily diverse set of cutaneous lesions that occur in patients with LE (Table 156-1).

The essence of LE is in its heterogeneity, and the challenge for those who treat it is to recognize clinically useful patterns within the mosaic of features that constitute this protean illness. An overview of the systemic manifestations of LE can be seen in the American College of Rheumatology's (ACR) classification criteria for SLE,[1] which are presented in Table 156-2, and from the outline of the systemic manifestations of SLE presented in Table 156-3. It should be noted that a study to refine SLE criteria, including addressing definition of CLE, is ongoing.[2]

EPIDEMIOLOGY

The epidemiology and socioeconomic impact of LE in general,[3] and CLE specifically,[4] have been reviewed. Skin disease is the second most frequent clinical manifestation of LE after joint inflammation. As many as 45 percent of patients with CLE experience some degree of vocational handicap.

Malar, or butterfly rash (localized ACLE), has been reported in 20 percent to 60 percent of large cohorts of patients with LE. Limited data suggest that the maculopapular or SLE rash of generalized ACLE is present in about 35 percent to 60 percent of patients with SLE. ACLE, like SLE in general, is much more common in women than men (8:1). All races are affected; however, the early clinical manifestations of ACLE can be overlooked in a dark-skinned individual.

Patients presenting with SCLE lesions constitute 7 percent to 27 percent of LE patient populations. SCLE is primarily a disease of white females, with the mean age of onset in the fifth decade.

The most common form of CCLE, a classic DLE skin lesion, is present in 15 percent to 30 percent of SLE populations selected in various ways. Approximately 5 percent of patients presenting with isolated localized DLE subsequently develop SLE. It has been suggested that SLE is sevenfold more common than DLE. Although DLE can occur in infants and the elderly, it is most common in individuals between 20 and 40 years of age. DLE has a female-male ratio of 3:2 to 3:1, which is much lower than that of SLE. All races are affected, but investigations suggest that DLE might be more prevalent in blacks.

ETIOLOGY AND PATHOGENESIS

The cause(s) of and pathogenetic mechanisms responsible for LE-specific skin disease are not fully understood, although recent work has provided many new insights. The pathogenesis of LE-specific skin disease is inextricably intertwined with SLE pathogenesis. Simply put, SLE is a disorder in which the interplay between host factors (susceptibility genes, hormonal milieu, etc.) and environmental factors [ultraviolet (UV) radiation, viruses, drugs] leads to loss of self-tolerance, and induction of autoimmunity. This is followed by activation and expansion of the immune system, and eventuates in immunologic injury

LUPUS AT A GLANCE

- A group of heterogeneous illnesses that have in common the development of immunity to particles of self-DNA, with skin-only disease at one end of the spectrum and severe visceral involvement at the other.
- Skin lesions may be specific to lupus or non-specific and are be seen in other conditions as well.
- Acute cutaneous lupus erythematosus (malar rash) is almost always associated with underlying visceral involvement, subacute cutaneous lupus patients meet systemic lupus erythematosus criteria about 50 percent of the time, and chronic cutaneous lupus (discoid lupus erythematosus, lupus panniculitis, chilblain lupus, and tumid lupus erythematosus) patients most often have skin-only or skin-predominant disease.
- Discoid lupus erythematosus causes scarring and can be permanently disfiguring. Subacute cutaneous lupus and acute cutaneous lupus erythematosus are highly photosensitive and are characteristically non-scarring.
- Lupus erythematosus–non-specific skin lesions include non-scarring alopecia, mouth ulcers, photosensitivity, Raynaud phenomenon, and vasculitis/vasculopathy, among others. They often herald a systemic lupus erythematosus flare.
- Treatment consists of sunscreens, local and systemic (short-term) glucocorticoids, antimalarials, retinoids, immunosuppressives, thalidomide, and biologic therapies.
- Lupus erythematosus occurs much more commonly in women (9:1 female-male ratio).

TABLE 156-1
The Gilliam Classification of Skin Lesions Associated with Lupus Erythematosus

I. LE-specific skin disease [cutaneous LE (CLE)]
- A. Acute cutaneous LE (ACLE)
  - 1. Localized ACLE (malar rash; butterfly rash)
  - 2. Generalized ACLE (lupus maculopapular lupus rash, SLE rash, rash, photosensitive lupus dermatitis)
- B. Subacute cutaneous LE (SCLE)
  - 1. Annular SCLE (lupus marginatus, symmetric erythema centrifugum, autoimmune annular erythema, lupus erythematosus gyratus repens)
  - 2. Papulosquamous SCLE (disseminated DLE, subacute disseminated LE, superficial disseminated LE, psoriasiform LE, pityriasiform LE, and maculopapular photosensitive LE)
- C. Chronic cutaneous LE (CCLE)
  - 1. Classic discoid LE (DLE)
    - a. Localized DLE
    - b. Generalized DLE
  - 2. Hypertrophic/verrucous DLE
  - 3. Lupus profundus/lupus panniculitis
  - 4. Mucosal DLE
    - a. Oral DLE
    - b. Conjunctival DLE
  - 5. Lupus tumidus (urticarial plaque of LE)
  - 6. Chilblain LE (chilblain lupus)
  - 7. Lichenoid DLE (LE/lichen planus overlap, lupus planus)

II. LE–non-specific skin disease
- A. Cutaneous vascular disease
  - 1. Vasculitis
    - a. Leukocytoclastic
      - (1) Palpable purpura
      - (2) Urticarial vasculitis
    - b. Periarteritis nodosa–like cutaneous lesions
  - 2. Vasculopathy
    - a. Degos disease–like lesions
    - b. Secondary atrophie blanche (livedoid vasculitis, livedo vasculitis)
  - 3. Periungual telangiectasia
  - 4. Livedo reticularis
  - 5. Thrombophlebitis
  - 6. Raynaud phenomenon
  - 7. Erythromelalgia (erythermalgia)
- B. Non-scarring alopecia
  - 1. "Lupus hair"
  - 2. Telogen effluvium
  - 3. Alopecia areata
- C. Sclerodactyly
- D. Rheumatoid nodules
- E. Calcinosis cutis
- F. LE–non-specific bullous lesions
- G. Urticaria
- H. Papulonodular mucinosis
- I. Cutis laxa/anetoderma
- J. Acanthosis nigricans (type B insulin resistance)
- K. Erythema multiforme
- L. Leg ulcers
- M. Lichen planus

LE = lupus erythematosus; SLE = systemic lupus erythematosus.

to end organs and clinical expression of disease (Fig. 156-1).

Host Factors

SUSCEPTIBILITY GENES A genetic contribution to susceptibility to LE is supported by an increased sibling risk (as much as 20-fold) and by increased disease concordance in monozygotic twins. This heterogeneous disease is likely polygenic, with different genetic abnormalities predisposing to different clinical phenotypes of disease. This idea has been supported by Liu and Mohan,[5] whose congenic mouse model has suggested a multi-step process, in which LE is initiated by one gene and is further exacerbated by additional susceptibility loci or genes. For example, breach of immune tolerance to nuclear antigens mediated by the Sle1 gene appears to be essential for the development of lupus in the inbred New Zealand mouse. However, Sle1 by itself does not lead to the development of fatal lupus, rather only modest serologic autoreactivity. In contrast, Sle1 in epistasis with Sle3,5 or lpr genes mediates highly penetrant fatal glomerulonephritis.[5]

In humans, the genetic association between LE-specific skin disease and serologically determined major histocompatibility complex (MHC) class II DR specificities is well known. For example, patients with SCLE and overlapping features of Sjögren syndrome are more likely to have the HLA-DR3, DQA1*0501, DQB1*0502 haplotype. Significant increases of HLA-B7, -B8, -DR2, -DR3, and -DQA0102 and a significant decrease in HLA-A2 have been reported for patients with DLE. The combination of HLA-DR3, HLA-DQA0102, and HLA-B7 conferred the maximum relative risk (7.4) for DLE. Although there is a strong theoretical basis that MHC alleles can act as disease susceptibility genes by shaping the T-cell repertoire, it is also increasingly recognized that HLA class II alleles are more closely associated with specific autoantibody and clinical phenotypes of disease. In addition, genetic linkage studies in multiplex families have suggested that discoid LE skin lesions in African American SLE patients are linked to a candidate region at 11p13.[6]

Other susceptibility genes outside the MHC region that have been implicated. These include interleukin 1 (IL-1) receptor antagonist and tumor necrosis factor-α (TNF-α). Werth and colleagues[7] found a substantial increase in the prevalence of a promoter polymorphism of TNF-α (-308A) in patients with SCLE. Additionally, they found that there was a striking synergy between UVB and added IL-1α (a photo-induced cytokine) in the induction of transcription of the TNF-α -308A promoter.[7] This finding suggests that this polymorphism may directly contribute to the photosensitivity of patients with SCLE. An alternate explanation is that TNF-α may be a marker allele for the extended HLA-A01,B08, DRB1*0301 haplotype that is associated with a number of autoimmune conditions, including SCLE.[8]

Genetic deficiency of the early complement components C1q, C4, and to a lesser extent, C2 predispose patients to the development of lupus.[9] In fact, complete congenital deficiency of C1q is the strongest single genetic risk factor yet identified for the development of photosensitive SLE.[10]

SEX HORMONES One of the most striking clinical observations in SLE is the disease's female predilection. Indeed, there is a lifetime female-male ratio of 9:1. This sexually dimorphic prevalence is likely due to the effect of sex hormones on the immune system. High levels of estrogen and progesterone promote humoral autoreactivity. Patients with lupus metabolize estrogens differently and have up to a 20-fold increase in the fraction of high-potency to low-potency estrogens when compared with healthy controls. High levels of estrogen have been shown to cause patients with SLE to have an increase in (1) the number of self-reactive lymphocytes that bypass developmental deletion, (2) an increase in CD4/CD8 ratio (favoring humoral responsiveness), and (3) the number of B cells leaving the

TABLE 156-2
The 1982 Revised Criteria for Classification of Systemic Lupus Erythematosus[a]

CRITERION	DEFINITION
1. Malar rash	Fixed erythema, flat or raised, over the malar eminences, tending the spare the nasolabial folds
2. Discoid rash	Erythematous raised patches with adherent keratotic scaling and follicular plugging; atrophic scarring may occur in older lesions
3. Photosensitivity	Skin rash as a result of unusual reaction to sunlight, by patient history or physician observation
4. Oral ulcers	Oral or nasopharyngeal ulceration, usually painless, observed by a physician
5. Arthritis	Non-erosive arthritis involving two or more peripheral joints, characterized by tenderness, swelling, or effusion
6. Serositis	a. Pleuritis—convincing history of pleuritic pain or rub heard by a physician or evidence of pleural effusion *or* b. Pericarditis—documented by electrocardiogram or rub or evidence of pericardial effusion
7. Renal disorder	a. Persistent proteinuria— > 0.5 g/day or greater than 3+ if quantitation not performed *or* b. Cellular casts—may be red cell, hemoglobin, granular, tubular, or mixed
8. Neurologic disorder	a. Seizures—in the absence of offending drugs or known metabolic derangements (e.g., uremia, ketoacidosis, or electrolyte imbalance) *or* b. Psychosis—in the absence of offending drugs or known metabolic derangements (e.g., uremia, ketoacidosis, or electrolyte imbalance)
9. Hematologic disorder	a. Hemolytic anemia—with reticulocytosis *or* b. Leukopenia— < 4000 μL total on two or more occasions *or* c. Lymphopenia— < 1500/μL on two or more occasions *or* d. Thrombocytopenia— < 100,000 μL in the absence of offending drugs
10. Immunologic disorder	a. Anti-DNA—antibody to native DNA in abnormal titer *or* b. Anti-Sm—presence of antibody to Sm nuclear antigen *or* c. Positive finding of anti-phospholipid antibodies based on (1) an abnormal serum level of immunoglobulin G or immunoglobulin M anticardiolipin antibodies, (2) a positive test result for lupus anticoagulant using a standard method, or (3) a false-positive serologic test for syphilis known to be positive for at least 6 mo and confirmed by *Treponema pallidum* immobilization or fluorescent treponemal antibody absorption test
11. Anti-nuclear antibody	An abnormal titer of anti-nuclear antibody by immunofluorescence of an equivalent assay at any point in time and in the absence of drugs known to be associated with "drug-induced lupus" syndrome

[a]The proposed classification is based on 11 criteria. For the purpose of identifying patients in clinical studies, a person shall be said to have systemic lupus erythematosus if any 4 or more of the 11 criteria are present, serially or simultaneously, during any interval or observation.
From Tan EM et al: The 1982 revised criteria for the classification of systemic lupus erythematosus. *Arthritis Rheum* **25**:1271, 1982, copyright 1982, with permission of the American College of Rheumatology.

bone marrow that express high-affinity recognition of self-DNA.[11]

Androgens, on the other hand, shift the cytokine profile to that of a T helper 1 (Th1) cell-mediated immune response. Both males and females with SLE have decreased availability of testosterone, dihydrotestosterone, dehydroepiandrosterone (DHEA), and DHEA sulfate. Additionally, androgen-deficient males with Klinefelter syndrome have a higher incidence of Th2-driven autoimmune disease including SLE. These observations led investigators to study the use of exogenous DHEA for the treatment of SLE flares. Administration of 200 mg of DHEA for 7 to 12 months reduced corticosteroid requirements and the frequency of disease flares.[12] A controversy exists regarding the use of exogenous estrogens in patients with SLE. Oral contraceptives have been thought to produce disease flares. However, a large multicenter trial showed that estrogens are safe and do not cause worsening of SLE in both post- and pre-menopausal women.[13]

Higher prolactin levels are associated with the presence of high anti-DNA titers and an accelerated autoimmune disease course among females with SLE. Although high estrogen levels explain pregnancy-related increases in SLE disease severity, the continuation of the disease exacerbation into the postpartum period may be due to increased prolactin associated with lactation.

Environmental Factors

Genetic predisposition for a lupus diathesis does not, in itself, produce disease. Rather, it appears that induction of autoimmunity in such patients is triggered by some inciting event, likely an environmental exposure. Drugs, viruses, UV light, and, possibly, tobacco, have been shown to induce development of SLE.

ULTRAVIOLET RADIATION UV radiation (UVR) is probably the most important environmental factor in the induction phase of SLE and especially of LE-specific skin disease. Early studies demonstrated that CLE lesions could be provoked in the clinically normal skin of patients with both SLE and CLE by repeated delivery of high doses of UVB radiation to the same test site. More recent studies argue that UVA radiation can also induce CLE lesions.

UV light likely leads to self-immunity and loss of tolerance because it causes apoptosis of keratinocytes, which in turn, makes previously cryptic peptides available for immunosurveillance (see below under Apoptosis and Complement). UVB radiation has been shown to displace autoantigens such as Ro/SS-A and related autoantigens, La/SS-B, and calreticulin, from their normal locations inside epidermal keratinocytes to the cell surface.[14]

UV light causes an exaggerated release of immune mediators in patients with SLE. Recent work by Meller and colleagues[15] shows that UVB irradiation induces the release of CCL27 (cutaneous T cell-attracting chemokine), which upregulates the expression of chemokines that activate autoreactive T cells and interferon-α (IFN-α), producing dendritic cells (DCs), which likely play a central role in lupus pathogenesis (see Dendritic Cells and Interferon-α).[15] UV light may

TABLE 156-3
Overview of the Extracutaneous Manifestations of Systemic Lupus Erythematosus

- General
  - Fever, fatigue, malaise, weight loss
- Musculoskeletal
  - Symmetric small joint arthralgia, arthritis, (non-deforming and deforming), morning stiffness
  - Myalgia, myositis
  - Tendinitis
  - Avascular (aseptic) bone necrosis
- Hematologic
  - Anemia
    - Normocytic, normochromic
    - Hemolytic
  - Leukopenia
    - Lymphopenia
    - Granulocytopenia
  - Thrombocytopenia
- Cardiopulmonary
  - Pleurisy, pleural effusions, aseptic pneumonitis, pulmonary, hemorrhage
  - Pericarditis, tachycardia, cardiomegaly, congestive heart failure, arrhythmias, conduction defects, coronary arteritis, Libman-Sacks endocarditis
- Renal
  - Mesangial glomerulitis (WHO class II)
    - Mild proteinuria
  - Focal proliferative glomerulonephritis (WHO class III)
    - Proteinuria, hematuria, occasionally nephrotic syndrome, hypertension
  - Diffuse proliferative glomerulonephritis (WHO class IV)
    - Proteinuria, hematuria, red cell casts, renal insufficiency, nephrotic syndrome, hypertension
  - Membranous glomerulonephritis (WHO class V)
    - Severe proteinuria, nephrotic syndrome
- Neuro-psychiatric
  - Peripheral neuropathy, transverse myelitis, Guillain-Barré syndrome
  - Chorea, choreoathetosis
  - Seizures
  - Headaches (severe, migraine-like)
  - Brain infarcts secondary to cerebral arteritis
  - Organic brain syndrome
    - Psychosis due to diffuse cerebritis
  - Psychological
    - Depression
- Gastrointestinal
  - Anorexia, nausea, vomiting, abdominal pain
  - Bowel infarction/perforation secondary to mesenteric vasculitis
  - Pancreatitis
  - Peritonitis, ascites
  - Hepatomegaly, chronic active hepatitis
- Ocular
  - Conjunctivitis, episcleritis
  - Blindness secondary to central retinal artery occlusion
  - Cytoid bodies
  - Keratoconjunctivitis sicca
- Lymphatic system
  - Lymphadenopathy
  - Splenomegaly

◀ **FIGURE 156-1** Model of systemic lupus erythematosus pathogenesis. DCs = dendritic cells; TNF = tumor necrosis factor; UV = ultraviolet.

additionally have an early critical role in the induction phase by directly altering cellular DNA. UV light may affect immunoregulatory cells, which normally help suppress "abnormal" patterns of cutaneous inflammation.

TOBACCO EXPOSURE A recent, large, case-control study reported that smokers are at a greater risk of developing SLE than are nonsmokers and former smokers. Investigators suggest that this fact may be related to lipogenic aromatic amines, which are contained in tobacco smoke. Two abstracts from the Baltimore Lupus Cohort suggest an increased frequency of DLE in smokers, and several authors have shown that patients with LE-specific skin disease who smoke are less responsive to antimalarial treatment.[16,17,18]

DRUGS Numerous drugs have been implicated in inducing various features of SLE (see Drug-Induced Cutaneous Lupus Erythematosus). A mechanism for drug-induced LE by which the provocative agent induces T-cell DNA hypomethylation inducing altered repair of DNA has been proposed. A decrease in the amount of methylation of DNA correlates with increased biologic autoreactivity of lymphocytes. The drugs that induce CLE can be linked by their photosensitizing properties. It has been suggested that these drugs cause an increase in keratinocyte apoptosis, exposure of previously intracellular peptides on epidermal cell surfaces, and enhance pro-inflammatory cytokines such as TNF-α and IFN-α.[19]

VIRUSES There has been much speculation about the role of infectious agents, particularly viruses, in the induction of SLE and CLE. Infections of all types have long been known to exacerbate SLE. Infection by α viruses, such as Sindbis, rubella, and cytomegalovirus, appears able to induce cell surface expression of Ro/SS-A and related autoantigens in cells undergoing virus-induced apoptosis. Seroconversion to Epstein-Barr virus (EBV) among patients with SLE is nearly universal, and recent data have demonstrated that patients with SLE have defective control of latent EBV infection that probably stems from altered T-cell responses against EBV.[20]

Key Constituents in the Pathogenesis of Lupus

DENDRITIC CELLS AND INTERFERON-α DCs have a key role in antigen recognition and stimulation of the immune system. They perform a watchdog-like role in all peripheral tissues in an immature state. Immature DCs are essential to the maintenance of peripheral tolerance to self-antigens. They constantly sample their environment, capture self-antigens released in normal tissue turnover (apoptosis), and in the absence of inflammation, primarily act as housekeepers, keeping self-antigens in check. In the company of inflammation or microbes, they mature and move to draining lymph nodes, where they present antigen to T cells via MHCs. With appropriate co-stimulatory molecules, T- and B-cell activation ensues, with subsequent launching of an adaptive immune response.[21]

DCs develop from precursor monocytes and have two different lineages, myeloid DCs, which then differentiate into immature and mature DCs and plasmacytoid DCs. Plasmacytoid DCs are found in lymphoid organs, such as bone marrow, spleen, tonsils, and lymph nodes, and are noteworthy for producing large amounts of IFN-α in response to many viruses and certain bacteria. They have recently been found to infiltrate LE-specific skin lesions as well. IFN-α causes monocytes to differentiate into myeloid DCs, which are able to capture circulating apoptotic cells. These can then present self-antigens to autoreactive CD4 T cells and also support B-cell proliferation and differentiation, leading to the clinical expression of LE.[22]

Recent findings place IFN-α at the center of immunologic abnormalities observed in SLE, and suggest that IFN-α and IFN-α–producing cells are novel potential therapeutic targets. It is well established that levels of IFN-α are increased in the serum of SLE patients, and recombinant IFN-α, when administered as a therapy to patients with malignancy or hepatitis infection, can induce SLE, and even neonatal lupus in one case.[23,24]

More recently, several important studies using microarray data, have revealed a genomic "signature" of upregulated IFN-α–inducible genes from peripheral blood mononuclear cells of SLE patients, as well as from lesions of LE-specific skin disease.[25] Additionally, it has been shown that IFN-α increases as patients' disease flares. Recent studies have shown that local production of type I IFNs in CLE induces Th1-biased inflammation via induction of IFN-inducible chemokines, with recruitment of pathogenic T lymphocytes into the skin.[26] In short, there has been convergence of data from several studies, leading to the suggestion that IFN-α plays a central role in the pathogenesis of lupus.

It seems that LE patients produce IFN-α in an unabated fashion, either as a consequence of complex genetic alterations or because of a persistent stimulus such as a virus. Regardless of the mechanisms leading to its excess, IFN-α turns on the adaptive immune system through the activation of myeloid DCs, leading to a break of tolerance to self-antigens and activation of autoreactive T and B cells.

TOLL-LIKE RECEPTORS Toll-like receptors (TLRs) are important in innate immunity and have a potent microorganism-sensing capacity. They do so by recognizing bacterial DNA (unmethylated cytosine and guanosine dinucleotides sequence motifs). It appears that circulating DNA/anti-DNA complexes trigger TLR signaling, which then induces (1) proliferation of autoreactive B cells, and (2) IFN-α secretion from DCs. Lupus mice that lack TLR9 do not produce double-stranded DNA (dsDNA) antibodies. Thus, blocking the TLRs may have therapeutic implications in lupus.

APOPTOSIS AND COMPLEMENT In SLE, the rate of in vitro apoptosis of peripheral blood mononuclear cells is increased. In CLE, there is an additional abundance of apoptotic keratinocytes, especially in response to UVR.[27] Regulated cell death is accomplished by endonuclease degradation of DNA, whereby apoptotic cells remain intact while they are dying. If clearance of apoptotic material is not expeditious, apoptotic cells become necrotic, with dissolution of the cellular membrane and release of previously sequestered intracellular contents (e.g., ribonucleoproteins, dsDNA, and Ro/SS-A antigens). Patients with lupus have dysregulation of both apoptosis and apoptotic cell clearance. Normally, complement proteins bind to apoptotic cells, which are then disposed of by "housekeeping" macrophages. When complement proteins are deficient (a common characteristic of patients with lupus) and are not present on apoptotic cells, the apoptotic cells are then recognized by DCs that are able to stimulate the adaptive immune response, rather than housekeeping macrophages. These DCs subsequently process the apoptotic cells and present antigens, which leads to a break in self-tolerance followed by activation of the immune cascade.[28]

TUMOR NECROSIS FACTOR-α TNF is likely involved in the pathogenesis of cutaneous lupus. TNF induces apoptosis

through the FAS-associated death domain. TNF has been shown to be elucidated by keratinocytes exposed to UVR. It induces HLA-DR expression on keratinocytes and causes stimulation of an adaptive immune response. It also stimulates release of nuclear factor κB, which causes upregulation of pro-inflammatory adhesion molecules. TNF is produced in large amounts by epidermal keratinocytes in patients with SCLE.[29] It stands to reason that inhibition of TNF likely will help cutaneous lupus.

However, there have also been several reports of the development or worsening of cutaneous lupus while on anti-TNF therapy; and the development of dsDNA antibodies and lupus-like syndromes is well described with drugs such as etanercept and infliximab. Banchereau and colleagues have shown that TNF regulates IFN-α production in vitro by inhibiting the generation of plasmacytoid DCs.[30] As mentioned above under Dendritic Cells and Interferon-α, overexpression of IFN-α is thought to be a key event in immune dysregulation in lupus. Thus, too much TNF may induce lesions of cutaneous lupus, whereas not enough may do the same and may even lead to unmasking of SLE or the development of a drug-induced lupus-like illness.

T CELLS T cells play a key role in both the induction and expansion phases in the development of SLE. T cells are involved in the development of both central and peripheral tolerance. Self-antigens are presented by DCs to autoreactive T cells. Binding of the surface signaling molecules, such as the T-cell receptor, to their ligands leads to T-cell activation. In SLE, and in CLE, T cells display markers of increased activation, increased numbers of DR^+ antigens.[31,32] T cells also provide cognate help to autoreactive B cells, leading to production of autoantibodies. For example, SLE patients demonstrate increased production of T-cell–dependent immunoglobulin G (IgG) anti-dsDNA antibodies. Last, T cells facilitate tissue damage in end organs, and may be of particular importance in CLE. Recent investigations have highlighted the relevance of cytotoxic lymphocytes in tissue damage in SLE, including in CLE. One group of authors found that scarring skin lesions of DLE are characterized by high numbers of skin-homing cytotoxic lymphocytes associated with expression the IFN-α–induced protein MxA.[32]

B CELLS B cells are involved in the expansion phase of LE pathogenesis, in that they can present antigen to autoreactive T cells and further amplify T-cell activation. The production by B cells of autoantibodies against nuclear antigens is the hallmark of SLE.[33] Several of these autoantibodies are thought to be directly pathogenic, including dsDNA and Ro/SS-A antibodies. Such autoantibodies likely play a direct role in the injury phase of LE. They form immune complexes, which may cause tissue damage by means that include direct cell death, cellular activation, opsonization, and the blocking of target molecule function. B cells may not be as important in CLE as they are in other manifestations of the disease, as supported by the suggestion that anti–B-cell therapies such as Rituximab are less effective for CLE.

Clearly, there are several key constituents involved in the pathogenesis of LE. The sheer number of potential players in disease development is one the main reasons for the highly variable expression of the disease. Recent data uncovering convergence points (i.e., IFN-α) in the pathogenetic expression of disease have already led to early development of new drugs for LE. Additionally, the complexity of the pathogenesis of LE suggests that multiple pharmacotherapeutics (a layering of drugs with different pathomechanisms) may be required to treat patients with recalcitrant disease.

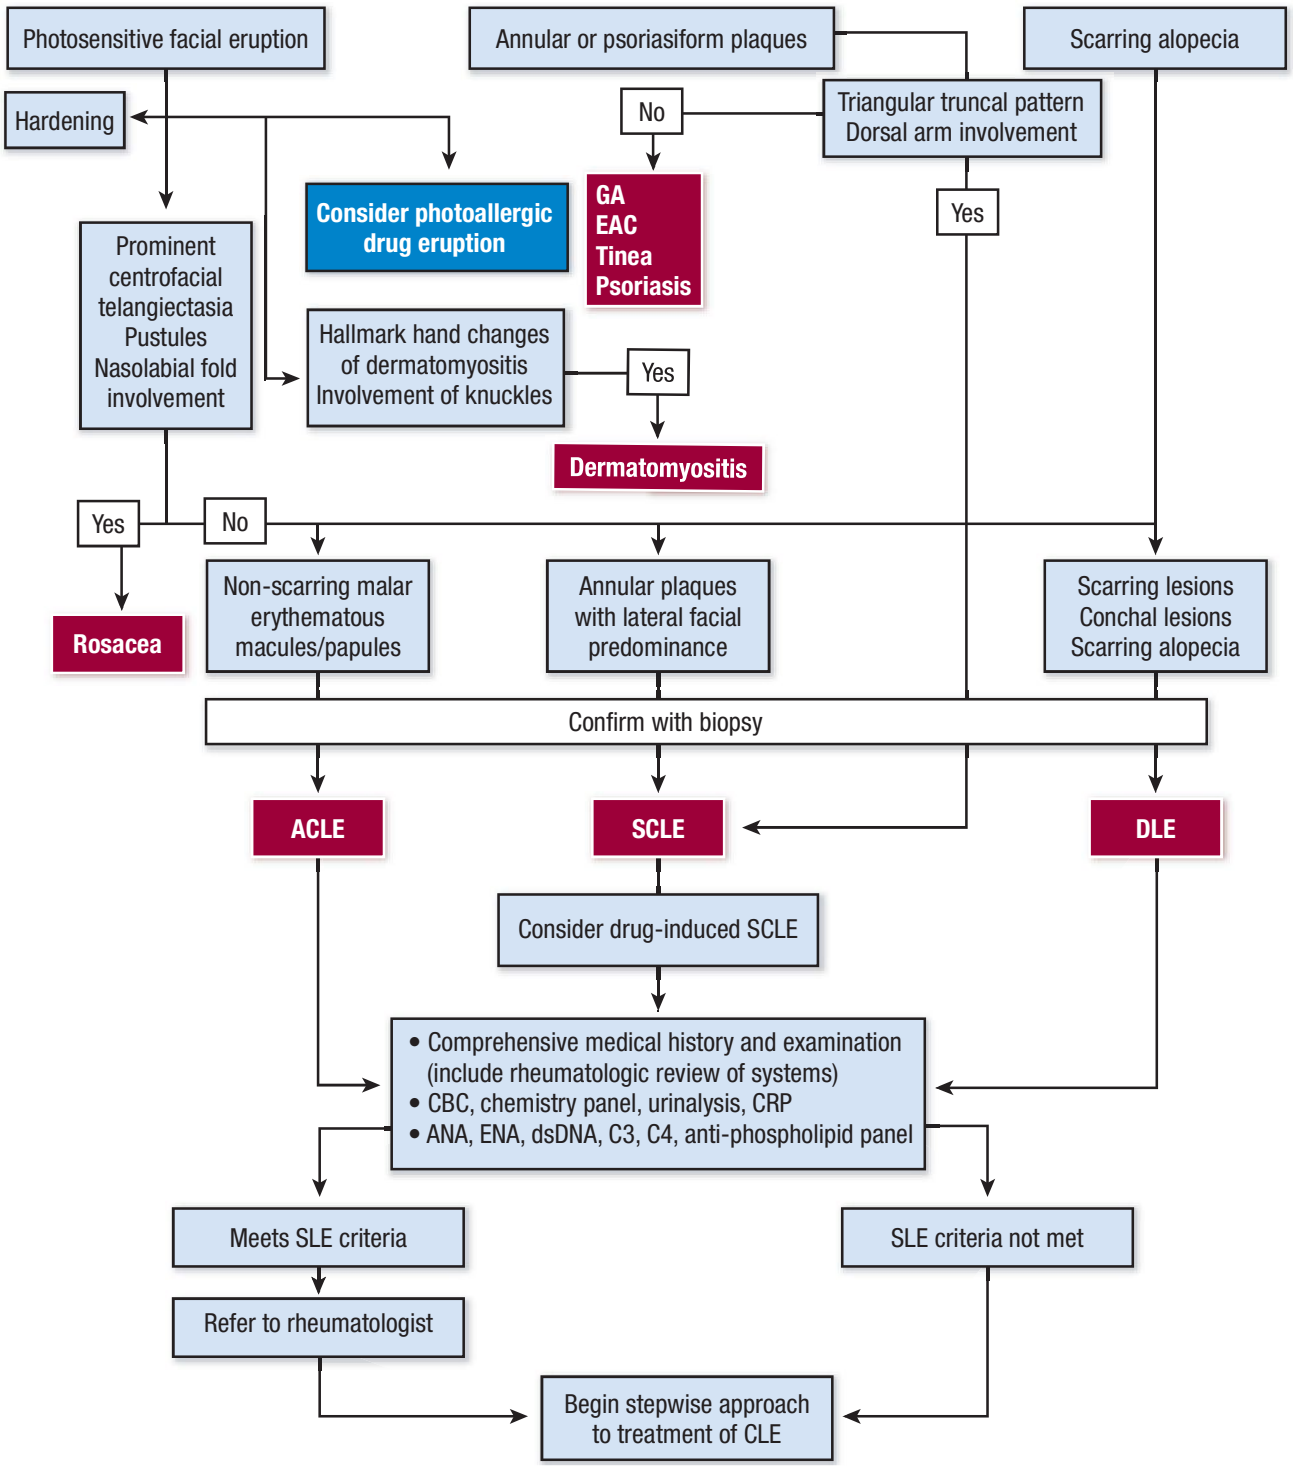
CLINICAL FINDINGS (Fig. 156-2)

Cutaneous Lesions

Table 156-4 compares the key clinical, histopathologic, and laboratory features of patients presenting with ACLE, SCLE, and CCLE (classic DLE) skin lesions. It is important to distinguish among the subtypes of LE-specific skin disease, because the type of skin involvement in LE can reflect the underlying pattern of SLE activity. In fact, the designations acute, subacute, and chronic, in regard to CLE, refer to the pace and severity of any associated SLE and are not necessarily related to how long individual lesions have been present. For example, ACLE almost always occurs in the setting of acutely flaring SLE, whereas CCLE often occurs in the absence of SLE or in the presence of mild smoldering SLE. SCLE occupies an intermediate position in this clinical spectrum. Subclassification, although important for assigning risk, is sometimes difficult, as it is not uncommon to see more than one sub-type of LE-specific skin disease in the same patient, especially in patients with SLE.

ACUTE CUTANEOUS LUPUS ERYTHEMATOSUS Although ACLE localized to the face is the usual pattern of presentation, ACLE can assume a generalized distribution. Localized ACLE has commonly been referred to as the *classic butterfly rash* or *malar rash of SLE* (Fig. 156-3). In localized ACLE, confluent symmetric erythema and edema are centered over the malar eminences and bridges over the nose (unilateral involvement with ACLE has been described). The nasolabial folds are characteristically spared. The forehead, chin, and V area of the neck can be involved, and severe facial swelling may occur. Occasionally, ACLE begins as small macules and/or papules on the face that later may become confluent and hyperkeratotic. Generalized ACLE presents as a widespread morbilliform or exanthematous eruption often focused over the extensor aspects of the arms and hands and characteristically sparing the knuckles (Fig. 156-4A). Although perivascular nail fold erythema and telangiectasia can occur (see Fig. 156-4B), they are considerably more common and occur in more exaggerated forms in dermatomyositis (see Fig. 157-5). Generalized ACLE has been indiscriminately referred to as the *maculopapular rash of SLE*, *photosensitive lupus dermatitis*, and *SLE rash*. An extremely acute form of ACLE is rarely seen that can simulate toxic epidermal necrolysis (TEN). This form of LE-specific vesiculobullous disease results from widespread apoptosis of epidermal keratinocytes, and eventuates in areas of full-thickness epidermal skin necrosis, which is subsequently denuded. It can be differentiated between true TEN because it occurs on predominantly sun-exposed skin and has a more insidious onset.[34] Mucosa may or may not be involved, as in TEN.

ACLE is typically precipitated or exacerbated by exposure to UV light. This form of CLE can be quite ephemeral, lasting only hours, days, or weeks; however, some patients experience more prolonged periods of activity. Post-inflammatory pigmentary change is most prominent in patients with heavily pigmented skin. Scarring does not occur in ACLE unless the process is complicated by secondary bacterial infection. ACLE occasionally occurs in conjunction with SCLE; however, the simultaneous occurrence of ACLE and active DLE is unusual. Both localized and generalized ACLE wax and wane in par-



▲ **FIGURE 156-2** Approach to the patient with skin lesions suspicious for cutaneous lupus erythematosus. ACLE = acute cutaneous lupus erythematosus; ANA = anti-nuclear antibody; CBC = complete blood cell count; CLE = cutaneous lupus erythematosus; CRP = C-reactive protein; DLE = discoid lupus erythematosus; dsDNA = doubled-stranded DNA; EAC = erythema annulare centrifugum; ENA = extractable nuclear antibody; GA = granuloma annulare; SCLE = subacute cutaneous lupus erythematosus; SLE = systemic lupus erythematosus.

allel with underlying SLE disease activity, including LE nephritis.

SUBACUTE CUTANEOUS LUPUS ERYTHEMATOSUS A number of names have been used to describe SCLE skin lesions: *symmetric erythema centrifugum*; *disseminated DLE*; *autoimmune annular erythema*; *subacute disseminated LE*; *superficial disseminated LE*; *psoriasiform LE*; *pityriasiform LE*; *maculopapular photosensitive LE*; and *lupus erythematosus gyratum repens*. A disease presentation dominated by SCLE lesions marks the presence of a distinct subset of LE having characteristic clinical, serologic, and genetic features. Although a finding of circulating autoantibodies to the Ro/SS-A ribonucleoprotein particle strongly supports a diagnosis of SCLE, the presence of this autoantibody specificity is not required to make a diagnosis of SCLE.

SCLE initially presents as erythematous macules and/or papules that evolve

TABLE 156-4
Comparison of the Major Types of Lupus Erythematosus–Specific Skin Disease

Disease Features	ACLE	SCLE	Classic DLE
Clinical features of skin lesions			
Induration	0	0	+++
Dermal atrophy	0	0	+++
Pigment changes	+	++	+++
Follicular plugging	0	0	+++
Hyperkeratosis	+	++	+++

into hyperkeratotic papulosquamous or annular/polycyclic plaques (Fig. 156-5). Whereas most patients have either annular or papulosquamous SCLE, a few develop elements of both morphologic varieties. SCLE lesions are characteristically photosensitive and occur in predominantly sun-exposed areas (i.e., upper back, shoulders, extensor aspects of the arms, V area of the neck, and, less commonly, the face). SCLE lesions typically heal without scarring but can resolve with long-lasting, if not permanent, vitiligo-like leukoderma and telangiectasias.

Several variants of SCLE have been described. On occasion, SCLE lesions present initially with an appearance of erythema multiforme (see Chap. 38). Such cases are similar to Rowell syndrome (erythema multiforme–like lesions occurring in patients with SLE in the presence of La/SS-B autoantibodies). As a result of intense injury to epidermal basal cells, the active edge of an annular SCLE lesion occasionally undergoes a vesiculobullous change that can subsequently produce a strikingly crusted appearance. Such lesions can mimic Stevens-Johnson syndrome/TEN (see Chap. 39). Pathogenesis is similar to that described above for TEN-like ACLE.[34] Rarely, SCLE presents with exfoliative erythroderma or displays a curious acral distribution of annular lesions. Pityriasiform and exanthematous variants of SCLE have been reported. The skin lesions of neonatal LE (transient, photosensitive, non-scarring LE-specific skin lesions in neonates who have received IgG anti-Ro/SS-A, and, occasionally, other autoantibody specificities transplacentally) share many features with SCLE.

Between 15 percent and 20 percent of patients with SCLE lesions may also develop ACLE or classic DLE at some point. ACLE skin lesions tend to be more transient than SCLE lesions and heal with less pigmentary change. They are also more edematous and less hyperkeratotic than SCLE lesions. ACLE more commonly affects the malar areas of the face, whereas SCLE focuses more on the neck, shoulders, upper extremities, and trunk. When the face is involved, it is most often the lateral face, with sparing of the central, malar regions. DLE lesions occurring in the context of SCLE are generally associated with a greater degree of hyper- and hypopigmentation, atrophic dermal scarring, follicular plugging, and adherent

▲ **FIGURE 156-3** Localized acute cutaneous lupus erythematosus. Erythematous, slightly edematous, sharply demarcated erythema is seen on the malar areas in a "butterfly" distribution.

▲ **FIGURE 156-4** Generalized acute cutaneous lupus erythematosus. **A.** Well-demarcated patches of erythema with fine overlying scale on the dorsal aspect of the hands, fingers, and periungual areas. Note the characteristic sparing of the knuckles, which are preferentially involved in dermatomyositis. **B.** Close-up view of periungual erythema and grossly visible telangiectasia. Although these lesions can be seen in lupus erythematosus, they are more typical of dermatomyositis.

▲ **FIGURE 156-5** Subacute cutaneous lupus erythematosus (SCLE). **A.** Annular SCLE on the upper back of a 38-year-old woman. Note the central areas of hypopigmentation in which no dermal atrophy is present. **B.** Papulosquamous SCLE over the extensor aspect of the forearm of a 26-year-old woman.

scale. A consistent clinical difference is that DLE lesions are characteristically indurated, whereas SCLE lesions are not; this difference reflects the greater depth of inflammation seen histopathologically in DLE lesions.

Approximately one-half of patients with SCLE meet the ACR's revised criteria for the classification of SLE. However, manifestations of severe SLE, such as nephritis, central nervous system disease, and systemic vasculitis, develop in only 10 percent to 15 percent of patients with SCLE. It has been suggested that the papulosquamous type of SCLE, leukopenia, high titer of anti-nuclear antibody (ANA) (> 1:640), and anti-dsDNA antibodies are risk factors for the development of SLE in a patient presenting with SCLE lesions.

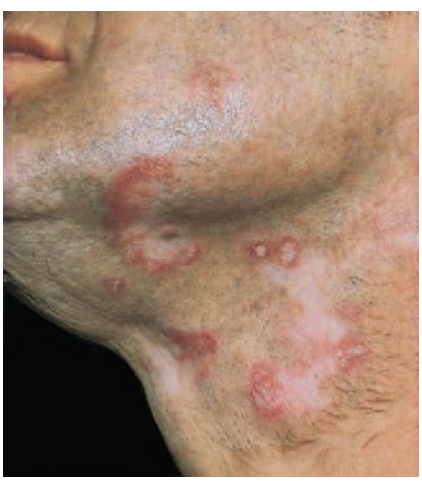
SCLE can overlap with other autoimmune diseases, including Sjögren syndrome, rheumatoid arthritis, and Hashimoto thyroiditis. Other disorders that have been anecdotally related to SCLE are Sweet syndrome, porphyria cutanea tarda, gluten-sensitive enteropathy, and Crohn disease. There has also been the suggestion that SCLE can be associated with internal malignancy (breast, lung, gastric, uterine, hepatocellular, and laryngeal carcinomas) as well as with Hodgkin lymphoma.[35]

CHRONIC CUTANEOUS LUPUS ERYTHEMATOSUS Classic DLE lesions, the most common form of CCLE, begin as red-purple macules, papules, or small plaques and rapidly develop a hyperkeratotic surface. Early classic DLE lesions typically evolve into sharply demarcated, coin-shaped (i.e., discoid) erythematous plaques covered by a prominent, adherent scale that extends into the orifices of dilated hair follicles (Fig. 156-6).

DLE lesions typically expand with erythema and hyperpigmentation at the periphery, leaving hallmark atrophic central scarring, telangiectasia, and hypopigmentation (Fig. 156-7). DLE lesions at this stage can merge to form large, confluent, disfiguring plaques. DLE in persons of certain ethnic backgrounds, such as Asian Indians, can present clinically as isolated areas of macular hyperpigmentation. When present on hair-bearing skin (scalp, eyelid margins, eyebrows), DLE causes scarring alopecia, which can lead to disfigurement and markedly impact quality of life. Follicular involvement in DLE is a prominent feature. Keratotic plugs accumulate in dilated follicles that soon become devoid of hair. When the adherent scale is lifted from more advanced lesions, keratotic spikes similar in appearance to carpet tacks can be seen to project from the undersurface of the scale (i.e., the "carpet tack" sign). DLE lesions can be difficult to diagnose in Caucasian patients because the characteristic peripheral hyperpigmentation is often absent. Such lesions are often confused with actinic keratoses, squamous cell carcinoma, or acne.

DLE lesions are most frequently encountered on the face, scalp, ears, V area of the neck, and extensor aspects of the arms. Any area of the face, including the eyebrows, eyelids, nose, and lips, can be affected. A symmetric, hyperkeratotic, butterfly-shaped DLE plaque is occasionally found over the malar areas of the face and bridge of the nose. Such le-

▲ **FIGURE 156-6** Classic discoid lupus erythematosus. Typical early erythematous plaque on the forehead demonstrating hyperkeratosis and accentuation of follicle orifices in a 60-year-old man with a 25-year history of cutaneous lupus erythematosus. The lesion had been present for 3 months; no dermal atrophy was present at this stage.



▲ **FIGURE 156-7** Classic discoid lupus erythematosus. Sharply demarcated, round-to-ovoid, slightly indurated, erythematous plaques on the neck and face. Most plaques show a mild degree of hyperkeratosis, and some show dermal atrophy. Noninflamed areas of hypopigmentation and scarring mark the sites of prior lesions that have resolved.

sions should not be confused with the more transient, edematous, minimally scaling ACLE erythema reactions that occur in the same areas. Facial DLE, like ACLE and SCLE, usually spares the nasolabial folds. It may be difficult to distinguish early lesions of malar DLE from ACLE, but induration and recalcitrance to topical steroids/calcineurin inhibitors favors the former diagnosis. When DLE lesions occur periorally, they resolve with a striking acneiform pattern of pitted scarring. DLE characteristically affects the external ear, including the outer portion of the external auditory canal (Fig. 156-8A). Such lesions often present initially as dilated, hyperpigmented follicles. The scalp is involved in 60 percent of patients with DLE; irreversible, scarring alopecia resulting from such involvement has been reported in one-third of patients (see Fig. 156-8B). The irreversible, scarring alopecia resulting from DLE differs from the reversible, non-scarring alopecia that patients with SLE often develop during periods of systemic disease activity. This type of hair loss, so-called *lupus hair*, may be telogen effluvium occurring as the result of flaring systemic disease.

Localized DLE lesions occur only on the head or neck, whereas generalized DLE lesions occur both above and below the neck. DLE lesions below the neck most commonly occur on the extensor aspects of the arms, forearms, and hands, although they can occur at virtually any site on the body. The palms and soles can be the sites of painful, and at times disabling, erosive DLE lesions. On occasion, small DLE lesions occurring only around follicular orifices appear at the elbow and elsewhere (follicular DLE). We have observed that elbow/extensor arm lesions seem to co-occur with acral finger lesions of DLE, and that patients with this combination of findings more frequently have active systemic disease. DLE activity can localize to the nail unit. The nail can be impacted by other forms of CLE as well as SLE, producing nail fold erythema and telangiectasia, red lunulae, clubbing, paronychia, pitting, leukonychia striata, and onycholysis.

DLE lesions can be potentiated by sunlight exposure but to a lesser extent than ACLE and SCLE lesions. DLE, as well as other forms of LE skin disease activity, can be precipitated by any form of cutaneous trauma (i.e., the Koebner phenomenon or isomorphic effect).

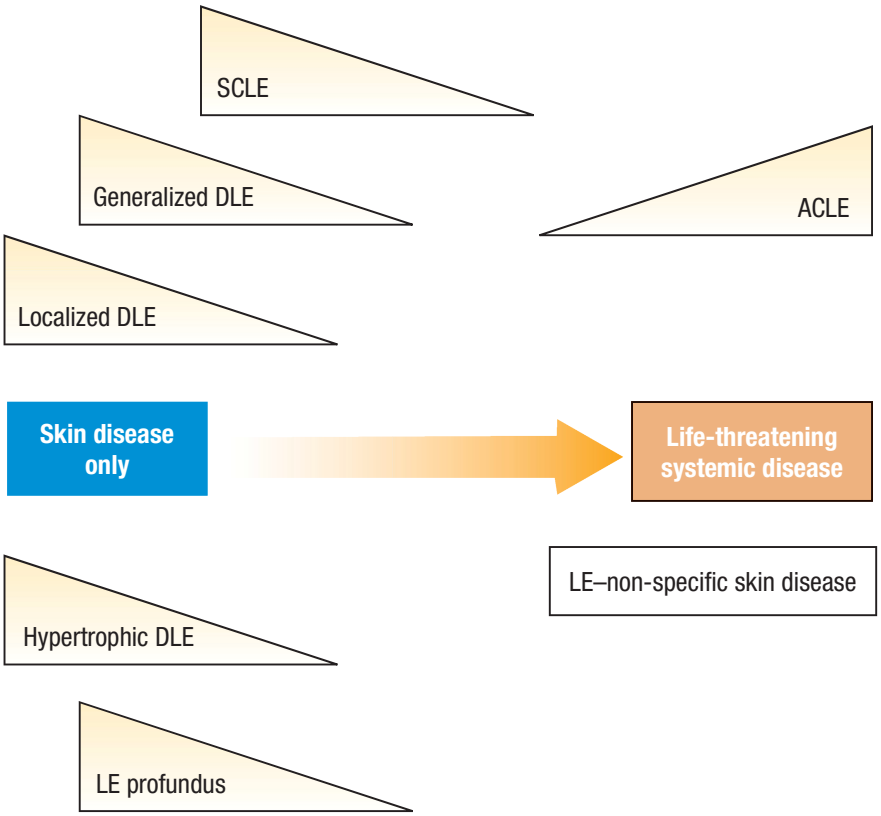
The relationship between classic DLE and SLE has been the subject of much debate.[5] The following summary points can be made: (1) 5 percent of patients presenting with classic DLE lesions subsequently develop unequivocal evidence of SLE; and (2) patients with generalized DLE (i.e., lesions both above and below the neck) have somewhat higher rates of immunologic abnormalities, a higher risk for progressing to SLE, and a higher risk for developing more severe manifestations of SLE than patients with localized DLE.

▲ **FIGURE 156-8** Classic discoid lupus erythematosus (DLE) and mucosal DLE in a 45-year-old African American woman with a 20-year history of untreated cutaneous lupus erythematosus. **A.** Characteristic involvement of the ear shows lesions with atrophy and post-inflammatory hyperpigmentation as well as inflammatory red plaques on the scalp with post-inflammatory hypopigmentation. **B.** Confluent lesions on the scalp have resulted in extensive scarring alopecia. **C.** Plaques of DLE on the palatal mucosa showing morphologic features similar to those of cutaneous lesions.

The following have been suggested as risk factors for the development of SLE in patients with DLE: generalized lymphadenopathy; SCLE/ACLE skin lesions; LE–non-specific skin lesions such as vasculitis, diffuse non-scarring alopecia, periungual nail fold telangiectasia, Raynaud phenomenon; unexplained anemia; marked leukopenia; false-positive tests for syphilis; persistently positive high-titer ANA assay; anti–single-stranded DNA antibody; hypergammaglobulinemia; an elevated erythrocyte sedimentation rate (especially > 50 mm/hour); positive, sun-protected, non-lesional lupus band test (LBT) and elevated levels of soluble IL-2 receptor.

Roughly one-fourth of patients with SLE develop DLE lesions at some point in the course of their disease, and such patients tend to have less severe forms of SLE. Fig. 156-9 illustrates the relative risks for systemic disease activity that are associated with the clinical varieties of LE-specific skin disease.

Hypertrophic DLE, also referred to as *hyperkeratotic* or *verrucous DLE*, is a rare variant of CCLE in which the hyperkeratosis normally found in classic DLE lesions is greatly exaggerated. The extensor aspects of the arms, the upper back, and the face are the areas most frequently affected. Overlapping features of hypertrophic LE and lichen planus have been described under the rubric *lupus planus*. The entity *lupus erythematosus hypertrophicus et profundus* appears to represent a rare form of hypertrophic DLE, affecting the face with the additional features of violaceous/dull red, indurated, rolled borders and striking central, crateriform atrophy. The name for this clinical entity is ambiguous because LE panniculitis is not characteristic of its histopathology. Patients with hyper-



▲ **FIGURE 156-9** Relative risk for co-existence of or progression to systemic lupus erythematosus in patients presenting with various forms of lupus erythematosus (LE)–specific skin disease. The spectrum of LE is depicted as a disease continuum ranging from skin disease alone to life-threatening systemic disease. ACLE = acute cutaneous lupus erythematosus; DLE = discoid lupus erythematosus; SCLE = subacute cutaneous lupus erythematosus.

trophic DLE probably do not have a greater risk for developing SLE than do patients with classic DLE lesions.

Patients with DLE in a linear configuration following Blaschko's lines have been described. This rare sub-type of DLE appears most frequently in children and seems to be associated with a low incidence of associated SLE.[36]

Mucosal DLE occurs in approximately 25 percent of patients with CCLE. The oral mucosa is most frequently affected; however, nasal, conjunctival, and genital mucosal surfaces can be targeted. In the mouth, the buccal mucosal surfaces are most commonly involved, with the palate (see Fig. 156-8C), alveolar processes, and tongue being sites of less frequent involvement. Lesions begin as painless, erythematous patches that evolve to chronic plaques that can be confused with lichen planus. Chronic buccal mucosal plaques are sharply marginated and have irregularly scalloped, white borders with radiating white striae and telangiectasia. The surfaces of these plaques overlying the palatal mucosa often have a honeycomb appearance. Central depression often occurs in older lesions, and painful ulceration can develop. Rarely, oral mucosal DLE lesions can degenerate into squamous cell carcinoma, similar to long-standing cutaneous DLE lesions. Any degree of nodular asymmetry within a mucosal DLE lesion should be evaluated for the possibility of malignant degeneration. Chronic DLE plaques also appear on the vermilion border of the lips. At times, DLE involvement of the lips can present as a diffuse cheilitis, especially on the more sun-exposed lower lip.

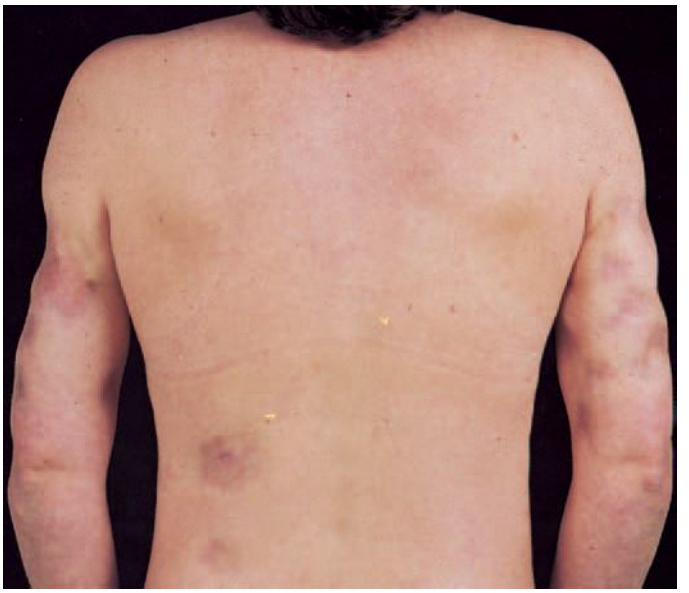
DLE lesions may present on the nasal, conjunctival, and anogenital mucosa. Perforation of the nasal septum is more often associated with SLE than DLE. Conjunctival DLE lesions affect the lower lid more often than the upper lid. Lesions begin as focal areas of nondescript inflammation most commonly affecting the palpebral conjunctivae or the lid margin. Scarring becomes evident as lesions mature, and the permanent loss of eyelashes and ectropion can develop, producing considerable disability.

The risk for systemic disease activity in patients with LE and mucosal involvement is a function of the type of mucosal lesion present. Chronic mucosal DLE plaques are seen most commonly in patients with LE who do not have life-threatening manifestations of SLE. However, transient superficial oral or nasal mucosal ulcerations with a relatively non-specific histopathology occur in patients with active SLE. Mucosal lesions of this type represent one of the 11 revised ACR classification criteria for SLE.

DRUG-INDUCED CUTANEOUS LUPUS ERYTHEMATOSUS Drug-induced lupus shares symptoms and laboratory characteristics with idiopathic SLE, and numerous drugs have been implicated in inducing various features of SLE [e.g., procainamide, hydralazine, isoniazid, chlorpromazine, phenytoin, minocycline, and most recently, anti-TNF medications].[37] Classic drug-induced SLE is associated with antihistone antibodies and manifests similarly to SLE but without cutaneous involvement.

Drugs can also induce or exacerbate lupus-specific skin lesions. Drug-induced SCLE has been convincingly associated with exposure to hydrochlorothiazide, calcium channel blockers, angiotensin-converting enzyme inhibitors, and cinnarizine. Recently, there have been accounts of patients with terbinafine-induced SCLE. Other drugs reported to precipitate SCLE include piroxicam, D-penicillamine, sulfonylureas, oxprenolol, parenteral gold therapy, griseofulvin, naproxen, spironolactone, IFN-β, ranitidine, efalizumab, propylthiouracil, carbamazepine, systemic 5-fluorouracil, lansoprazole, bupropion, acebutolol, and tiotropium inhaled. Both SCLE and DLE skin lesions have been induced in patients on anti-TNF therapy.[30,38] SCLE has recently been reported with use of leflunomide for rheumatoid arthritis.[39]

LESS COMMON SUB-TYPES OF LUPUS ERYTHEMATOSUS–SPECIFIC SKIN DISEASE LE profundus/LE panniculitis (Kaposi-Irgang disease) is a rare form of CCLE typified by inflammatory lesions in the lower dermis and subcutaneous tissue. Approximately 70 percent of patients with this type of CCLE also have typical DLE lesions, often overlying the panniculitis lesions. Some have used the term *LE profundus* to designate those patients who have both LE panniculitis and DLE lesions, and *LE panniculitis* to refer to those having only subcutaneous involvement. Typical subcutaneous lesions present as firm nodules, 1 to 3 cm in diameter. The overlying skin often becomes attached to the subcutaneous nodules and is drawn



▲ **FIGURE 156-10** Lupus erythematosus panniculitis. Lupus panniculitis has resulted in large, sunken areas of overlying skin; erythema and atrophy of the skin are present.

inward to produce deep, saucerized depressions (Fig. 156-10). The head, proximal upper arms, chest, back, breasts, buttocks, and thighs are the sites frequently affected. LE panniculitis, in the absence of overlying DLE, may produce breast nodules that can mimic carcinoma clinically and radiologically (lupus mastitis). Confluent facial involvement can simulate the appearance of lipoatrophy. Dystrophic calcification frequently occurs in older lesions of LE profundus/LE panniculitis, and pain associated with such calcification can, at times, be the dominant clinical problem. Roughly 50 percent of patients with LE profundus/panniculitis have evidence of SLE. However, the systemic features of patients with LE panniculitis/profundus tend to be less severe, similar to those of patients with SLE who have DLE skin lesions.

Chilblain LE/perniotic LE lesions initially develop as purple-red patches, papules, and plaques on the toes, fingers, and face, which are precipitated by cold, damp climates and are clinically and histologically similar to idiopathic chilblains (pernio) (see Chap. 93). As they evolve, these lesions usually assume the appearance of scarred atrophic plaques with associated telangiectases. They may resemble old lesions of DLE or may mimic acral lesions of small vessel vasculitis. Histologic findings include a superficial and deep lymphocytic vascular reaction in addition to fibrin deposition in reticular, dermal-based blood vessels. Patients with chilblain LE often have typical DLE lesions on the face and head. It is possible that chilblain LE begins as a classic acral, cold-induced lesion that then koebnerizes DLE lesions, thus explaining the spectrum of clinicohistologic findings, which seem to vary based on when, in the course of the lesion, the biopsy sample is taken.

Chilblain LE appears to be associated with anti–Ro/SS-A antibodies.[40] A recent study suggests that persistence of lesions beyond the cold months, a positive ANA, or presence of one of the other ACR criteria for SLE at the time of diagnosis of chilblain lesions helps to distinguish chilblain LE from idiopathic chilblains.[41] Approximately 20 percent of patients presenting with chilblain LE later develop SLE. Chilblain LE is an under-recognized entity, yet it is likely that it is one of the most common causes of digital lesions in patients with LE. A recent study by Bouaziz et al.[42] examined digital lesions in a cohort of 50 such patients. A clinical diagnosis of vasculitis was suggested by the referring physician in 36 percent of cases. However, the vast majority of patients were found to have LE-specific skin lesions, especially chilblain LE and atrophic scarring DLE.[42]

Lupus erythematosus tumidus (LET; tumid LE) is a variant of CCLE in which the dermal findings of DLE, namely excessive mucin deposition and superficial perivascular and periadnexal inflammation, are found on histologic evaluation. The characteristic epidermal histologic changes of LE-specific skin disease are only minimally expressed, if at all. This results in succulent, edematous, urticaria-appearing plaques with little surface change (Fig. 156-11). The paucity of epidermal change often produces confusion concerning the diagnosis of LET as a form of CLE.

Recently, there have been several reports of patients with this clinico-pathologic presentation that have helped to alleviate some of this confusion. Ruiz and Sanchez[43] reported four patients who had firm diagnoses of classic DLE and/or SLE in addition to red-violet plaques on the upper body; histologic examination showed the dermal changes that occur in LE-specific skin disease. Kuhn et al.[44] reported a cohort of 40 patients with similar clinical and histologic features who were markedly photosensitive and who had a very high response rate to antimalarial therapy.[44] This cohort had a very low incidence of SLE, further suggesting that LET is a subset of CCLE. The authors noted that unlike classic DLE, however, LET lesions tend to resolve completely without either scarring or atrophy.[44,45] A third study, a review of 26 patients, confirmed that patients with LET have little clinically overt epidermal involvement, intense photosensitivity, a benign course, absence of systemic disease, good response to antimalarial treatment, and a tendency to recur.[46]

▲ **FIGURE 156-11** Lupus erythematosus tumidus. Note succulent, indurated plaques.

Some authors have suggested the Jessner lymphocytic infiltrate overlaps with LET, in that both (1) have similar clinical and histologic findings, (2) occur with other forms of CLE and SLE, and (3) rarely present with visceral organ involvement of SLE. They further propose that LET, Jessner lymphocytic infiltrate, papulonodular mucinosis, and reticular erythematous mucinosis are all dermal variants of LE-specific skin disease and, as such, should be included in the current classification scheme.[47]

VESICULOBULLOUS SKIN CHANGE IN LUPUS ERYTHEMATOSUS Vesiculobullous skin change in LE is a very confusing subject. As with non-bullous LE skin disease, vesiculobullous skin lesions in patients with LE can be divided on the basis of histopathology into those that are LE-specific and those that are LE–non-specific (Table 156-5). Bullae may develop in ACLE and SCLE as a manifestation of particularly aggressive liquefactive degeneration of the epidermal basal layer, resulting in basal cell dissolution and simulating the clinical and histopathologic appearance of TEN. Vesiculo-bullous changes can develop at the active edge of annular SCLE lesions, and sub-epidermal bullous changes occasionally develop in DLE lesions.

The cutaneous entity described as bullous SLE is an example of LE–non-specific bullous skin change. Patients who typically have or subsequently develop active SLE including nephritis occasionally develop a severe vesiculobullous eruption. Histopathologically, marked neutrophilic infiltration with papillary microabscess formation is present similar to that of dermatitis herpetiformis (DH) and the inflammatory variant of epidermolysis bullosa acquisita (see Chap. 58). However, the direct immunofluorescence findings are more typical of those of LE. Type VII collagen autoantibodies are present in some patients. Although the vague term *bullous SLE* is most often used to describe such lesions, more descriptive terms such as *DH-like vesiculobullous LE* or *epidermolysis bullosa acquisita–like vesiculobullous LE* seem more appropriate, inasmuch as other forms of bullous skin lesions can occur in patients with SLE.

Other bullous skin diseases that have been linked anecdotally to LE include bullous pemphigoid, pemphigus erythematosus (see Senear-Usher syndrome in Chap. 52), DH, and porphyria cutanea tarda. It is not clear whether there is a primary association between these bullous skin disorders and LE, or whether their co-existence is the result of chance alone.

TABLE 156-5
Proposed Classification Scheme for Vesiculobullous Skin Disorders Encountered in Patients with Lupus Erythematosus

LE-Specific Vesiculobullous LE
- Acute cutaneous LE
  - Toxic epidermal necrolysis–like acute cutaneous LE
- Subacute cutaneous LE
  - Toxic epidermal necrolysis–like SCLE
  - Vesiculobullous annular subacute cutaneous LE
- Chronic cutaneous LE
  - Bullous discoid LE

LE–Non-Specific Vesiculobullous LE
- "Bullous systemic LE" (proposed alternative terms: *dermatitis herpetiformis–like LE–non-specific skin disease*; *epidermolysis bullosa acquisita–like LE–non-specific skin disease*; *LE–non-specific vesiculobullous eruption of SLE*)
- Vesiculobullous skin disorders anecdotally reported to occur in LE patients but whose relationship to LE has not yet been firmly established
  - Bullous pemphigoid
  - Dermatitis herpetiformis
  - Pemphigus erythematosus
  - Porphyria cutanea tarda

LE = lupus erythematosus.
From Sontheimer RD: The lexicon of cutaneous lupus erythematosus—A review and personal perspective on the nomenclature and classification of the cutaneous manifestations of lupus erythematosus. *Lupus* **6**:84, 1997, with permission from Stockton Journals, Macmillan Press, Ltd.

Lupus Erythematosus–Non-Specific Skin Lesions

A large number of cutaneous lesions that are found in LE patients are not specific for LE; that is, they also occur in patients that don't have or never develop LE and do not share the histologic features of LE-specific skin disease. Such skin lesions are usually found in the context of SLE or a significant risk thereof. These LE–non-specific skin lesions are listed in Table 156-1.

LUPUS ERYTHEMATOSUS–NON-SPECIFIC LESIONS AS DIAGNOSTIC CRITERIA FOR SYSTEMIC LUPUS ERYTHEMATOSUS As with some forms of LE-specific skin disease (e.g., ACLE), the presence of non-specific skin lesions may be an indicator of underlying SLE activity. In studies looking at skin lesions in patients with SLE, higher activity scores were seen in association with photosensitivity, Raynaud phenomenon, oral ulcers, non-scarring alopecia (all lupus non-specific lesions), in addition to malar rash and cicatricial alopecia.[48–50]

The high prevalence rates of these conditions in SLE has led to their past and/or present inclusion in the ACR criteria for diagnosis of SLE. Photosensitivity, defined clinically as an *abnormal response to UVR*, appears to be a relatively sensitive indicator of SLE. Several different studies have documented between 50 percent and 93 percent incidence rates of photosensitivity in patients with SLE. Because of the frequency of photosensitivity in SLE, all patients should be taught the importance of protecting skin from UVR. Oral ulcers are present in roughly 25 percent to 45 percent of SLE patients[51,52] and up to 25 percent of DLE patients.[53] Although these lesions can show LE-specific histopathologic changes on biopsy, particularly in DLE patients, they often are non-specific. LE–non-specific alopecia, diffuse non-scarring alopecia that is different than the scarring alopecia associated with DLE, has been referred to as *lupus hair* and presents as course, dry hair that has increased fragility. It often results in broken hairs and may be more prominent over the frontal hairline. This likely has considerable overlap with a diffuse non-scarring alopecia caused by telogen effluvium.

CUTANEOUS VASCULAR REACTIONS Reactions that are focused on the cutaneous vasculature are important to recognize in patients with SLE, as they can frequently indicate underlying systemic vascular pathology. Raynaud phenomenon (see Chap. 171) is the most common vascular reaction in lupus patients: one study documented Raynaud phenomenon in 39.6 percent of patients with SLE.[54] Additionally, it has been shown that Raynaud phenomenon seems to herald a worse prognosis and is associated with higher disease activity scores.[48,50] The presence of Raynaud phenomenon in patients with SLE may correlate with an increase in DLE lesions on the hands. Skin changes that can be seen in association with chronic severe Raynaud phenomenon include focal ulcerations on the fingertips and periungual areas that result in pitted scarring on resolution, prominent nail fold capillary ectasia and drop out, punctate cuticular hemorrhage due to incompetent nail fold capillaries, fingertip tuft atrophy, digital calcinosis, and pterygium inversus unguium.

Patients with SLE often develop vessel pathology in the form of vasculitis. In SLE, all sizes of vessels may be affected.[55] When leukocytoclastic vasculitis (LCV) presents in patients with SLE, other causes of LCV, such as medications and infections, should be excluded before a diagnosis of primary lupus-associated LCV is assigned. Urticarial vasculitis is not uncommon in SLE patients and presents as tender urticarial papules and plaques, often over bony prominences, which last longer than 24 hours. Involvement of medium and/or large vessels may present as purpuric plaques with stellate or retiform borders with or without cutaneous necrosis and ulceration, or subcutaneous nodules. LE–non-specific vasculitis must be distinguished from vasculopathy due to thromboembolism because it may present with similar clinical findings. LE–non-specific vasculopathy is most commonly the result of antiphospholipid antibodies.

Livedo reticularis should be considered as a separate LE–non-specific cutaneous vascular reaction, although it has clear overlap with vasculopathy. It manifests as net-like, blanchable, complete or incomplete, red-purple rings on the extremities and is the result of impeded flow of blood through vessels. Macular erythema over the hyper- and hypothenar eminences of the palms has been reported in lupus patients. Reticulated palmar erythema can also be a sign of vasculopathy associated with anti-phospholipid antibodies. Dilated capillaries of the nail folds have been found in LE patients but less frequently than in patients with dermatomyositis (including clinically amyopathic dermatomyositis) or systemic sclerosis. Erythromelalgia (erythermalgia) is characterized by intense burning pain in the feet and hands, accompanied by local macular erythema and warmth. It differs from Raynaud phenomenon in that it worsens with exposure to heat instead of cold. It may be seen as an isolated clinical entity or in association with several different underlying illnesses, including SLE. Telangiectasia and erythema of the proximal nail fold were found in 76 percent of patients who had both DLE and SLE, but none in patients with DLE in the absence of SLE, suggesting that it, too, is a rather sensitive indicator for systemic disease activity.[54]

OTHER LUPUS ERYTHEMATOSUS–NON-SPECIFIC SKIN LESIONS Urticaria is sometimes associated with LE and is thought to be a manifestation of the immune dysregulation of the disease process. One study found chronic urticaria in 44 percent of 73 SLE patients.[51] SLE patients may present with LE–non-specific cutaneous mucinosis. Patients may develop indurated erythematous papules, nodules, or plaques, typically on the trunk and/or arms. Histopathologic examination of these lesions reveals diffuse dermal mucin deposits. A number of nail changes have been noted in LE patients, including leukonychia, nail pitting or ridging, onycholysis, onychomadesis, and red lunula.[56–58]

Other conditions seen more commonly in the setting of LE that are on the list of LE–non-specific skin lesions include lichen planus, acanthosis nigricans, cutis laxa, anetoderma, multiple dermatofibroma, acquired ichthyosis, and interstitial granulomatous dermatitis.[59–64]

TABLE 156-6
Autoantibodies Associated with Unselected Systemic Lupus Erythematosus

Antigen	Autoantibody Frequency (%) ID	SPA/RIA	Molecular Specificity	Clinical Association
High disease specificity for SLE				
dsDNA		60	Native DNA	LE nephritis
Sm	25		Ribonucleoprotein	—
rRNP	10		Ribosomal P protein	CNS LE
PCNA	3		Cyclin	—
Low disease specificity for SLE				
ssDNA		60	Denatured DNA	Risk for SLE in patients with DLE
Histones		50	Histones	Drug-induced SLE
U1RNP	25		Ribonucleoprotein	Overlap CTD (MCTD)
Ro/SS-A	25	50	Ribonucleoprotein	SLCE, SSj, neonatal LE
La/SS-B	10	20	Ribonucleoprotein	SSj, SCLE
Ku	10		Transcription factor	Overlap CTD

CNS = central nervous system; CTD = connective tissue disease; DLE = discoid lupus erythematosus; dsDNA = doubled-stranded DNA; ID = immunodiffusion; MCTD = mixed CTD; PCNA = proliferating cell nuclear antigen; RIA = radioimmunoassay; RNP = ribonucleoprotein; SCLE = subacute cutaneous lupus erythematosus; SLE = systemic lupus erythematosus; SPA = solid phase immunoassay (i.e., enzyme-linked immunoassay); ssDNA = single-stranded DNA; SSj = Sjögren syndrome.

LABORATORY TESTS

Table 156-4 summarizes the major laboratory findings associated with the varieties of LE-specific skin disease, and Table 156-6 presents the autoantibody associations of SLE. Because of the strong association between ACLE and SLE, the laboratory features of ACLE are those associated with SLE (high-titer ANA, anti–dsDNA, anti-Sm, hypocomplementemia).

The laboratory markers for SCLE are the presence of anti-Ro/SS-A (70 percent to 90 percent) and, less commonly, anti-La/SS-B (30 percent to 50 percent) autoantibodies. ANA are present in 60 percent to 80 percent of patients with SCLE, and rheumatoid factor is present in approximately one-third. Other autoantibodies in patients with SCLE include false-positive serologic tests for syphilis (VDRL rapid plasma reagin) (7 percent to 33 percent), anticardiolipin (10 percent to 16 percent), antithyroid (18 percent to 44 percent), anti-Sm (10 percent), anti–ds-DNA (10 percent), and anti-U1 ribonucleoprotein (10 percent). Patients with SCLE, particularly those with systemic involvement, may have a number of laboratory abnormalities, including anemia, leukopenia, thrombocytopenia, elevated erythrocyte sedimentation rate, hypergammaglobulinemia, proteinuria, hematuria, urine casts, elevated serum creatine and blood urea nitrogen, and depressed complement levels (resulting from genetic deficiency or increased complement consumption).

ANA are present in low titer in 30 percent to 40 percent of patients with DLE; however, fewer than 5 percent have the higher ANA levels that are characteristic of patients with overt SLE (> 1:320). Antibodies to single-stranded DNA are not uncommon in DLE, but antibodies to dsDNA are distinctly uncommon. Precipitating antibodies to U1RNP are sometimes found in patients whose disease course is dominated by DLE lesions; however, such patients usually have only mild manifestations of SLE or overlapping connective tissue

disorders such as mixed connective tissue disease. Precipitating Ro/SS-A and La/SS-B autoantibodies are rare in patients with DLE; low levels of anti–Ro/SS-A antibody detected by enzyme-linked immunoassay are more common. A small percentage of patients with DLE have low-grade anemia, biologic false-positive serologic tests for syphilis (VDRL rapid plasma reagent), positive rheumatoid factor tests, slight depressions in serum complement levels, modest elevations in γ globulin, and modest leukopenia. It has been suggested that such findings are risk factors for the development of SLE. ANA are present in 70 percent to 75 percent of patients with LE profundus/panniculitis, but anti–dsDNA antibodies are rare.

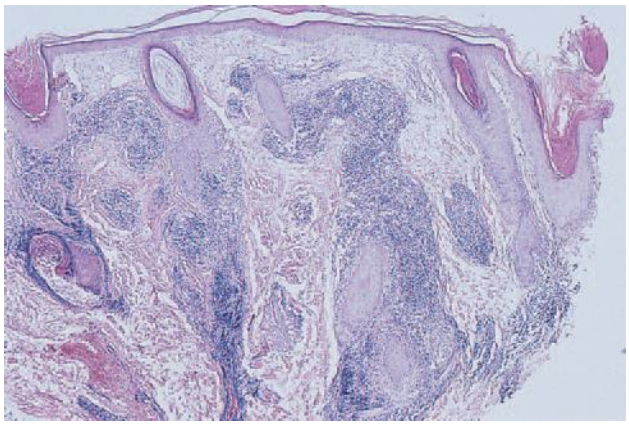
The laboratory findings associated with SLE, as well as with CLE, in both adults and newborns, have been reviewed.[65–67]

HISTOPATHOLOGY

The LE-specific skin disease histopathology is a distinctive constellation of hyperkeratosis, epidermal atrophy, vacuolar basal cell degeneration, dermal-epidermal junction basement membrane thickening, dermal edema, dermal mucin deposition, and mononuclear cell infiltration of the dermal-epidermal junction and dermis, focused in a perivascular and periappendageal distribution (Fig. 156-12). Variable degrees of these features are encountered in the different forms of LE-specific skin disease (see Chap. 6). Differences of opinion exist as to whether ACLE, SCLE, and DLE lesions can be distinguished reliably on the basis of their histopathologic appearances alone.[65,68,69]

Acute Cutaneous Lupus Erythematosus

The histopathologic changes in ACLE lesions are generally less impressive than those in SCLE and DLE lesions, and are mainly those of a cell-poor interface dermatitis. The lymphohistiocytic cellular infiltrate is relatively sparse. Some authors have noted an increase in the number of neutrophils in the infiltrate. A mild degree of focal vacuolar alteration of basal keratinocytes can be seen, in addition to telangiectases and extravasation of erythrocytes. One may see individually necrotic keratinocytes, and in its most severe form, ACLE can display extensive epidermal necrosis similar to TEN. The upper dermis usually shows pronounced mucinosis and may be very helpful in distinguishing ACLE from other causes of a cell-poor interface dermatitis. It is uncommon to see basement membrane zone thickening, follicular plugging, or alteration of epidermal thickness in ACLE, although epidermal atrophy is sometimes present.[69]



▲ **FIGURE 156-12** Histopathology of lupus erythematosus–specific skin disease. Histology of a discoid lupus erythematosus lesion demonstrating marked basal cell layer damage with vacuolization and irregularity of basal cell size. Mild hyperkeratosis is present.

Subacute Cutaneous Lupus Erythematosus

SCLE also frequently presents as an interface dermatitis, with foci of vacuolar alteration of basal keratinocytes alternating with areas of lichenoid dermatitis. Pronounced epidermal atrophy is often present. SCLE is in the differential diagnosis of atrophic lichenoid dermatitis, along with atrophic lichen planus and lichenoid drug eruptions. Dermal changes include edema, prominent mucin deposition, and sparse mononuclear cell infiltration usually limited to areas around blood vessels and periadnexal structures in the upper one-third of the dermis. Lesser degrees of hyperkeratosis, follicular plugging, mononuclear cell infiltration of adnexal structures, and dermal melanophages might help distinguish SCLE lesions from DLE lesions. It has not been possible to differentiate papulosquamous from annular SCLE by histopathologic criteria alone.[68]

Chronic Cutaneous Lupus Erythematosus

In classic DLE lesions, epidermal changes include hyperkeratosis, variable atrophy, and interface changes similar to those described for SCLE. The epidermal basement membrane is markedly thickened. Dermal changes include a dense mononuclear cell infiltrate composed primarily of CD4 T lymphocytes and macrophages predominantly in the periappendageal and perivascular areas, melanophages, and dermal mucin deposition. The infiltrate is often quite dense and typically extends well into the deeper reticular dermis and/or subcutis, which may help to distinguish it from ACLE or SCLE. In chronic scarring DLE lesions, the dense inflammatory cell infiltrate subsides and is replaced by dermal fibroplasia. A folliculotropic variant of DLE, in which the inflammatory infiltrate is predominantly around hair follicles, has been described, as have lymphomatoid variants, in which there are extremely dense infiltrates that may contain atypical lymphoid cells.[69]

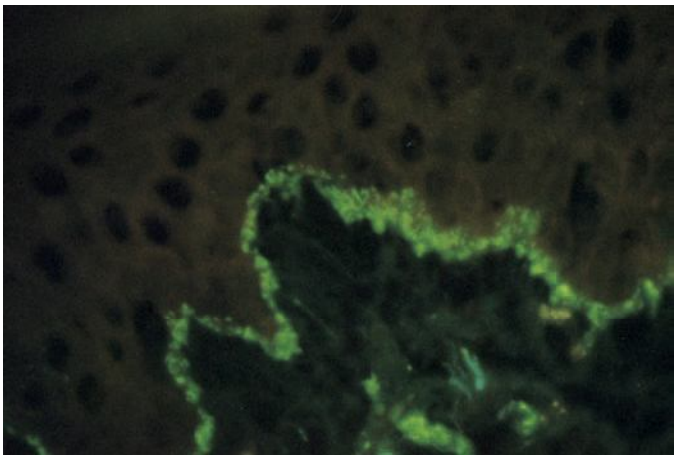
Less Common Sub-Types of Lupus Erythematosus–Specific Skin Disease

The histopathology of hypertrophic DLE lesions is similar to that of classic DLE lesions except for a much greater degree of epidermal acanthosis and hyperkeratosis. At times, prominent acanthosis may simulate keratinocytic neoplastic processes such as squamous cell carcinoma.

In LE panniculitis (see Chap. 68), the absence of the characteristic epidermal and dermal changes of LE can make the histologic diagnosis difficult. In LE panniculitis, subcutaneous tissue displays a lobular lymphocytic panniculitis with perivascular infiltration with lymphocytes, plasma cells, and histiocytes in the deep dermis and subcutaneous fat (including lymphoid nodule formation); vessel wall thickening and invasion by

mononuclear cells (lymphocytic vasculitis); absence of polymorphonuclear leukocytes; hyaline fat necrosis; prominent fibrinoid degeneration of collagen; and mucinous degeneration and calcification in old, established lesions. Except for the differences related to the absence of hair follicles and stratum corneum in mucous membranes, the microscopic changes of mucosal DLE are highly reminiscent of those in cutaneous DLE lesions.

Chilblain LE shows an interface dermatitis, with superficial and deep perivascular lymphocytic infiltration much like classic DLE. However, a lymphocytic vasculitis and fibrin within the lumina of dermal blood vessels are present in addition.[68,69] In tumid LE, the dermal changes of DLE are present, namely a variable perivascular mononuclear infiltrate with prominent mucin between collagen bundles; but the classic epidermal changes that occur in other forms of LE-specific skin disease are not present.[43,45] Histopathologic changes in vesiculo-bullous lesions of LE are noted above under Vesiculobullous Skin Change in Lupus Erythematosus.



▲ **FIGURE 156-13** Immunopathology of lupus erythematosus–specific skin disease. Direct immunofluorescence examination of a discoid lupus erythematosus lesional skin biopsy showing a continuous band of granular fluorescence at the dermal-epidermal junction as a result of staining with fluorescein isothiocyanate-conjugated goat anti-immunoglobulin G.

IMMUNOHISTOLOGY

Immunohistology is often helpful in confirming a diagnosis of LE-specific skin disease and has been shown to boost the sensitivity and specificity of diagnosis.[69] Because it is not uncommon to see negative immunofluorescence studies in patients with acute, subacute, and chronic LE, and false-positive studies in healthy individuals, immunohistology must be interpreted in the context of clinical and histologic findings in a given patient.

IgG, IgA, IgM and complement components (C3, C4, Clq, properdin, factor B, and the membrane attack complex C5b-C9) deposited in a continuous granular or linear band-like array at the dermal-epidermal junction have been observed in the lesional and non-lesional skin of patients with LE since the early 1960s (Fig. 156-13). However, debate about terminology in this area continues to cloud the field.[65] Some restrict the use of the term *lupus band test* to refer to the examination of non-lesional skin biopsies for the presence of this band-like array of immunoreactants at the dermal-epidermal junction. Others qualify the LBT as being either "lesional" or "non-lesional." Less confusion might exist if the terms *lesional LBT* (lesional lupus band) and *non-lesional LBT* (non-lesional lupus band) were uniformly adopted.

Acute Cutaneous Lupus Erythematosus

The sparse data that exist suggest that 60 percent to 100 percent of ACLE lesions display a lesional lupus band. However, the realization that sun-damaged skin from otherwise healthy individuals can display similar immunopathology has diluted the clinical value of this finding.

Subacute Cutaneous Lupus Erythematosus

Initial studies indicated that approximately 60 percent of patients with SCLE had lesional lupus bands. A "dust-like particle" pattern of IgG deposition focused around epidermal basal keratinocytes has been suggested to be more specific for SCLE by reflecting the presence of in vivo-bound Ro/SS-A autoantibody.

Chronic Cutaneous Lupus Erythematosus

Early reports suggested that more than 90 percent of classic DLE lesions had lesional immunoreactants at the dermal-epidermal junction, often extending along the basement membrane of the hair follicle, but subsequent studies report somewhat lower rates. Lesions on the head, neck, and arms are positive more frequently (80 percent) than those on the trunk (20 percent). The lesional lupus band also appears to be a function of the age of the lesion being examined, with older lesions (> 3 months) being positive more often than younger ones. Ultrastructural localization of immunoglobulin at the dermal-epidermal junction confirms that these proteins are deposited on the upper dermal collagen fibers and along the lamina densa of the epidermal basement membrane zone.

In LE profundus, immunoglobulin and complement deposits are usually found in blood vessel walls of the deep dermis and subcutis. Immunoglobulin deposits at the dermal-epidermal junction may or may not be present, depending on the site biopsied, the presence or absence of accompanying SLE, and the presence or absence of overlying changes of DLE at the dermal-epidermal junction.

Non-Lesional Lupus Band Test

There has been much debate over the past three decades regarding the diagnostic and prognostic significance of an immunoglobulin/complement band at the dermal-epidermal junction of non-lesional skin taken from patients with LE.[65,68] When totally sun-protected non-lesional skin (e.g., buttocks) is sampled, the diagnostic specificity for SLE appears to be very high when three or more immunoreactants are present at the dermal-epidermal junction. Prospectively ascertained follow-up data also suggest that the presence of a non-lesional LBT correlates positively with risk for developing LE nephritis. However, the non-lesional LBT has fallen out of favor as a clinical tool largely because

Box 156-1

Differential Diagnosis of Lupus Erythematosus

Most Likely	*Consider*	*Always Rule Out*
ACLE	ACLE	ACLE
• Localized	• Localized	• Generalized
~ Acne rosacea	~ Seborrheic dermatitis	~ Toxic epidermal necrolysis
~ Dermatomyositis	~ Polymorphous light eruption	DLE
• Generalized	~ Photoallergic contact dermatitis	• Tinea incognito
~ Drug hypersensitivity reaction	• Generalized	Cutaneous T-cell lymphoma
~ Photoallergic/phototoxic drug reactions	~ Dermatomyositis	• Lupus panniculitis

ACLE = acute cutaneous lupus erythematosus; DLE = discoid lupus erythematosus; LET = lupus erythematosus tumidus; SCLE = subacute cutaneous lupus erythematosus.

the information gained has not been proven to be of significantly greater value than the results of more readily available serologic assays such as antibody to dsDNA.

DIFFERENTIAL DIAGNOSIS

(Boxes 156-1 and 156-2)

PROGNOSIS AND CLINICAL COURSE

Acute Cutaneous Lupus Erythematosus

Both localized and generalized forms of ACLE lesions flare and abate in parallel with underlying SLE disease activity. Therefore, the prognosis for any given patient with ACLE is dictated by the pattern of the underlying SLE. Both 5-year (80 percent to 95 percent) and 10-year (70 percent to 90 percent) survival rates for SLE have progressively improved over the past four decades as a result of earlier diagnosis made possible by more sensi-

Box 156-2

Complications

- ACLE/SCLE
  - Associated flaring SLE with potentially organ-threatening involvement
  - Ulceration with risk for superinfection
  - Progression to TEN-like ACLE/SCLE
  - Post-inflammatory hyperpigmentation
- DLE
  - Associated flaring SLE with potentially organ-threatening involvement (especially if disseminated)
  - Scarring/disfigurement, including scarring alopecia
  - Ulceration with risk for superinfection
  - Post-inflammatory hyperpigmentation
  - LE panniculitis
  - Dystrophic calcification
  - Depressed atrophic disfigurement
  - Lupus mastitis
- LE–non-specific skin disease
- Vasculitis/vasculopathy
  - Associated systemic involvement with life- or organ-threatening involvement
  - Cutaneous necrosis/ulceration
- Raynaud phenomenon
  - Digital ulceration/dry gangrene/loss of digits

ACLE = acute cutaneous lupus erythematosus; DLE = discoid lupus erythematosus; LE = lupus erythematosus; SCLE = subacute cutaneous lupus erythematosus ; SLE = systemic lupus erythematosus; TEN = toxic epidermal necrolysis.

tive laboratory testing and improved immunosuppressive treatment regimens. Ominous prognostic signs in SLE are hypertension, nephritis, systemic vasculitis, and central nervous system disease.

Subacute Cutaneous Lupus Erythematosus

Because SCLE has been recognized as a separate disease entity for only two decades, the long-term outcome associated with SCLE lesions has yet to be determined. It is the authors' experience that most patients with SCLE have intermittent recurrences of skin disease activity over long periods of time without significant progression of systemic involvement (we are aware of only one death directly attributable to SLE in approximately 150 patients with SCLE). Other patients enjoy long-term if not permanent remissions of their skin disease activity. A few patients have experienced unremitting cutaneous disease activity.

It has also been the authors' experience that approximately 15 percent of the patients with SCLE develop active SLE, including lupus nephritis. This subgroup of patients is marked by the presence of papulosquamous SCLE, localized ACLE, high-titer ANA, leukopenia, and/or antibodies to dsDNA. Long-term follow-up studies of SCLE are required to determine the true risk of severe systemic disease progression in patients presenting with SCLE skin lesions. CCLE lesions, typically classic DLE, have also arisen in patients initially presenting with SCLE.

Evidence suggests that overlap occurs between SCLE and Sjögren syndrome. Patients with SCLE who develop Sjögren syndrome are at risk for developing the extraglandular systemic complications associated with Sjögren syndrome, including vasculitis, peripheral neuropathy, autoimmune thyroiditis, renal tubular acidosis, myositis, chronic hepatitis, primary biliary cirrhosis, psychosis, lymphadenopathy, splenomegaly, and B-cell lymphoma.

Chronic Cutaneous Lupus Erythematosus

Most patients with untreated classic DLE lesions suffer indolent progression to large areas of cutaneous dystrophy and scarring alopecia that can be psychosocially devastating and occupationally disabling. However, with treatment, skin disease can be largely controlled. Spontaneous remission occurs occasionally, and the disease activity can recrudesce at the sites of older, inactive lesions. Rebound after discontinuation of treatment is typical, and slower taper of medications during periods of inactivity is recommended. Squamous cell carcinoma occasionally develops in chronic smoldering DLE lesions.

Death from SLE is distinctly uncommon in patients who present initially with localized DLE. As discussed in Epidemiology, patients presenting with localized DLE have only a 5 percent chance of subsequently developing clinically significant SLE disease activity. Generalized DLE and persistent, low-grade laboratory abnormalities appear to be risk factors for such disease progression. Unrecognized squamous-cell carcinoma developing within a long-standing DLE skin lesion could be a cause of morbidity and mortality.

Outcomes Measures

The recent development of a validated instrument to measure activity of CLE, the Cutaneous Lupus Erythematosus Area and Severity Index, has made it possible to objectively follow patients' disease course and response to therapy. The instrument has separate scores for damage (scarring) and activity which is important, because one would not expect a "burned-out" scarred area to normalize with drugs that were meant to abate LE activity.[70] The creation of this utility tool is timely because the U.S. Food and Drug Administration has recently called for new drug development for lupus, including disease in which only one organ is affected (i.e., skin-only DLE). A Brazilian group has recently used the Dermatology Life Quality Index and SF-36 to measure quality of life in patients with CLE. Both questionnaires showed that patients with active skin lesions had lower quality of life and that patients with associated alopecia were particularly impacted.[71]

TREATMENT

The initial management of patients with any form of CLE should include an evaluation to rule out underlying SLE disease activity at the time of diagnosis. All patients with CLE should receive instruction about protection from sunlight and artificial sources of UVR and should be advised to avoid the use of potentially photosensitizing drugs such as hydrochlorothiazide, tetracycline, griseofulvin, and piroxicam. With regard to specific medical therapy, local measures should be maximized and systemic agents used if significant local disease activity persists or systemic activity is superimposed.

ACLE lesions usually respond to the systemic immunosuppressive measures required to treat the underlying SLE disease activity that so frequently accompanies this form of CLE (e.g., systemic glucocorticoids, azathioprine, cyclophosphamide). Increasing evidence suggests that aminoquinoline antimalarial agents such as hydroxychloroquine can have a steroid-sparing effect on SLE, and these drugs can be of value in ACLE. The local measures discussed in Local Therapy below can also be of value in treating ACLE. Because the lesions of SCLE and CCLE are often found in patients who have little or no evidence of underlying systemic disease activity, unlike the lesions of ACLE, nonimmunosuppressive treatment modalities are preferred for SCLE and CCLE (Table 156-7). For the most part, SCLE and CCLE lesions respond equally to such agents.

Local Therapy

SUN PROTECTION Advise patients to avoid direct sun exposure, wear tightly woven clothing and broad-brimmed hats, and regularly use broad-spectrum, water-resistant sunscreens [SPF ≥ 30 with an efficient UVA blocking agent such as a photostabilized form of avobenzone (Parsol 1789), micronized titanium dioxide, micronized zinc oxide, or Mexoryl SX]. UV-blocking films should be applied to home and automobile windows, and acrylic diffusion shields should be placed over fluorescent lighting. Corrective camouflage cosmetics such as Dermablend® and Covermark® offer the dual benefit of being highly effective physical sunscreens as well as aesthetically pleasing cosmetic masking agents. An in-depth discussion of practical and theoretical photoprotection and local therapy for autoimmune connective tissue skin disease such as diabetes mellitus has been discussed by Ting and Sontheimer (see Chap. 223).[72]

LOCAL GLUCOCORTICOIDS Although some prefer intermediate-strength preparations, such as triamcinolone acetonide 0.1 percent, for sensitive areas such as the face, superpotent topical class I agents, such as clobetasol propionate 0.05 percent or betamethasone dipropionate 0.05 percent, produce the greatest benefit in CLE. Twice-daily application of the superpotent preparations to lesional skin for

TABLE 156-7
Therapeutic Options for Lupus Erythematosus–Specific Skin Disease

	Drug	Dose
First line	Topical glucocorticoids Topical calcineurin inhibitor Intralesional: triamcinolone acetonide	Class I steroid qd–bid for 2 wk alternating with class IV pimecrolimus, 1% bid; tacrolimus, 0.1% bid 2.5–10.0 mg/cc
Second line (low threshold for use if scarring, widespread lesions, systemic symptoms)	Hydroxychloroquine Chloroquine Quinacrine (if monotherapy fails, add quinacrine to either hydroxychloroquine or chloroquine)	6.5 mg/kg/day ideal body weight 3.5 mg/kg/day ideal body weight 100 mg daily (available at compounding pharmacies)
Short courses only (2–16 wk) (must have patient on concomitant alternative agent to prevent rebound on discontinuation)	Prednisone Thalidomide	5–60 mg/day 50 mg qd–200 mg/day; taper to 50 mg qod on response
Third line (safer immunosuppressives)	Azathioprine Mycophenolate mofetil Methotrexate	1.5–2.5 mg/kg/day 2.5–3.5 g/day 7.5–25 mg PO or SQ/wk
Worth consideration	Dapsone Accutane or Acitretin Gold	50–200 mg/day 0.5–2 mg/kg/day 10–50 mg/day Work up to 50 mg weekly, taper after 1 g
Fourth line (limited by side effects)	Cyclophosphamide Clofazimine	1.5–2.0 PO mg/kg/day
Investigational (some currently available)	Efalizumab (Raptiva) Leflunomide (Arava) Anti-tumor necrosis factor agents Rituximab (Rituxan) Abatacept Epratuzumab Anti–interferon-α agents	

2 weeks followed by a 2-week rest period can minimize the risk of local complications such as steroid atrophy and telangiectasia. Ointments are more effective than creams for more hyperkeratotic lesions such as hypertrophic DLE. Occlusive therapy with glucocorticoid-impregnated tape (e.g., flurandrenolide) or glucocorticoids with plastic food wrap (e.g., Saran or Glad Press-N-Seal) can potentiate the beneficial effects of topical glucocorticoids but also carries a higher risk of local side effects. Class I or class II topical glucocorticoid solutions and gels are best for treating the scalp. Unfortunately, even the most aggressive regimen of topical glucocorticoids by itself does not provide adequate improvement for most patients with SCLE and CCLE.

TOPICAL CALCINEURIN INHIBITORS Pimecrolimus 1 percent cream and tacrolimus 0.1 percent ointment have demonstrated variable efficacy in the treatment of ACLE, DLE, and SCLE.[73–75]

INTRALESIONAL GLUCOCORTICOIDS Intralesional glucocorticoids (e.g., triamcinolone acetonide suspension, 2.5 to 5.0 mg/mL for the face with higher concentrations allowable in less sensitive sites) are more useful in the management of DLE than SCLE. Intralesional glucocorticoids themselves can produce cutaneous and subcutaneous atrophy (deep injections into the subcutaneous tissue enhances this risk). A 30-gauge needle is preferred because it produces only mild discomfort on penetration, especially when injected perpendicularly to the skin. The active borders of lesions should be thoroughly infiltrated. Intralesional therapy is indicated for particularly hyperkeratotic lesions or lesions that are unresponsive to topical glucocorticoids, but most patients with CLE have too many lesions to be managed exclusively by intralesional glucocorticoid injections.

Systemic Therapy

ANTIMALARIALS One or a combination of the aminoquinoline antimalarials can be effective for approximately 75 percent of patients with CLE who have failed to benefit adequately from the local measures described in Local Therapy.[65] The risks of retinal toxicity should be discussed with the patient, and a pre-treatment ophthalmologic examination should be performed. However, the risk of antimalarial retinopathy is extremely rare if recommended daily dose maximum levels of these agents are not exceeded (hydroxychloroquine, 6.5 mg/kg/day based on ideal body weight; chloroquine, 4 mg/kg/day). Patients should have follow-up ophthalmologic evaluations every 6 to 12 months while on therapy.

Hydroxychloroquine sulfate (Plaquenil), 400 mg/day by mouth, should be given for the first 6 to 8 weeks of treatment to reach equilibrium blood levels. Once an adequate clinical response has been achieved, the daily dose should be decreased to a maintenance dose of 200 mg/day for at least 1 year to minimize chances of recurrence (some authorities recommend even longer periods of inductive treatment). If no response is seen after 8 to 12 weeks, quinacrine hydrochloride, 100 mg/day (currently available in the United States only through compounding pharmacies), can be added to the hydroxychloroquine without enhancing the risk of retinopathy (quinacrine does not cause retinopathy). If, after 4 to 6 weeks, adequate clinical control has not been achieved, consideration should be given to replacing the hydroxychloroquine with chloroquine diphosphate (Aralen), 250 mg/day. In Europe, chloroquine is generally felt to be more efficacious than hydroxychloroquine in treating CLE, perhaps due to the earlier therapeutic responses that might occur as a result of the shorter time period required to reach equilibrium blood levels with chloroquine as compared to hydroxychloroquine. Hydroxychloroquine and chloroquine should not be used simultaneously because of enhanced risk for retinal toxicity.

Multiple side effects other than retinal toxicity are associated with the use of antimalarials. Quinacrine is associated with

a higher incidence of side effects, such as headache, gastrointestinal intolerance, hematologic toxicity, pruritus, lichenoid drug eruptions, and mucosal or cutaneous pigmentary deposition, than is either hydroxychloroquine or chloroquine. Quinacrine commonly produces a yellow discoloration of the entire skin and sclera in fair-skinned individuals, which is completely reversible when the drug is discontinued. Quinacrine can produce significant hemolysis in patients with glucose-6-phosphate dehydrogenase deficiency (this adverse effect has also been reported to occur rarely with hydroxychloroquine and chloroquine). Each of the aminoquinoline antimalarials can produce bone marrow suppression, including aplastic anemia, although this effect is exceedingly rare with the current dosage regimens. Toxic psychosis, grand mal seizures, neuromyopathy, and cardiac arrhythmias occurred with the use of high doses of these drugs in the past; these reactions are uncommon with the lower daily dose regimens used today.

Before therapy with hydroxychloroquine and chloroquine is begun, complete blood cell counts, as well as liver and renal function tests, should be performed; these tests should be repeated 4 to 6 weeks after therapy has been initiated, and every 4 to 6 months thereafter. A screen for hematologic toxicity when quinacrine is used is recommended more often. Patients with overt or sub-clinical porphyria cutanea tarda are at particularly high risk for developing acute hepatotoxicity, which often simulates an acute surgical abdomen, when treated with therapeutic doses of antimalarials for CLE. It is also recommended to check urine levels of β–human chorionic gonadotropin initially in women with childbearing potential, although recent evidence indicates that the risk to pregnant women of currently recommended dose regimens of antimalarials is minimal.

NONIMMUNOSUPPRESSIVE OPTIONS FOR ANTIMALARIAL-REFRACTORY DISEASE Some patients with refractory CLE (SCLE more than DLE) respond to diaminodiphenylsulfone.[76] An initial dose of 25 mg by mouth twice daily can be increased up to 200 to 400 mg/day, if necessary. Significant dose-related hemolysis and/or methemoglobinemia can result from the use of diaminodiphenylsulfone, especially in individuals deficient in glucose-6-phosphate dehydrogenase activity, and, therefore, complete blood counts and liver function tests should be performed regularly. Isotretinoin, 0.5 to 2.0 mg/kg/day, and acitretin, 10 to 50 mg/day, have also been used in this setting, but their efficacy is limited by their side effects (teratogenicity, mucocutaneous dryness, hyperlipidemia). In addition, breakthrough of CLE activity has been a problem with the long-term use of retinoids.

Thalidomide (see Chap. 236) (50 to 200 mg/day) is strikingly effective for CLE that is refractory to other medications. Numerous studies have cited response rates between 85 percent and 100 percent, with many patients experiencing complete remission.[77] However, strict prescribing regulations put in place in the United States in 1998 because of severe teratogenicity, make thalidomide challenging to dispense to women of childbearing potential. Sensory neuropathy is another toxicity associated with thalidomide, and 25 percent to 75 percent of patients with CLE develop peripheral neuropathy while taking the drug. Most cases are reversible when therapy is stopped. Neuropathy seems to correlate with total treatment times so that short courses are preferred. Relapses after the drug is stopped are common. Excess somnolence as well as constipation and other minor side effects sometimes limit its use, although these effects usually abate with lower daily doses.[78] Thromboembolism is a serious adverse event that can happen in patients with a pre-existing hypercoagulable state (e.g., presence of anti-phospholipid antibodies). Oncologists who use thalidomide for multiple myeloma frequently initiate concomitant anticoagulation therapy to prevent this side effect. Lenalidomide (Revlamid, Celgene) is a thalidomide analog that is more efficacious but has similar rates of teratogenicity, peripheral neuropathy, thromboembolism, and also has the additional potential side effect of profound leukopenia.

Other drugs reported to be of value in the treatment of refractory CLE are gold and clofazimine; however, the benefit varies from case to case and both of these agents are associated with the risk of significant side effects. Vitamin E, phenytoin, sulfasalazine, danazol, DHEA, and phototherapy (UVAI phototherapy, photopheresis) have also been reported in uncontrolled trials to be of value in CLE.

SYSTEMIC GLUCOCORTICOIDS Every effort should be made to avoid the use of systemic glucocorticoids in patients with LE limited to the skin. However, in occasional patients who have especially severe and symptomatic skin disease, intravenous pulse methylprednisolone has been used. In less acute cases, moderate daily doses of oral glucocorticoids (prednisone, 20 to 40 mg/day, given as a single morning dose) can be used as supplemental therapy during the loading phase of therapy with an antimalarial agent. The dose should be reduced at the earliest possible time because of the complications of long-term glucocorticoid therapy, especially avascular (aseptic) bone necrosis, a side effect to which patients with LE are particularly susceptible.

Because steroid-induced bone loss occurs most rapidly in the first 6 months of use, all patients who do not have contraindications should begin agents to prevent osteoporosis with the initiation of steroid therapy. An excellent review describing current recommendations for prevention of bone loss and other side effects of systemic glucocorticoids has been published.[39] When the disease activity is controlled, the daily dosage should be reduced by 5- to 10-mg decrements until activity flares again or until a daily dosage of 20 mg/day is achieved. The daily dose should then be lowered by 2.5-mg decrements (some physicians prefer to use 1-mg dose decrements below 10 mg/day). Alternate-day glucocorticoid therapy has not been successful in suppressing disease activity in most patients with CLE or SLE. Prednisolone rather than prednisone should be used in patients who have significant underlying liver disease, because prednisone requires hydroxylation in the liver to become biologically active. Any amount of prednisone given as a single oral dose in the morning has less adrenal-suppressing activity than the same amount given in divided doses throughout the day. However, any given amount of this drug, taken in divided doses, has a greater LE-suppressing activity than does the same amount of drug given as a single morning dose.

OTHER IMMUNOSUPPRESSIVES Azathioprine (Imuran) (1.5 to 2.0 mg/kg/day orally) can play a glucocorticoid-sparing role in the severely affected patient with CLE. Mycophenolate mofetil (MMF) (2.5 to 3.0 g/day orally) is a purine analogue similar to azathioprine, but with more specific inhibition of the de novo pathway in lymphocytes. This characteristic may allow for more efficacy and less toxicity in treating severe, recalcitrant CLE, and such results have been reported in several studies.[79–82] Although one study describes inefficacy of

MMF in CLE,[83] one of the authors (M.I.C.) has noted complete or partial response in most patients treated with an average daily dose of 3 g of MMF. Strict observance of dietary restrictions seems to enhance efficacy. Methotrexate (7.5 to 25.0 mg orally 1 day per week) is effective for severe refractory CLE. A double-blind, randomized, placebo-controlled trial in patients with SLE showed that moderate doses of methotrexate (15 to 20 mg weekly) effectively controlled cutaneous and articular activity and permitted a reduction in prednisone dose.[84] Leflunomide is an inhibitor of de novo pyrimidine synthesis that is approved for the treatment of rheumatoid arthritis. Several small series have reported beneficial results in SLE patients. However, there have also been reports of leflunomide-induced cutaneous lupus, thus this drug should be used carefully in patients with LE.[39]

Other immunosuppressives that have been used anecdotally include cytosine arabinoside and cyclosporine. Immunotherapy with high-dose intravenous γ globulin has also been used.

BIOLOGIC THERAPIES (See Chap. 235) There have been reports documenting efficacy of anti-TNF medications (etanercept, adalimumab, infliximab) in the treatment of recalcitrant CLE, particularly SCLE.[85–87] However, these agents are also well known to induce both SLE and CLE, highlighting the importance of TNF homeostasis in patients predisposed to LE.[30,38]

Rituximab, a genetically engineered chimeric monoclonal antibody directed against the CD20 antigen found on the surface of developing B cells, has been studied systematically in SLE and might also have use in CLE.[88] Epratuzumab, a monoclonal antibody against CD22 B-cell antigen, is another drug initially developed for non-Hodgkin lymphoma, and is being studied in murine lupus.[89] B-lymphocyte stimulator (BLyS) is a recently discovered member of the TNF cytokine family. BLyS is made by monocytes and macrophages with subsequent release when these cells are activated. BLyS binds to a receptor found only on B cells, which stimulates maturation into antibody-secreting plasma cells. A fully human monoclonal antibody directed against BLyS, belimumab, inhibits the biologic activity of BLyS. Belimumab was initially studied in murine lupus models, resulting in increased survival. A phase II trial showed improvement in patients with high titer dsDNA antibodies.[89]

Abatacept is a fully human recombinant fusion protein that selectively modulates T-cell activation by blocking co-stimulation via the B7 (CD80/86):CD 28 pathway. This results in decreased T-cell activation, proliferation, cytokine secretion, and subsequent autoantibody production without depletion of T or B cells. It has effectively prevented SLE onset in several murine models. Two observational studies are planned.[39] Modulation of T-cell activation by blocking co-stimulization is likely the same way efalizumab might impact recalcitrant CLE.

Efalizumab, a recombinant humanized monoclonal IgG1 antibody directed against CD11a/LFA-1, has been recently reported to be effective in SCLE.[90] In addition, a series of 15 therapeutically refractory DLE patients have been informally reported to have experienced good to excellent clinical responses to efalizumab with minimal adverse effects (personal communication, Dr. Mark Goodfield, September 2006). There is currently an ongoing phase II clinical trial in the United States of efalizumab in scalp DLE. Interestingly, there has been one report noting induction of SCLE in a patient treated with efalizumab for erosive lichen planus.[91]

As previously discussed under Dendritic Cells and Interferon-α, abnormal regulation of IFN-α appears to play a central role in the pathogenesis of both cutaneous and systemic manifestations of LE. A phase I clinical trial is currently underway in the United States that examines the clinical efficacy of a monoclonal antibody to IFN-α (MEDI-545-MedImmune) in LE skin lesions of various sub-types occurring in the context of SLE.

Surgical and Cosmetic Therapy

DLE lesions can produce permanent scarring alopecia, cosmetically disturbing dermal atrophy, and pigmentary changes. Patients so affected often ask about the possibility of cosmetic correction of these changes. Surgical interventions such as hair transplantation and dermabrasion carry finite risks because CLE is characterized by a tendency for non-specific mechanical trauma, including surgical incision or laser ablation, to exacerbate disease activity (i.e., Koebner phenomenon/isomorphic effect). Some patients tolerate scar revision techniques, including dermabrasion, if they are on maintenance systemic therapy (e.g., antimalarials). Anecdotal reports of the successful management of active CLE with argon and pulsed dye laser therapy have appeared. Resurfacing of atrophic scars with the erbium:yttrium-aluminum-garnet laser or carbon dioxide resurfacing laser has been reported to be beneficial.[92,93] The injection of atrophic lesions with collagen or other similar materials should be avoided.

PREVENTION

Predicting and preventing the initial clinical manifestation of LE, whether it is skin disease or systemic, is not feasible at this time. However, as many LE patients exhibit worsening of their skin disease activity with UV light exposure, physical protection from sunlight and artificial sources of UV light as well as the regular use of broad-spectrum sunscreens having a SPF of 30 or greater should be encouraged.

CHAPTER 157

Dermatomyositis

Richard D. Sontheimer
Melissa I. Costner

The idiopathic inflammatory myopathies (IIMs) are a heterogeneous group of genetically determined autoimmune disorders that predominately target the skeletal musculature and/or skin and typically result in symptomatic skeletal muscle weakness and/or cutaneous inflammatory disease (Table 157-1). This group of diseases was previously referred to as *polymyositis/dermatomyositis* (PM/DM). Among the IIMs, DM is of special interest to the dermatologist due the universal presence of a hallmark pattern of cutaneous inflammation. DM is the only IIM that expresses a characteristic pattern of primary cutaneous inflammation.

In this chapter, the term *classic DM* is used to refer to DM as traditionally defined (i.e., the concurrence of myositis resulting in clinically significant proximal muscle weakness and a set of hallmark inflammatory skin lesions occurring in a specific anatomical distribution). Also of interest to the dermatologist is the subgroup of patients who express the hallmark cutaneous manifestations of DM

TABLE 157-1
Dermatomyositis (DM)–Related Terminology Used in This Chapter[a]

TERM	DEFINITION
Amyopathic DM[b]	Subset of DM characterized by biopsy-confirmed hallmark cutaneous manifestations of classical DM occurring for 6 mo or longer with no clinical evidence of proximal muscle weakness and no serum muscle enzyme abnormalities. If more extensive muscle testing is carried out, the results should be within normal limits [if such results are positive or abnormal, the patient should be classified as having "hypomyopathic dermatomyositis" (see below)]. Exclusion criteria for amyopathic DM for the purpose of clinical studies include the following: 1. Treatment with systemic immunosuppressive therapy for 2 consecutive months or longer within the first 6 mo after skin disease onset (such therapy could prevent the development of clinically significant myositis). 2. Use of drugs known to be capable of producing isolated DM-like skin changes (e.g., hydroxyurea, statin cholesterol-lowering agents) at the time of onset of the cutaneous DM changes.
Classic DM	Presence of the hallmark cutaneous manifestations of DM, proximal muscle weakness, and objective evidence of muscle inflammation characteristic of DM.
Clinically amyopathic DM (CADM)	Functional umbrella designation that refers both to amyopathic DM and to hypomyopathic DM. This designation emphasizes that the predominant clinical problem is skin disease in affected patients.
DM sine myositis	Historic term synonymous with *clinically amyopathic DM*.
DM-specific skin disease	Clinicopathologic pattern of skin changes appearing only in DM (analogous to the concept of "lupus erythematosus–specific skin disease" proposed by Gilliam in 1975).[113]
Hallmark cutaneous lesions/changes of DM	Skin lesions that alone or in combination are seen only in patients with some form of DM (synonymous with *DM-specific skin disease*).
Hypomyopathic DM	DM-specific skin disease but no clinical evidence of muscle disease (i.e., no muscle weakness) but sub-clinical evidence of myositis on laboratory, electrophysiologic, and/or radiologic evaluation.
Idiopathic inflammatory dermatomyopathies (IIDMs)	More inclusive term used to designate the spectrum of illness that has conventionally been referred to as the *idiopathic inflammatory myopathies* and *dermatomyositis/polymyositis*.

[a]Derivation of new term discussed elsewhere.[1,2]
[b]Both adult-onset and juvenile-onset amyopathic DM and hypomyopathic DM can be subcategorized as "provisional" or "confirmed" when patients have biopsy-confirmed hallmark cutaneous manifestations of DM without muscle weakness and with normal muscle enzyme levels for ≥ 6 mo (provisional) or 24 mo (confirmed).[112]

DERMATOMYOSITIS AT A GLANCE

- Dermatomyositis (DM) is thought to evolve through multiple sequential phases: (1) a genetically determined susceptibility phase, (2) an induction phase triggered by an environmental stimulus (e.g., ultraviolet light, infection) involving loss of tolerance to self-antigens in skin and skeletal muscle, (3) an autoimmune expansion phase, and (4) an injury phase involving multiple immunologic effector mechanisms.
- All clinical types of the idiopathic inflammatory dermatomyopathies are rare, orphan diseases.
- Some clinical subphenotypes of DM such as clinically amyopathic DM have been underdiagnosed in the past, often being confused with isolated forms of cutaneous lupus erythematosus.
- Clinical features are a function of age of onset (e.g., juvenile-onset classic DM: vasculopathy, dystrophic calcification; adult-onset classic DM: associated occult malignancy, interstitial lung disease).
- The sine qua non of DM is a hallmark constellation of inflammatory skin changes presenting as patchy or confluent, macular, violaceous erythema that assumes a highly characteristic anatomic distribution and is often photoaccentuated. With time, additional diagnostic skin changes appear, including Gottron papules, prominent periungual nail fold microvascular changes, and poikiloderma atrophicans vasculare.
- Joint disease (arthritis/arthralgia), pulmonary disease (interstitial lung disease, aspiration pneumonia), esophageal disease (dysphagia), vasculopathic injury of multiple organ systems (gastrointestinal system, central nervous system, eye), and cardiac disease (conduction defects, cardiomyopathy) may be related features.
- Pathologic features include the following: In skin—a cell-poor interface dermatitis with dermal mucin accumulation; in muscles—a characteristic pattern of inflammatory myositis.

for prolonged periods (6 months or longer) without developing clinically evident muscle weakness. This pattern of DM expression is referred to as *clinically amyopathic DM* (CADM); this term is synonymous with the predominately historical designation, *dermatomyositis sine myositis*.

On occasion, other organ systems, such as the lungs (interstitial lung disease), joints (arthritis), and heart (cardiomyopathy, conduction defects), are targeted by inflammatory injury in IIM patients. In addition, differences exist between classic DM presenting in adults and that presenting in children. For example, juvenile-onset classic DM is associated with higher rates of vasculopathy/vasculitis resulting in the complication of dystrophic calcification, whereas adult-onset classic DM is associated with a significantly increased risk of internal malignancy and interstitial lung disease.

The diagnostic criteria for DM under the current consensus IIM classification system have not allowed for the inclusion of cutaneous-only or cutaneous-predominant subsets of DM, such as amyopathic DM and hypomyopathic DM, which together are referred to here as CADM. A more inclusive disease category designation, "idiopathic inflammatory dermatomyopathies" (IIDM), has been proposed by one of the authors (R.D.S.) as an alternative to the "IIM" designation because it allows for the inclusion of these cutaneous subsets of DM[1] (Table 157-2). For further discussion, the reader is referred to several comprehensive reviews of all aspects of DM,[1–16] including a historical perspective emphasizing the cutaneous manifestations of DM.[2]

Thus, IIDM represents a heterogeneous group of clinical disorders that can be conveniently conceptualized as a continuum of illness with subgroups of patients who share common clinical and immunologic features at distinct positions along this spectrum (Fig. 157-1).

TABLE 157-2
Comprehensive Classification of Idiopathic Inflammatory Dermatomyopathies

Dermatomyositis (DM)
- Adult onset
  - Classic DM
    - ~ Classic DM alone
    - ~ Classic DM with malignancy
    - ~ Classic DM as part of an overlap connective tissue disorder
  - Clinically amyopathic DM
    - ~ Amyopathic DM
    - ~ Hypomyopathic DM
- Juvenile onset
  - Classic DM
  - Clinically amyopathic DM
    - ~ Amyopathic DM
    - ~ Hypomyopathic DM

Polymyositis (PM)
- PM alone
- PM as part of an overlap connective tissue disorder
- PM associated with internal malignancy[a]

Inclusion Body Myositis

Other Clinical-Pathologic Subgroups of Myositis
- Focal myositis
- Proliferative myositis
- Orbital myositis
- Eosinophilic myositis
- Granulomatous myositis

[a]Although population-based European studies have now clearly confirmed that adult-onset classic DM is associated with a significant risk for internal malignancy, if such a relationship exists for PM, it is much weaker.

EPIDEMIOLOGY

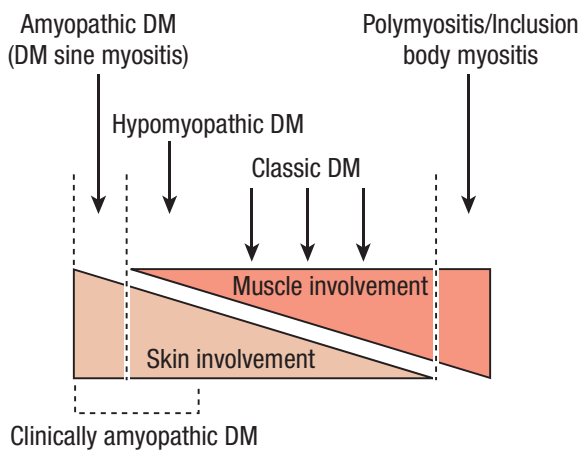
Classic Dermatomyositis

Cutaneous involvement occurs in 30 percent to 40 percent of adults and in 95 percent of children with IIDM. By definition, skin disease is absent in patients with PM and present in 100 percent of patients with classic DM and CADM. Skin disease activity can precede muscle disease activity in classic DM by weeks to several months.

Classic DM can occur from infancy to adulthood and most frequently presents in the fifth and sixth decades (PM is extremely rare in children). The incidence of classic IIDM between 1963 and 1982 was estimated to be 5.5 cases per million. The incidence probably is higher, inasmuch as this study[16a] was based only on hospital inpatient–ascertained diagnoses and did not include cases of CADM. Black women during their childbearing years were affected most frequently, and DM might be underdiagnosed in blacks because of the more subtle coloration of inflammatory changes in their skin. More recent reports from Asia have indicated that individuals of those ethnic backgrounds with classic DM are more likely to be male than female (females are affected twice as often as males in white populations). DM-associated interstitial lung disease appears to occur more commonly in Japanese patients than in other ethnic groups. Familial concordance occurs rarely, and concordant disease expression has been reported in identical twins.

The epidemiology of juvenile-onset classic DM in the United States has been reviewed.[17] For children 2 to 17 years of age, the estimated annual incidence rates from 1995 to 1998 in the United States ranged from 2.5 to 4.1 cases per million children, and the 4-year average annual rate was 3.2 per million children. Estimated annual incidence rates by race were 3.4 for white non-Hispanics, 3.3 for African American non-Hispanics, and 2.7 for Hispanics. Girls were affected more than boys (ratio of 2.3:1). Cutaneous ulceration occurring as a result of infarctive vasculopathy and subsequent calcification is more common in the childhood form of the disease.

Environmental factors have been implicated as disease triggers. Seasonality has been noted in both juvenile-onset and adult-onset classic DM, which suggests the possibility of an infectious etiology. DM- and PM-like syndromes



▲ **FIGURE 157-1** Graphic representation of the relationships between the cutaneous and muscular manifestations of the idiopathic inflammatory dermatomyopathies, including the nosologic entities within this spectrum of illness. DM = dermatomyositis.

have been reported in patients infected with coxsackievirus, parvovirus B19, Epstein-Barr virus, human immunodeficiency virus, and human T-cell leukemia virus type 1.

Approximately 50 percent of DM patients experience an exacerbation of their skin disease activity as a result of exposure to sunlight. It has been suggested that the intensity of global surface ultraviolet radiation may modulate the clinical and immunologic expression of autoimmune disorders such as the IIDM.[18]

In addition, exposure to drugs such as hydroxyurea, penicillamine, statin-type cholesterol-lowering agents, niflumic acid/diclofenac, phenytoin, tryptophan, and practolol can induce skin changes that mimic both classic DM and CADM.[1,19]

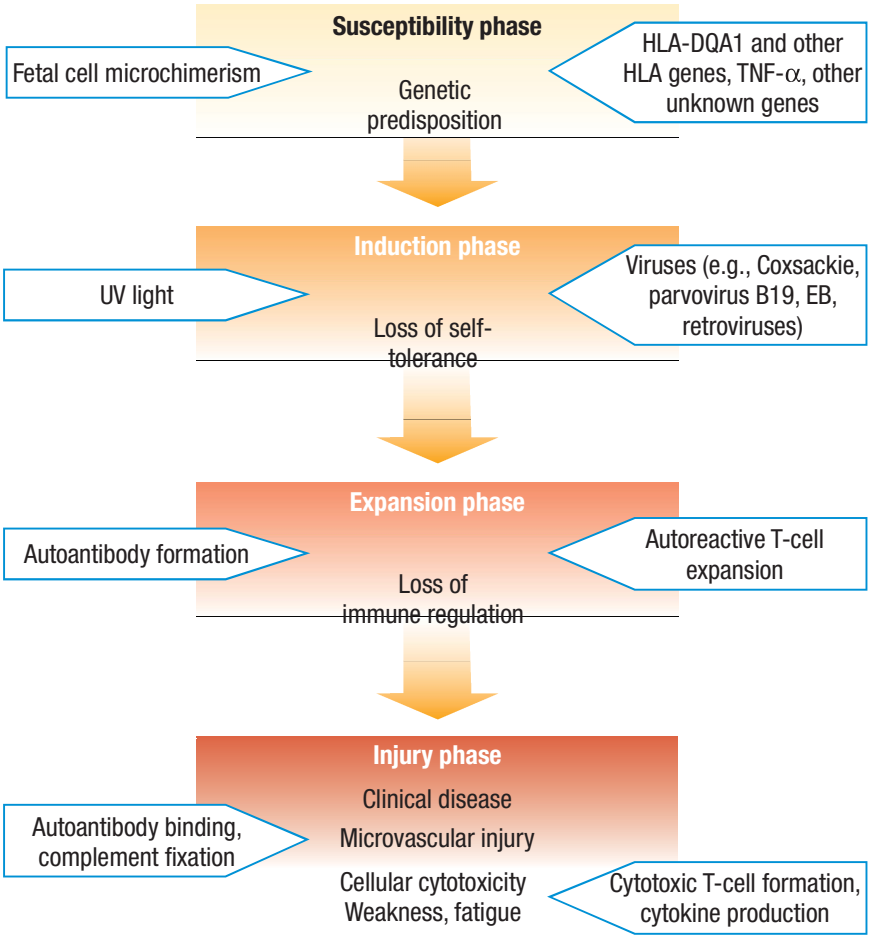
Clinically Amyopathic Dermatomyositis

The prevalence of CADM in the United States is unknown, because no such population-based studies concerning this question have yet been carried out.

A systematic review of the published literature on adult-onset CADM has been presented.[24] Two hundred ninety-one reported cases of adult-onset CADM (18 years or older) in over 19 countries were analyzed. The average duration of DM skin disease was 3.74 years [range, 6 months (by definition) to 20 years], and 73 percent of cases were females. Among 37 patients with hypomyopathic DM who were identified, the average duration of disease was 5.4 years, and none had developed clinically significant weakness at the time the case reports were published. Thirty-seven of the reported CADM patients developed muscle weakness longer than 6 months after onset of their skin disease (15 months to 6 years). The data for such patients were subanalyzed under the designation "CADM evolving to classic DM." Somewhat surprisingly, 36 of 291 (13 percent) of the identified reported patients with adult-onset CADM developed interstitial lung disease.

Very little information currently exists about the incidence of juvenile-onset CADM. In a retrospective analysis of data for all children with DM seen at an academic medical center in Pennsylvania between 1968 and 1998, 2 of 16 (12 percent) were categorized as having CADM.[25] A systematic review of the published literature on juvenile-onset CADM has recently been performed that included 69 cases of juvenile-onset CADM reported from 1963 to 2005.[26] Of these, 38 (56 percent) could be subclassified as juvenile-onset amyopathic DM and 12 (18 percent) as juvenile-onset hypomyopathic DM. In 18 (26 percent) of the patients identified as having juvenile-onset CADM, the disorder was reported to have subsequently evolved into juvenile-onset classic DM. Overall, the mean age at diagnosis was 10.5 years (range, 2 to 17 years), with a nearly equal number of males and females affected. The mean follow-up time was 3.9 years.

As previously mentioned (see Classic Dermatomyositis), certain drugs can induce cutaneous DM-like skin changes in the absence of systemic manifestations of IIDM.[1,19] Such drug-induced syndromes can simulate CADM. Long-term hydroxyurea therapy for chronic myelogenous leukemia can produce a DM-like cutaneous eruption that is clinically and histopathologically similar to that of idiopathic DM-specific skin disease.[27] However, muscle weakness and other systemic symptoms are absent. Painful leg ulcers are often seen in association, as are xerosis and cutaneous atrophy. This symptom complex usually occurs only after the patient has been treated with hydroxyurea for long periods (2 to 10 years). The presence of concurrent therapy with hydroxyurea has been proposed as the exclusion criterion for CADM.[1] The other drug class most frequently implicated in this regard has been the statin-type cholesterol-lowering agents.



▲ **FIGURE 157-2** Etiology and pathogenesis of dermatomyositis: Current concepts. See text for discussion. EB = Epstein-Barr; TNF-α = tumor necrosis factor-α; UV = ultraviolet.

ETIOLOGY AND PATHOGENESIS

The inflammatory nature of the muscle and skin manifestations coupled with the characteristic humoral autoimmune abnormalities has led to the hypothesis that DM results from a genetically determined, aberrant autoimmune response to environmental agents. Fig. 157-2 presents a summary overview of current thought in this area. Like other systemic autoimmune diseases involving autoantibody production such as systemic lupus erythematosus (SLE), DM is thought to evolve through multiple sequential phases: the susceptibility phase, the induction phase, the expansion phase, and the injury phase.

TABLE 157-3
Autoantibodies in the Idiopathic Inflammatory Dermatomyopathies

Autoantibody	Median Prevalence[a]	Molecular Specificity	Clinical Association
High Specificity for DM/PM			
155 kd and/or Se	20–80%	Uncharacterized polypeptides	Classic DM, clinically amyopathic DM (?)
140 kd	53%	Uncharacterized polypeptides	Clinically amyopathic DM (?)
Jo-1	20%	Histidyl tRNA synthetase	PM, antisynthetase syndrome
Mi-2	15%	Helicase nuclear proteins	Shawl sign, cuticular overgrowth
SRP	5%	Signal-recognition particle	Fulminant DM/PM, cardiac involvement
PL-7	3%	Threonyl tRNA synthetase	Antisynthetase syndrome
PL-12	3%	Alanyl tRNA synthetase	Antisynthetase syndrome
OJ	Rare	Isoleucyl tRNA synthetase	Antisynthetase syndrome
EJ	Rare	Glycyl tRNA synthetase	Antisynthetase syndrome, possibly increased frequency of skin changes
Fer	Rare	Elongation factor 1α	—
Mas	Rare	Small RNA	—
KJ	Rare	Translation factor	—
Low Specificity for DM/PM			
ANA (most common nuclear immunofluorescence patterns—specked and nucleolar)	40%		Clinically amyopathic DM (80%)
ssDNA	40%		SLE, SSc
PM-Scl (PM-1)	40%	Ribosomal RNA processing enzyme	Overlap with scleroderma
Ro (52-kd Ro)	15%	RNP	Overlap with SSJ, SCLE, neonatal LE/CHB, SLE
U1RNP	10%	U1RNP	Overlap connective tissue disease
Ku	3%	DNA end-binding repair protein complex	Overlap with scleroderma
U2RNP	1%	U2RNP	Overlap with scleroderma

ANA = anti-nuclear antibody; CHB = chronic hepatitis B; DM = dermatomyositis; LE = lupus erythematosus; PM = polymyositis; ssDNA = single-stranded DNA; SLE = systemic lupus erythematosus; SRP = signal recognition particle; SSc = systemic sclerosis; SSJ = Sjögren syndrome; tRNA = transfer RNA.
[a]Using current assay techniques.

The susceptibility phase of DM is thought to result largely from a genetic predisposition. DM is one of the human autoimmune diseases that is linked to the 8.1 ancestral haplotype (HLA-A1, C7, B8, C4AQ0, C4B1, DR3, DQ2).[28] PM and DM have been specifically associated with HLA-B8, DR3, and DRw52, especially in white patients. This association is likely a result of linkage disequilibrium with HLA-DQA1*0501. The production of antisynthetase antibodies such as Jo-1 is strongly linked to HLA-DR3 and even more strongly linked to its super-typic specificity HLA-DRw52.

A single nucleotide polymorphism in the tumor necrosis factor-α promoter (TNF-α308A), which is also a component of the 8.1 ancestral haplotype, has been associated with disease chronicity, calcinosis, and high levels of TNF-α in a cohort of white patients with juvenile-onset classic DM.[29] This same TNF-α promoter polymorphism has been associated with photosensitive subacute cutaneous LE.[32] This same TNF-α promoter polymorphism has been associated with photosensitive subacute cutaneous LE.[30] In addition, several gene polymorphisms associated with low production of mannose-binding protein, a molecule involved in the physiologic clearance of apoptotic cells, have been associated with adult DM.[31] There has also been a single case report of adult-onset CADM that evolved to classic DM in a young Japanese woman who was shown to be genetically deficient in the fifth component of complement.[32]

The cutaneous manifestations of DM are precipitated or exacerbated by natural and artificial sources of ultraviolet light. Approximately 50 percent of patients with DM experience photosensitivity. The action spectrum appears to include both ultraviolet B and ultraviolet A light. Environmental stimuli, including ultraviolet radiation and infection, could represent inductive factors in DM leading to loss of self-tolerance. Various types of infections have been circumstantially implicated as causative factors in DM. These include infection with RNA viruses such as coxsackievirus, echovirus, and human retroviruses (i.e., human T-cell leukemia/lymphoma virus type 1 and human immunodeficiency virus). Nonviral pathogens such as *Toxoplasma gondii* have also been implicated. However, repeated attempts to confirm persistent myotropic infection by viruses or other pathogens have not been successful.

The expansion phase of DM is marked by autoantibody production signaling the loss of normal immune regulation. DM is associated with the production of a number of specific autoantibodies that probably predates by some period the first evidence of clinical disease activity (Table 157-3). Whether these autoantibodies are truly pathogenetic or represent only a by-product of muscle injury is unknown. It has been suggested that CADM might be associated with a specific autoantibody profile (antibodies to 140-kd, 155-kd, and Se antigens).[33,34]

It is thought that autoantibodies, immune complexes, and/or autoreactive T cells play a major role in the tissue injury phase of DM. Cell-mediated immune activity against muscle autoantigens is thought to be primarily responsible for the muscle injury that occurs in PM. Both myocytotoxic $CD3^+$ T-cell clones and non–HLA-restricted myocytotoxic cells of other lineages have been identified in the peripheral blood of patients with inflammatory myopathies.[35] Little has been done in the past experimentally to date to probe for T-cell–mediated cytotoxic epidermal or dermal cell injury in DM skin lesions.

Predominately humoral autoimmune mechanisms targeting the microvasculature have been implicated in the pathogenesis of muscle injury in DM. Microvascular ischemia is an early feature of DM muscle involvement. Components of the C5 to C9 membrane attack complex are regularly found in the walls of microvessels in muscle biopsy specimens from DM patients.

There is not always good agreement between the degree of muscle weakness or fatigue experienced by patients with classic DM and the degree of inflammation noted in muscle biopsy specimens and the elevation of serum muscle enzyme levels. This observation has led to the idea that inflammatory cytokines might be capable of mediating metabolic disturbances within muscle that can exacerbate muscle weakness and fatigue.[36] As with other rheumatic diseases such as systemic sclerosis, maternal microchimerism has been observed in children with juvenile classic DM.[37] The pathogenetic significance of the presence of alloreactive maternal lymphoid cells in the circulation, muscle, and skin of patients with juvenile DM is unknown.

The pathogenesis of cutaneous inflammation in classic DM and CADM and has received little attention, owing in part to the lack of an experimental animal model of this pattern of cutaneous inflammation. Histopathologic analysis of cutaneous DM reveals three general abnormalities: (1) a cell-poor interface dermatitis, (2) a vasculopathy of dermal microvessels, and (3) prominent dermal mucin deposition. These histopathologic elements can be precipitated or exacerbated by exposure to ultraviolet radiation.

The predominate infiltrating cell types in hallmark inflammatory DM skin lesions are activated macrophages and CD4 memory phenotype T cells (45RO) that are focused around microvessels in the dermis.[39] Plasmacytoid dendritic cells, a potent cellular source of interferon-α, have been shown to be present in substantial numbers in affected DM muscle[40,41] and skin tissue.[42] In addition, products of genes induced by interferon-α/β, including the myxovirus-resistance protein A (MxA) and the CXCL10 chemokine ligand (syn. IP10), are also highly overexpressed in DM muscle tissue[39] and skin tissue.[42] These observations have been used to support a hypothesis that T cells bearing the CXCR3 chemokine receptor are recruited into the skin of DM patients by CXCL10 after the local cutaneous generation of type I interferons (α/β) by activated plasmacytoid dendritic cells. The recruited CXCR3 receptor-bearing T cells then produce a T helper 1–biased immune effector reaction that results in features of cutaneous DM, including the characteristic interface dermatitis and microvascular endothelial cell injury.[42]

The dermal microvasculature is more prominently altered in cutaneous DM than in cutaneous lupus erythematosus (LE). It has been suggested that humoral factors can produce microvascular injury by triggering local activation of complement with deposition of C5 to C9, perhaps through endothelial-specific autoantibodies. Class II histocompatibility antigen expression by dermal endothelial cells is decreased in DM skin lesions, and this cell type appears to display an activation phenotype with respect to expression of adhesion molecules (intercellular adhesion molecule 1, vascular cell adhesion molecule 1, and E-selectin). The net effect of microvascular injury in cutaneous DM is dropout of microvessels, which results in microvascular ischemia.

CLINICAL FINDINGS

Approach to the Patient

The approach to a new patient with cutaneous DM is presented in Fig. 157-3.

History

In 60 percent of patients with classic DM, the cutaneous lesions and muscle weakness present simultaneously. In 30 percent of patients, the cutaneous findings appear before the onset of muscle weakness. In 10 percent, muscle weakness precedes the appearance of skin lesions. The onset of cutaneous disease is typically accompanied by pruritus and/or a burning skin sensation. Sensitivity to sunlight or artificial sources of ultraviolet light is often present. Muscle weakness initially affects the shoulder and hip girdle musculature, presenting clinically as difficulty raising the arms above the head and arising from a sitting position. Weakness can be accompanied by muscle pain and tenderness.

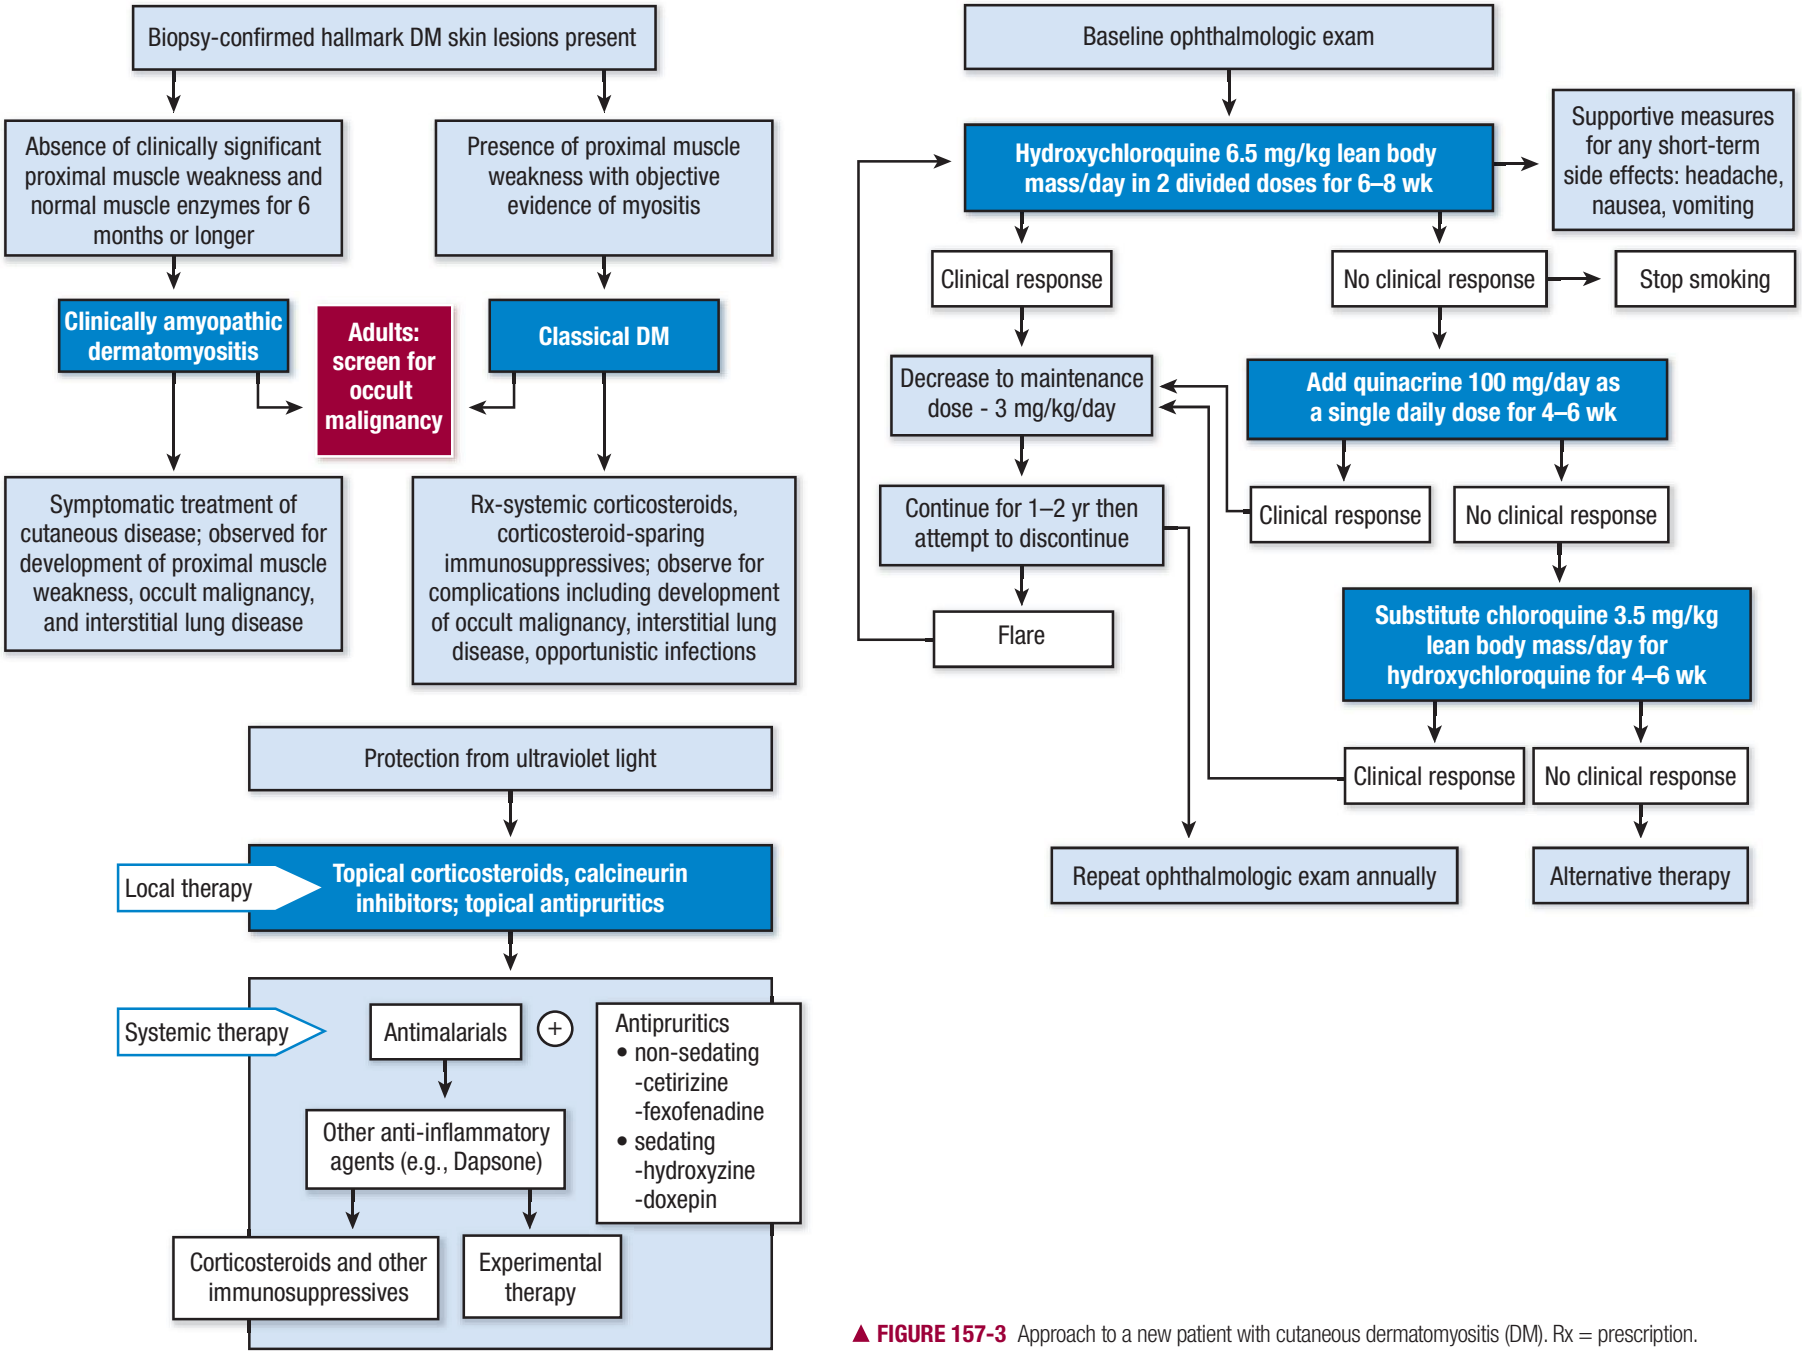
Cutaneous Lesions

HALLMARK SKIN LESIONS Table 157-4 presents the hallmark cutaneous manifestations of DM (to date, no recognizable differences in the clinical, histopathologic, and immunopathologic manifestations of classic DM and CADM have been reported). Some of these lesions, such as Gottron sign of DM (Fig. 157-4) and Gottron papules (see Fig. 157-4; Fig. 157-5), are pathognomic of this disease, whereas others, such as periorbital, confluent, macular, violaceous (heliotrope) erythema/edema and grossly visible periungual telangiectasia associated with dystrophic cuticles, are highly characteristic.

The primary skin change of DM is a highly characteristic, often pruritic, symmetric, confluent, macular violaceous erythema variably affecting the skin overlying the extensor aspect of the fingers, hands, and forearms; the arms, deltoid areas, posterior shoulders, and neck (the shawl sign); the V area of the anterior neck and upper chest; and the central aspect of the face, periorbital areas, forehead, and scalp (Figs. 157-6 and 157-7). Central facial involvement can occasionally simulate the appearance of seborrheic dermatitis with nasolabial fold involvement. The lateral aspects of the hips and thighs (holster sign) are also frequently involved.[44] Lesions such as poikiloderma atrophicans vasculare (poikilodermatomyositis) (see eFig. 157-7.1 in on-line edition) and calcinosis cutis are often present in patients with DM but may also appear in patients with cutaneous T-cell lymphoma (poikiloderma atrophicans vasculare) and scleroderma (SCL; calcinosis cutis). In addition, overlapping features of cutaneous DM and cutaneous SCL (see Chap. 158) can occur in the same individual (sclerodermatomyositis).

Table 157-5 presents the characteristic anatomic distribution of the hallmark cutaneous manifestations of DM. There is very little published information on the prevalence of involvement in these different anatomic locations. In some series reported by dermatologists, Gottron papules have been more commonly seen than periorbital heliotrope erythema, which by many outside of dermatology is felt to be the hallmark cutaneous manifestation of DM.

The violaceous hue of the cutaneous inflammation in lightly pigmented individuals is a striking clinical finding that usually is evident from the outset of disease activity. This hue helps to distinguish cutaneous DM from cutaneous LE, in which it is a late finding when present. It has been suggested that edema associated with the DM skin disease indirectly produces the violaceous hue by displacing the hyperemic cutaneous vasculature more deeply into the dermis. One might also speculate that this could result from the deoxygen-



▲ **FIGURE 157-3** Approach to a new patient with cutaneous dermatomyositis (DM). Rx = prescription.

TABLE 157-4
Classic Cutaneous Manifestations of Dermatomyositis (DM)

Pathognomonic

1. Gottron papules
   Papules with a violaceous hue typically overlying the dorsal-lateral aspect of interphalangeal and/or metacarpophalangeal joints. When typically fully formed, these papules become slightly depressed at the center, which can assume a white, atrophic appearance. Associated lacy scale and telangiectasia can be present.
2. Gottron sign of DM
   Symmetric confluent macular violaceous erythema with or without associated edema overlying the dorsal aspect of the interphalangeal/metacarpophalangeal joints, olecranon processes, patellae, and medial malleoli.

Characteristic

1. Periorbital confluent macular violaceous (heliotrope) erythema with or without associated edema of the eyelids and periorbital tissue.
2. Grossly visible periungual telangiectasia with or without dystrophic cuticles and cuticular hemorrhage.
3. Symmetric confluent macular violaceous erythema overlying the dorsal aspect of the hands and fingers (where it can track along the extensor tendons), extensor aspects of the arms and forearms, deltoids, posterior shoulders and neck (shawl sign), V area of anterior neck and upper chest (V sign), central aspect of the face and forehead, and scalp.
4. Mechanic's hand lesion
   Bilaterally symmetric confluent hyperkeratosis having the appearance of that produced by manual labor distributed along the ulnar aspect of the thumb and radial aspect of the fingers; also prominent on the index and middle fingers with occasional extension to the palmar surfaces.

Compatible with dermatomyositis

1. Poikiloderma atrophicans vasculare (poikilodermatomyositis)
   Circumscribed violaceous erythema with associated telangiectasia, hypopigmentation, hyperpigmentation, and superficial atrophy most commonly found over the posterior shoulders, back, buttocks, and V area of the anterior neck and chest. Often asymmetric.
2. Calcinosis cutis

Baltimore, Williams & Wilkins, 1996, p 73, and Euwer RL, Sontheimer RD: Dermatologic aspects of myositis. *Curr Opin Rheumatol* **6**:583, 1994, with the permission of Current Sciences and Williams & Wilkins.

ation of blood flowing through an abnormal dermal microvascular bed. In this regard, it is interesting to note that cutaneous DM often presents in the skin over joints that is frequently stretched and thus often made to become transiently ischemic under normal physiologic conditions.

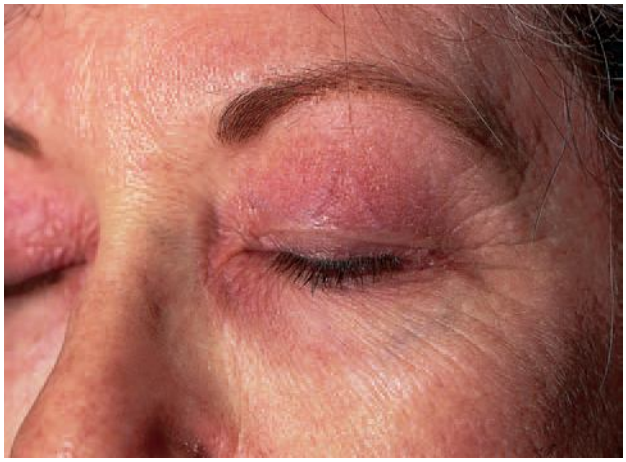
A striking clinical feature that helps to distinguish cutaneous DM from cutaneous LE is pruritus, which can be so severe in DM as to be disabling, even in the absence of systemic involvement. In addition to pruritus, DM patients often described severe burning, painful sensations associated with the DM skin inflammation. Some work has suggested that severe DM skin disease can have a greater impact on quality of life than other skin diseases such as psoriasis and atopic dermatitis for which aggressive systemic immunomodulatory therapies are often used.[48]

A number of other skin changes can be encountered in patients with DM. Hyperkeratosis may follow the onset of the confluent, macular, violaceous erythema; however, the scale in DM skin lesions is usually less prominent than that in subacute cutaneous LE and discoid LE. Secondary skin changes in DM skin lesions include excoriation with secondary infection and ulceration. Sub-epidermal vesicles and/or bullae occasionally occur in areas of particularly intense cutaneous inflammation. Post-inflammatory pigmentary changes, both hyperpigmentation and hypopigmentation, occur. Older lesions may have white lacy markings somewhat similar to those of Wickham's striae in lichen planus. Another similarity between cutaneous DM and lichen planus is the characteristic violaceous hue. Mucinous infiltration, a common histologic finding in the dermis of DM skin lesions, can be clinically prominent, producing an infiltrated, glistening appearance. Superficial erosions and ulcers can subsequently develop over the face and eyelids as well

▲ **FIGURE 157-4** Hand of a 30-year-old woman with a 15-year history of amyopathic dermatomyositis (DM). Note the confluent macular violaceous erythema, most pronounced over the metacarpophalangeal/interphalangeal joints, extending in a linear array overlying the extensor tendons of the hand and fingers. These changes, referred to as *Gottron sign*, are a hallmark cutaneous feature of DM. Early Gottron papules, an extension of Gottron sign, can be seen over the distal interphalangeal joints along with periungual erythema and dystrophic cuticles. In DM, the violaceous erythema is centered over the metacarpophalangeal/interphalangeal joints, whereas in lupus erythematosus these areas are relatively spared.

▲ **FIGURE 157-5** Fingers of an elderly woman with classic dermatomyositis (DM). Note the fully formed Gottron papules over the distal interphalangeal joints, a hallmark cutaneous feature of DM. Prominent grossly visible nail fold telangiectasias are also present, along with dystrophic cuticles. The combination of Gottron papules and nail fold changes such as these is pathognomic for DM. Such changes are seen to an equal degree in classic DM and amyopathic DM.

▲ **FIGURE 157-6** The confluent, macular, violaceous erythema of the V area of the upper chest and neck (V sign), when persistent over time, can evolve into poikilodermatous skin changes. Less evident in this photograph are periorbital edema and confluent, macular, violaceous (heliotrope) erythema of the upper eyelids. Note the absence of involvement of the malar areas, which are often involved in lupus erythematosus.



▲ **FIGURE 157-7** Periorbital confluent, macular, violaceous (heliotrope) erythema most prominent on the upper eyelids. Like Gottron papules and Gottron sign, this is a hallmark cutaneous feature of dermatomyositis.

as in other areas affected by intense and protracted inflammation. Deep, irregular, retiform ulcers can also develop in areas of poikiloderma in both adults and children. It has been suggested that the penetrating ulcers reflecting vasculopathy can be a bad prognostic sign in both juvenile-onset and adult-onset DM.

Clinical experience suggests that, as with cutaneous LE/SLE, the activity of IIDM can be precipitated or exacerbated by emotional and physical stress, although there is scant published evidence. Strenuous physical exertion can be detrimental to patients who have active myositis.

Magnetic resonance imaging (MRI) may identify edema/inflammation in skin, subcutaneous tissue, and fascia resulting from vasculopathy and vasculitis in patients with classic juvenile DM.[49] In approximately 80 percent of the 26 children studied, MRI abnormalities indicating skin, subcutaneous, and/or fascial edema were observed. Clinical skin disease activity scores correlated positively with MRI skin edema scores. Five children developed soft tissue calcification in areas previously found to be edematous by MRI after 4- to 9-month follow-up intervals. These observations suggest that the assessment of soft tissue by MRI could be of value in predicting risk for developing calcification and in monitoring treatment to prevent or minimize it.

Dystrophic calcification appears to be quite uncommon in both adult- and juvenile-onset CADM (see Fig. 138-1). Little relationship was found between MRI indices of edema/inflammation in the superficial (skin and subcutaneous tissue) and deep (fascial and muscle) tissue compartments of patients with juvenile-onset classic DM.[49]

DM can develop as a component of an overlap connective tissue disorder. Most common are overlaps with SLE (see Chap. 156) and systemic sclerosis (see Chap. 158). Raynaud phenomenon, sclerodactyly, sclerosis of the skin, and the characteristic hyperpigmentation can all be present in the latter setting. The term *sclerodermatomyositis* describes

TABLE 157-5
Anatomic Distribution of Hallmark Cutaneous Manifestations of Dermatomyositis

ANATOMIC LOCATION	LESIONS
Scalp	CMVE; non-scarring diffuse alopecia
Face	
Periorbital region	CMVE (usually most intense on the upper eyelids), edema
Malar eminences	CMVE sparing or involving the nasolabial fold[114]
Forehead, chin	CMVE
Neck and shoulders	
Anterior	CMVE evolving to poikiloderma
Posterior	CMVE (shawl sign)
Upper extremities	
Arms, forearms	CMVE on the extensor aspects
Elbows	CMVE usually most intense in this location (Gottron sign of dermatomyositis)
Hands, fingers	
Dorsal aspect	CMVE usually most intense over the extensor tendons and metacarpophalangeal/interphalangeal joints (Gottron sign), Gottron papules overlying the dorsal-lateral aspect of the metacarpophalangeal/interphalangeal joints, relative sparing of the dorsal aspects of the phalanges, periungual nail fold telangiectasia (often grossly visible), cuticular microvascular hemorrhage, dystrophic/ragged cuticles
Palmar aspect	Mechanic's hand lesion, mucinous plaques centered over the flexural creases
Trunk	CMVE evolving to large areas of poikiloderma (poikiloderma atrophicans vasculare) commonly seen over the flanks and lower back
Lower extremities	
Thighs	CMVE (holster sign)
Knees	CMVE (Gottron sign)
Lower legs, feet	CMVE, often focal, centered over the medial malleoli; Gottron sign overlying the medial malleoli

CMVE = confluent, macular, violaceous, erythema.

the disorder in patients who present with DM and who develop striking features of SCL 6 months to 3 years later. In addition, myositis occurs in approximately 5 percent of patients who test positive for anti–Ro/SSA autoantibody (most of whom have Sjögren syndrome (see Chap. 162). The cutaneous manifestations of DM are not usually found in this setting.

The highly pruritic/burning scaling scalp involvement in patients with adult-onset classic DM and CADM that can be associated with non-scarring alopecia[50] has also been found to occur in approximately 25 percent of patients with juvenile-onset DM.[25] Localized scalp involvement can at times be the presenting manifestation of DM.

OTHER ASSOCIATED SKIN LESIONS

Systemic Features

Table 157-6 outlines the systemic manifestations and associations of classic IIDM. Most of the extramuscular systemic features associated with classic DM have not been reported in CADM except for arthritis and interstitial lung disease.

MUSCLE DISEASE Muscle involvement typically presents as symmetric weakness of the proximal muscles of the extremities. Lower-extremity weakness manifested as difficulty in performing routine activities of daily living, such as rising from a chair or bathtub and climbing stairs, is often the initial clinical finding. Weakness of the upper extremities soon follows, often manifested by difficulty in raising the arms above the head to perform routine activities such as combing the hair. Pain or tenderness in the affected muscle groups commonly occurs. Some patients experience a fulminant disease course that results in disabling weakness within a few weeks. Weakness involving the upper one-third of the esophagus and/or the laryngopharyngeal muscles may present as dysphagia or a hoarse voice (dysphonia), respectively.

Confirmation that proximal muscle weakness is caused by the inflammatory myositis of IIDM can be difficult, because so many other clinical disorders produce proximal muscle weakness (Table 157-7). The diagnosis can be supported by demonstration of characteristic elevations in serum levels of muscle enzymes (CK, aldolase) as well as identification of diagnostic changes in electromyography (EMG) results, muscle imaging, and muscle biopsy specimens. Some patients with CADM have low-grade, sub-clinical muscle disease (i.e., hypomyopathic DM). However, in some patients who express the hallmark cutaneous manifestations of DM, no symptoms of muscular weakness have developed for up to 28 years (unpublished personal observation, R.D.S.).

Inclusion-body myositis is a pathologically distinctive type of steroid-resistant myositis that more commonly affects the distal muscle groups of men in an asymmetric pattern. Cutaneous involvement is not seen with this disorder or with classic PM.

A retrospective analysis encompassing all patients with DM seen at the Mayo Clinic between 1976 and 1994 revealed that 32 (4 percent) of 746 patients conformed to the definition of CADM[57]; 27 had amyopathic DM and 5 had what can be classified as hypomyopathic DM. Follow-up information was available on 16 of the patients with amyopathic DM. Ten had no muscle weakness after 2 to 10 years, four had no weakness at 1 year, and two developed weakness within 5 years after diagnosis. None of the three patients classified as having hypomyopathic DM showed evidence of muscle weakness 8 to 17 years after diagnosis. Thus, of these 19 patients with CADM, only 2 developed clinical evidence of myositis after prolonged periods of time. Therefore, the presence of sub-clinical muscle abnormalities at the time of diagnosis of CADM does not necessarily portend the subsequent development of clinically significant muscle disease.

For the definition of CADM to be fulfilled, clinical evidence of muscle weakness should not be present. Muscle strength testing is graded on a scale of 1 to 5, where 0 = no muscle action; 1 = trace contraction; 2 = visible contraction but with inability to overcome gravity; 3 = fair contraction with ability to overcome gravity; 4 = contraction with ability to offer some resistance; 5 = muscle contraction that cannot be overcome by the evaluator. The examination should focus on the proximal muscle groups that control the neck, shoulders, and hips. Manual muscle testing is reproducible; variables such as pain, contractures, voluntary effort, and motivation may influence the ability of an individual to exert maximal muscle effort.

PULMONARY DISEASE Among the most feared nonmuscular systemic manifestations of IIDM is pulmonary disease. Lung function can be compromised in a number of ways in patients with classic DM: by a restrictive lung defect resulting from

TABLE 157-6
Systemic Manifestations/Associations of Dermatomyositis/Polymyositis

respiratory muscle weakness; by aspiration pneumonia secondary to gastrointestinal reflux and impaired esophageal muscle function; by opportunistic infections; or by interstitial pneumonitis related to the underlying autoimmune disease process. In addition, some systemic drugs used to treat DM can produce pulmonary complications (e.g., methotrexate hypersensitivity pneumonitis).

Interstitial pneumonitis resulting from both classic DM and CADM has been reviewed.[61,62] Between 5 percent and 40 percent of patients with classic DM develop interstitial lung disease [high-resolution chest computed tomographic (CT) scan can identify lung involvement earlier than can routine chest radiography]. This complication presents clinically with symptoms of nonproductive cough and exertional dyspnea that are accompanied by bibasilar fine crackling rales. Pulmonary function test results show a restrictive pattern with reduced diffusion capacity. Several clinical patterns of interstitial lung disease have been described: usual interstitial pneumonia, non-specific interstitial pneumonia, diffuse alveolar damage, and bronchiolitis obliterans with organizing pneumonia.

Interstitial lung disease can present clinically as an acute/subacute type or a chronic type. In the acute/subacute type, patients experience severe, rapidly progressive dyspnea and progressive hypoxemia within a month of the onset of lung involvement. In such cases, the lung disease is often resistant to treatment, and patients are at risk for death. In the chronic type, patients experience a much slower pace of progressive dyspnea. Interstitial lung disease can also be identified by chest CT and/or pulmonary function tests in the complete absence of symptoms. It has been suggested that interstitial lung disease associated with the myositis-specific autoantibodies (antisynthetases) can occasionally occur in the absence of skin and muscle disease.[63] In some individuals, interstitial lung disease occurs before the clinical appearance of myositis. Patients with classic DM who have the antisynthetase syndrome (the presence of Jo-1, PL-7, PL-12, or other synthetase autoantibodies; arthritis; Raynaud phenomenon) have increased risk of developing interstitial lung disease. The antisynthetase syndrome and interstitial pneumonitis occur also in children with classic DM. Interstitial pneumonitis and air leakage were observed in one child with classic juvenile DM.[64]

Interstitial pneumonitis of various sub-types is increasingly being recognized as a potential complication of CADM.[24,65] Published data indicate that the prevalence of interstitial pneumonitis in CADM is approximately 13 percent.[24] A disproportionately high percentage of patients with CADM and interstitial lung disease has been reported in Japan related to the fact that interstitial pneumonitis appears to be an especially common complication of classic DM in the Japanese. Curiously, the acute/subacute pattern of disease presentation with rapidly progressive dyspnea, progressive hypoxemia, treatment resistance, and fatal outcome has been observed in CADM patients who develop interstitial pneumonitis.[66]

In most cases, interstitial pneumonitis has occurred in patients with CADM in the absence of antisynthetase autoantibodies such as Jo-1, which are considered to be markers for interstitial lung disease risk in patients with classic DM and the antisynthetase syndrome. However, it has been suggested that newly observed autoantibodies to 140-kd and 155-kd autoantigens that appear to be highly specific for classic DM and CADM might serve as a marker for interstitial lung disease in Japanese CADM patients.[34]

The appearance of symptoms of interstitial pneumonitis, especially the acute/subacute type, in a patient with any form of DM should be considered a medical emergency, and the assistance of a pulmonary medicine specialist should be obtained as soon as possible to ensure proper diagnosis and therapy. Aggressive multidrug systemic immunosuppressive therapy is typically required in such cases, and the patient is often admitted to a pulmonary intensive care unit.[67]

ARTHRITIS Arthritis occurs in 20 percent to 65 percent of patients with juvenile-onset classic DM.[68] Typically, this is a nonerosive arthritis involving knees, wrists, elbows, and fingers. It is seen early in the course of the disease. For some patients, arthritis can be a major symptomatic problem. Arthritis also occurs in some patients with juvenile-onset CADM. In one study, three of five patients with juvenile CADM followed over an average of 4.9 years were reported to have arthritis, whereas 49 of 80 children with classic DM had arthritis.[68]

Relationship Between Cutaneous and Systemic Manifestations

There is little correlation between skin and muscle disease activity in DM. In patients who have clinically significant skin and muscle disease at the outset of their illness and in whom all evidence of disease activity is suppressed by systemic immunosuppressive therapy, DM skin disease activity can return unaccompanied by muscle disease activity once treatment has been discontinued. The intensity of cutaneous symptoms, associated disability, and resistance to treatment in this setting can be marked.

Attempts have been made to correlate the periungual microvascular changes in patients with adult and juvenile classic DM as assessed by nail fold capillaroscopy (i.e., dilatation, tortuosity, budding or arborization, and avascularity) with the systemic manifestations of this disease process, including myositis. However, the periungual nail fold capillary changes in patients with CADM are qualitatively similar to and as prominent as those in patients with classic DM.[69] Thus, no simple relationship exists between the degree of abnormality of periungual nail fold vascular changes and myositis activity in DM patients. Both of the authors have observed that the disappearance or improvement of periungual telangiectasia often heralds remission or at least marked improvement of disease.

HISTOPATHOLOGY

The earliest histologic appearance of cutaneous DM is similar to that of normal skin except for periodic acid-Schiff–positive thickening of the basement membrane; a smudgy, homogeneous appearance of the papillary dermis; and increased dermal mucin and edema. No lymphocytic infiltrate is seen at this stage, and vacuolar alteration of basal keratinocytes, pigment incontinence, and colloid body formation are variably present.

Biopsy specimens from more advanced skin lesions (i.e., scaling violaceous erythema) show changes similar to or indistinguishable from those of LE. These changes include hyperkeratosis, epidermal atrophy, and effacement of the rete ridges. An interface dermatitis with vacuolar degeneration of the basal keratinocytes and a sparse, superficial, patchy, or band-like perivascular lymphocytic infiltration can also be seen, along with thickening of the basement membrane and pigment incontinence. The dermis is often pale as a result of the accumulation of edema and mucin.

In poikiloderma, these same features are encountered except that ectatic dermal vessels are present. Hyperkeratosis, acanthosis, undulating papillomatosis,

vacuolar alteration of basal keratinocytes, thickened basement membrane, variable lymphocytic exocytosis, and increased mucin deposition in the epidermis are seen in Gottron papules, although the histologic features of such lesions are often non-specific. Lipomembranous (membranocystic) changes previously thought to be specific for sclerosing panniculitis have been noted in the histopathologic examination of punched-out ulcers of DM.

Band-like granular deposits of immunoglobulin and complement along the dermal-epidermal junction, sub-epidermal cytoid bodies, dermal connective tissue staining, and epidermal cytoplasmic staining have been described in DM skin lesions. Lesional dermal-epidermal junction immunoglobulin and complement bands reportedly occur in 5 percent to 86 percent of patients, depending on the site of biopsy, with the nail fold being a high-prevalence area. However, similar findings can be observed in actinically exposed skin of otherwise normal individuals. It has been suggested that components of the complement membrane attack complex (C5 to C9) are more often present in the dermal microvessels than at the dermal-epidermal junction in cutaneous DM lesions, whereas the opposite occurs in cutaneous LE lesions. However, there is no general agreement at this time as to the validity of this point of distinction.

LABORATORY TESTS

Classic Dermatomyositis

MUSCLE ENZYMES An elevation in the serum level of CK is the most sensitive and specific laboratory indicator of muscle disease activity in IIDM. Ninety percent of patients with classic IIDM have elevated levels of CK at some point. The elevated CK activity is caused primarily by the CK-MM isoenzyme (muscle form of CK); however, elevations caused by the CK-MB isoenzyme (muscle and brain form of CK) are also seen. Elevated levels of CK can be associated with some of the disorders listed in Table 157-7 (e.g., other myopathies, hypothyroidism, and ingestion of certain drugs), as well as with strenuous physical exertion and needle trauma (intramuscular injection, EMG needle insertion). Enzymatic detection of CK activity can at times be inhibited by serum factors. Levels of CK may become elevated before the development of weakness and can normalize several weeks before the return of normal strength during treatment. Patients with IIDM who have normal CK levels may have a worse prognosis with respect to pulmonary disease and associated malignancy. Levels of CK are usually normal in patients with glucocorticoid-induced myopathy.

Serum aldolase level is a somewhat less sensitive indicator than CK for active myositis in IIDM. However, aldolase level is occasionally elevated in the presence of a normal CK level, especially in juvenile DM. Levels of transaminases (aspartate aminotransferase, alanine aminotransferase) and lactic dehydrogenase can also be elevated in active myositis, but these values are less useful clinically because of their low degree of specificity. Elevations of transaminase levels during treatment with methotrexate may reflect the activity of myositis as well as drug-induced hepatotoxicity. Urinary creatine excretion can also be used to monitor the status of myositis. However, the specificity is low because urinary creatine excretion can also be elevated in steroid myopathy. Serum myoglobin levels can also be elevated in severe IIDM.

AUTOANTIBODIES Elevated anti-nuclear antibody (ANA) levels with human tumor cell substrates are found in 60 percent to 80 percent of patients with both classic DM and CADM.[24] Autoantibodies of known molecular specificity in DM are now categorized into two groups: myositis-specific autoantibodies and myositis-associated autoantibodies.[70,71a] Myositis-specific autoantibodies include the antisynthetases [Jo-1, PL-7, PL-12, OJ, Mi-2, and signal-recognition particle (SRP)]. PM/Scl, Ro/SSA (Ro52, Ro60), and U1RNP represent the major myositis-associated autoantibodies. Table 157-3 lists the molecular specificities and clinical correlations of these autoantibodies. The fact that none of the myositis-specific autoantibodies occurs with a prevalence greater than one in five patients with DM makes routine testing for these autoantibodies of little clinical use.

Among the most frequently encountered myositis-specific autoantibodies are those that target the various aminoacyl transfer RNA synthetases. Of these antisynthetase autoantibodies, autoantibodies to Jo-1 (histidyl transfer RNA synthetase) are the most common and are found in 20 percent of patients with classic IIDM overall and 30 percent to 40 percent of adult patients with PM. Fever, interstitial lung disease, polyarthritis, Raynaud phenomenon, and incomplete response to therapy occur more often in patients who produce these antibodies (antisynthetase syndrome), as does the mechanic's hand skin lesion. Patients who produce Jo-1 antibodies less frequently display the classic cutaneous manifestations of DM.

SRP antibodies occur in 5 percent of patients with PM and are more common in those who exhibit acute-onset, severe, treatment-resistant forms of classic IIDM with cardiac involvement. Such patients rarely have any type of skin involvement. Autoantibodies to Mi-2, a nuclear protein complex containing histone deacetylase and nucleosome remodeling activities, are seen almost exclusively in patients with classic DM. Mi-2 antibody is found in 5 percent to 10 percent of patients with classic IIDM overall and in 15 percent to 20 percent of patients with classic DM. This autoantibody is associated with more treatment-responsive forms of classic DM as well as with the shawl sign and prominent cuticular changes. The clinical correlations of the myositis-specific autoantibodies found in adults (e.g., Jo-1) also occur in children with classic IIDM. IIDM autoantibodies that currently have less clinical significance are also listed in Table 157-3. An autoantibody to a 155-kd nuclear antigen (transcriptional intermediary factor-1 gamma [syn. ref fused gene 7]) has recently been reported to be highly specific for classic DM and CADM. In classic DM patients, this antibody has been suggested to be associated with an increased risk for internal malignancy.[71b]

OTHER LABORATORY ABNORMALITIES The erythrocyte sedimentation rate is elevated in about one-half of patients with classic IIDM, but it does not closely correlate with disease activity. Rheumatoid factor levels are elevated in 20 percent of cases, more often in patients with overlap disease. Levels of other serum factors such as neopterin and factor VIII–related antigen (von Willebrand factor) and $CD19^+$ B cells[29] have been reported to correlate with disease activity in children with classic DM. Messenger RNA for the interferon-α–induced protein MxA has been reported to be upregulated in peripheral blood mononuclear cells of patients with juvenile-onset classic DM and to correlate positively with muscle disease activity in that setting. Elevated levels of other markers of vascular activation, including

soluble forms of vascular cellular adhesion molecule 1 and E-selectin, have also been reported to occur in the circulation of patients with classic DM. KL-6 is a human mucin core protein 1 class mucin that is preferentially expressed on type II pneumocytes. KL-6 has been proposed to be a sensitive serum marker for the presence of interstitial pneumonia in the setting of classic DM in Japanese patients (reviewed in ref. 72). However, the laboratory assay for this marker has yet to become generally available in the United States.

Clinically Amyopathic Dermatomyositis

By definition, the levels of CK and other muscle enzymes are normal in CADM. Approximately two-thirds of patients reported as having CADM have tested positive for ANA.[24] However, such patients do not appear to produce myositis-specific or myositis-associated antibodies. Preliminary studies have indicated that several new autoantibodies (140 kd, 155 kd, and Se) might serve as serologic markers for CADM patients provided their disease specificity can be confirmed.[33,34,73]

When the results of immunoblot and immunoprecipitation studies using HeLa cell extracts were combined, 16 (89 percent) of 18 white adult patients with CADM showed autoantibodies to the 155-kd autoantigen and/or the Se autoantigen. With the exception of the 155-kd autoantigen, the molecular identities of these autoantigens have not yet been revealed. If these preliminary results can be corroborated, they could provide a useful clinical tool for confirming a diagnosis of CADM. In addition, it has been suggested that a newly observed autoantibody specific to a 140-kd autoantigen might also serve as a marker for interstitial lung disease in Japanese CADM patients.[34]

As in classic DM, serum levels of KL-6 are also suggested to correlate with the activity of interstitial pneumonia in patients with CADM.[74]

Special Tests (Including Imaging Studies)

ELECTROMYOGRAPHY The EMG changes of myositis include a myopathic pattern of the motor unit action potential, a myopathic recruitment pattern, increased insertional activity, and increased spontaneous activity. EMG changes of myositis can be erratically distributed. EMG recordings from the paraspinous muscles can be abnormal when those from the limb girdle musculature are normal. As many as 10 percent of patients with biopsy-documented myositis have normal EMG findings.

MUSCLE BIOPSY Muscle fiber degeneration/regeneration, perifascicular atrophy, and capillary injury are frequently present in the muscle biopsy specimens of patients with IIDM. A perivascular infiltrate of T lymphocytes and histiocytes and, occasionally, of B lymphocytes, plasma cells, and eosinophils is also seen. Biopsy specimens from patients with DM often show CD4 T cells and B cells in the perivascular areas, whereas CD8 T cells preferentially associate with damaged muscle fibers in patients with PM. The capillary density in muscle specimens from patients with DM is decreased. Inflammation may be absent in up to 25 percent of biopsy specimens from patients with otherwise typical muscle disease by clinical, EMG, or biochemical criteria.

An occlusive vasculopathy is a striking aspect of the pathology of juvenile-onset classic DM. Phlebitis and arteritis leading to intimal hyperplasia, fibrinous occlusion of vessels, and infarction of the involved tissues can be seen. The muscles, gastrointestinal tract, and nerves are particularly affected. This vasculopathy in muscles is noninflammatory and occurs predominately in the capillaries. There is a spectrum of endothelial changes from swelling to obliteration to necrosis. In muscles this occlusive vasculopathy is most commonly seen in small vessels, resulting in microvascular ischemia. The local production of interferon-induced angiostatic ELR-negative CXC chemokines has been implicated as a pathogenetic factor in the vasculopathy of juvenile-onset DM.[75]

MUSCLE IMAGING Myositic inflammation can be highly focal. A number of non-invasive techniques are currently being examined for their ability to localize affected muscle groups. MRI is the method of choice for diagnostic imaging of muscle abnormalities in patients with myositis.[76] However, the MRI signal associated with myositis is not specific for IIDM muscle involvement. The possibility that MRI-guided needle biopsy could obviate the need for the more costly and invasive open muscle biopsy is being explored. In addition, MRI and phosphorus 31 magnetic resonance spectroscopy are also useful in assessing the status of muscle disease activity during treatment with systemic glucocorticoids and other immunosuppressive drugs. These procedures are expensive and cannot be used in some individuals with metallic implants. Less costly approaches to monitoring muscle disease activity, such as power Doppler and gray-scale ultrasonography and ultrasonography with contrast material are being examined.[77]

Functional metabolic changes in muscles identified by magnetic resonance spectroscopy have been especially evident on exercise in some patients with amyopathic DM (such patients would better be classified as having hypomyopathic DM). Artificial neural networks have been proposed as an effective way to analyze the multichannel functional data that result from phosphorus 31 magnetic resonance spectroscopy examination.[78] A central issue in this area is whether the subtle muscular abnormalities that can be identified with these sensitive imaging systems have true prognostic value.

DIFFERENTIAL DIAGNOSIS (Box 157-1)

In the earlier stages, cutaneous DM might be confused with contact dermatitis, seborrheic dermatitis, lichen planus, psoriasis, polymorphic light eruption, and atopic dermatitis. In the later stages, when the more typical cutaneous manifestations of DM have evolved, the greatest challenge can be to distinguish the skin involvement of DM from that of cutaneous LE, especially acute cutaneous LE and subacute cutaneous LE (Table 157-8).

Periorbital heliotrope erythema and edema can occasionally be observed in SLE, but fully formed Gottron papules are never seen as a cutaneous manifestation of LE. It has been the authors' experience that, excluding the rare occurrence of hydroxyurea- or statin-induced DM-like skin changes, the concurrent presence of Gottron papules and grossly visible periungual nail fold telangiectasia is pathognomic of DM skin disease. Pruritus or related dysesthetic symptoms such as burning pain are typical of DM skin inflammation, whereas the various forms of LE-specific skin disease are characteristically not pruritic.

The pattern of involvement over the hands also differs; in LE the skin over the dorsal interphalangeal and metacarpophalangeal joints is spared, and the hair-bearing skin between these joints is preferentially involved. The opposite is true for DM: the skin overlying the dor-

Box 157-1

Differential Diagnosis of Dermatomyositis (DM)

CLASSIC DM

Most Likely

- Few illnesses can be confused with the fully expressed combination of hallmark skin changes and proximal weakness seen in classic DM. However, treatment with certain drugs, such as statin lipid-lowering agents, has been reported to be capable of triggering the appearance of both the cutaneous and muscle manifestations of DM.

Consider

- There are a number of causes of proximal muscle weakness other than myositis (see Table 157-7). It is possible that co-occurrence of one of these other causes of proximal muscle weakness with a common dermatologic condition mimicking the early manifestations of cutaneous DM could be confused with classic DM.

CLINICALLY AMYOPATHIC DM

Most Likely

- Cutaneous lupus erythematosus (acute cutaneous lupus erythematosus or subacute cutaneous lupus erythematosus, but not discoid lupus erythematosus)

Consider

- Seborrheic dermatitis
- Contact dermatitis
- Lichen planus
- Psoriasis
- Polymorphic light eruption
- Atopic dermatitis
- Overlap connective tissue disease
- DM-like skin changes induced by drugs (e.g., hydroxyurea, statins)

From Euwer RL, Sontheimer RD: Dermatomyositis, in *Cutaneous Manifestations of Rheumatic Disease,* edited by Sontheimer RD, Provost TT. Baltimore, Williams & Wilkins, 1996, p 73, with the permission of Williams & Wilkins.

sal interphalangeal and metacarpophalangeal joints is preferentially affected (see Fig. 157-4). When extensive, however, the linear streaking of violaceous erythema that tracks over the extensor tendons of the hands and fingers can sometimes obscure this point of differential diagnosis.

Poikiloderma commonly occurs in DM patients. Various forms of "poikilodermatous" cutaneous LE have also been reported. However, it has been the authors' personal experience that most of the patients with "poikilodermatous LE" that have been referred to them have turned out to have CADM. For most physicians outside of dermatology, the absence of clinically evident muscle weakness reflexively prevents further consideration of cutaneous DM, no matter how typical the skin features might be. This confusion is exacerbated by the fact that the majority of CADM patients test positive for ANA.

In addition, multicentric reticulohistiocytosis (see Chap. 149) has been reported to masquerade as DM. However, the "string of pearls" papules that occur in the periungual areas in multicentric reticulohistiocytosis can be clearly distinguished from the periungual inflammatory changes of DM by clinical and pathologic examination. Many conditions other than IIDM can be associated with proximal muscle weakness.[79] Table 157-7 outlines these disorders.

As previously noted (see Epidemiology), drugs such as hydroxyurea, penicillamine, niflumic acid/diclofenac, phenytoin, tryptophan, and practolol have been reported in rare cases to produce an eruption with clinical similarities to the hallmark cutaneous features of DM. In addition, statin-type lipid-lowering drugs (atorvastatin, fluvastatin, lovastatin, pravastatin, rosuvastatin, simvastatin) and other classes of lipid-lowering drugs (fenofibrate, gemfibrozil) are well known to produce a drug-induced myositis and/or rhabdomyolysis that can simulate the myositis seen in DM. Considering the high rate of usage of these drugs, however, confirmed reports of statins' and other lipid-lowering drugs' triggering the hallmark cutaneous manifestations of DM are quite rare. To prove that a case of classic DM or CADM is drug induced would require a rechallenge with the suspected drug once the cutaneous and/or muscle manifestations of DM have remit-

ted. Few patients or physicians would be willing to do this, and the ethics of such an attempt could be questioned. In addition, most cases of classic DM induced by lipid-lowering drugs are likely to be treated with prednisone and/or steroid-sparing systemic immunosuppressives in addition to cessation of the offending drug. Therefore, without a drug challenge, the argument can be made that the appearance of DM and treatment with potentially triggering drugs was merely fortuitous. More study of the epidemiology and pathogenesis of lipid-lowering drug–induced DM is needed.

COMPLICATIONS

Cutaneous Ulceration

Cutaneous ulcers are more common in juvenile than in adult classic DM and appear to be quite rare in both juvenile and adult CADM. The skin can ulcerate in DM as a result of a number of different mechanisms. Superficial erosion/ulceration can develop from vesiculobullous changes occurring within intensely inflamed DM skin lesions. Retiform ulcers can result from skin breakdown in poikilodermal areas. Deep penetrating ulcers can result from cutaneous infarction secondary to vasculopathy. The skin can ulcerate as a result of pressure from underlying calcium deposits. In addition, leg ulcers are a component of the clinical constellation of hydroxyurea-induced DM skin changes. Because of their frequent association with vasculopathy, deeply penetrating cutaneous ulcers have traditionally been thought to be a poor prognostic sign. One of the authors (M.I.C.) has noted that deeply penetrating ulcers may correlate with pulmonary involvement in DM.

Systemic Vasculopathy

Clinical manifestations of systemic vasculopathy are seen most often in patients with juvenile-onset classic DM. This can result in perforation of the gastrointestinal tract, ocular damage, and central nervous system damage.

Calcinosis

Extraosseous calcification is also more common in children than in adults with classic DM. As with cutaneous ulceration and systemic vasculopathy, calcinosis is seen less commonly in both children and adults with CADM. The higher rate of vasculopathy that occurs in juvenile DM is thought to be a forerunner of dystrophic calcification. Approximately 25 percent of children with classic DM have dystrophic calcification at the time of diagnosis, and 40 percent to 50 percent develop calcinosis sometime during the course of their illness.

DM patients experience several different patterns of calcinosis. In adults, cutaneous calcification often presents as firm dermal and/or subcutaneous papules or nodules that are often most prominent around the elbows and hands. Large subcutaneous tumoral deposits can also occur over the trunk of adults. Such lesions can be filled with a liquid suspension of calcium crystals (i.e., "milk of calcium"). Four types of calcification have been described in children with DM: (1) a superficial pattern consisting of small, firm nodules and plaques in the skin; (2) periarticular subcutaneous nodules (calcinosis circumscripta); (3) deposition along fascial planes in muscles (calcinosis universalis) (see eFig. 157-7.2 in on-line edition); and (4) a severe "exoskeleton" pattern of deposition in the subcutaneous tissue. Calcinosis cutis or calcium deposition in muscles and tendons is more common in the late phases of the disease in children. The TNF-α308A promoter polymorphism might represent a risk factor for developing calcinosis.[29] The complications of calcinosis, such as ulceration and sepsis, are a significant cause of both morbidity and mortality in patients with juvenile classic DM.

Internal Malignancy

Population-based studies document that adult-onset classic DM is associated with a higher than expected risk for internal malignancy.[80–84] Relative risks for malignancy range from 2.4 in males with DM to 3.4 in females with DM. The risk for malignancies was negligible in patients with PM. During the 5-year period after the diagnosis of DM, the risk of a woman developing ovarian cancer in these studies was 16.7-fold higher than the risk for women without DM. In a more recent study, the standardized incidence ratio for malignancy in adult patients with DM was 6.5.[81] In the first year after diagnosis, the relative risk for malignancy in patients with DM was 26.0. Females with DM in this study had a 32-fold higher risk of developing ovarian carcinoma. This study also found that PM was not associated with an increased risk of cancer and that the treatment of DM with cytotoxic drugs did not increase the risk of malignancy. Because of the risk of ovarian cancer in females with DM, it has been suggested that all women with DM (classic DM and CADM) undergo an initial comprehensive gynecologic examination and repeat examinations at 6- to 12-month intervals for at least the first 2 years after the diagnosis. Determination of serum levels of cancer antigen-125 and transvaginal ultrasonography have been recommended for females with DM who have intact ovaries. It is an unfortunate fact, however, that there is no foolproof way to screen for early ovarian cancer.

Tumors other than ovarian carcinoma have been reported with DM, including melanoma, mycosis fungoides, and Kaposi sarcoma. Carcinomas are more frequent than sarcomas, and lymphoproliferative malignancies are uncommon. Except for ovarian cancer in women, no preponderance of specific types of cancer is seen in whites with IIDM. Asian males most frequently develop nasopharyngeal carcinoma.[80,81]

The diagnosis of cancer is most often made by history, review of systems, physical examination, and routine laboratory and radiologic testing. Debate exists about the routine use of surveillance imaging techniques, such as chest, abdominal, and pelvic CT and/or MRI in this setting. Age appears to be a factor in malignancy risk. There is not a significant risk of occult malignancy in patients with juvenile-onset classic DM, whereas individuals 50 years of age or older at the time of onset of classic DM appear to have a definite increased risk of malignancy (20 percent to 30 percent). The leading cause of death in patients with IIDM who have malignancy is metastatic spread of the malignancy rather than complications directly related to the myositis. In patients with malignancy, the myositis and cutaneous manifestations are less responsive to systemic glucocorticoid therapy. In a few well-documented cases, definitive therapy for the malignancy resulted in resolution of the DM disease activity, and a recurrence of the cancer was associated with the reappearance of DM activity.

Older age, greater extent and severity of skin disease [i.e., intense generalized erythema ("malignancy suffusion"), blistering, ulceration], and elevated CK levels appear to enhance the risk of malignancy in adults with classic DM. It has been suggested that other systemic manifestations of DM, such as interstitial lung disease, are negatively correlated with risk for internal malignancy.[22]

All routine age- and sex-directed malignancy surveillance guidelines should be followed.

There are no population-based data concerning the risk of internal malignancy in patients with CADM. In a systematic review of the world literature, 291 reported cases of adult-onset CADM were identified,[24] and only 14 percent of these cases were associated with internal malignancy. However, publication bias could be at play here. It has been the personal experience of one of the authors (R.D.S.) that internal malignancy has been virtually absent in the approximately 100 patients with adult-onset CADM in whose care he has been personally involved at three different U.S. academic medical centers over the past three decades.[24] Population-based studies will be required to resolve the question of risk of malignancy in CADM. Until then, it is recommended that the same approach to occult malignancy surveillance be used for patients with CADM as is used for patients with classic DM.

Opportunistic Infections and Lymphoma

Early initiation of aggressive systemic immunosuppression is required for both juvenile-onset and adult-onset classic DM. Because DM frequently pursues a chronic and/or recurring course, such patients frequently are exposed to the consequences of long-term use of specific immunosuppressive regimens, including a panoply of opportunistic systemic infections (bacterial, mycobacterial, viral, fungal) and opportunistic infection–induced lymphoma (Epstein-Barr virus infection).[86,87a]

Effects of Pregnancy

Classic DM and CADM can occur for the first time during pregnancy, and pregnancy can be a complicating factor for pre-existing classic or DM and CADM. DM presenting in the first trimester of pregnancy is thought to have a worse effect on maternal health and fetal outcome than DM presenting in the second or third trimesters. The impact of pregnancy on DM is generally thought to be a function of the state of DM disease activity and maternal overall health status.

CADM has been reported to occur for the first time during the third trimester of pregnancy. However, one of the authors (R.D.S.) has personally observed two sisters with long-standing CADM who both experienced spontaneous clearing of their DM skin disease activity during the second and third trimesters of multiple pregnancies with consistent relapse of skin disease activity within the first 3 months after delivery of a healthy newborn.

PROGNOSIS AND CLINICAL COURSE

Classic Dermatomyositis

Reported mortality rates vary from 25 percent to 80 percent, depending on the case mix and the medical era in which the cases were collected. In the past two decades, the mortality rate has decreased considerably because of the more aggressive use of glucocorticoids and other immunosuppressives and better supportive medical care.[87b] The 5- and 8-year survival rates for 76 patients with IIDM studied in the 1980s were 80 percent and 73 percent, respectively. Global survival rates for the IIDMs have been more reported to be 95 percent, 92 percent, and 89 percent for 1, 5, and 10 years, respectively. Pulmonary and cardiac complications were the most frequent causes of death. Cancer-associated myositis had the worst prognosis, whereas juvenile-onset and overlap myositis had the best. Five- and 10-year survival rates were 94.2 percent and 89.4 percent for patients with primary PM and 90.1 percent and 86.4 percent for those with primary DM.[88] Individuals who receive early systemic treatment for their disease have a better prognosis. The early, aggressive use of glucocorticoids has reduced the mortality rate in children to less than 10 percent.

The presence of antisynthetase antibodies and TNF-α308A allele may represent risk factors for disease chronicity and severity in juvenile-onset classic DM.[29] African American children with DM tend to have more aggressive disease than do white or Hispanic children. Calcinosis remains a primary cause of both disease morbidity and mortality in patients with juvenile classic DM.

Certain types of skin lesions have also been said to correlate with a poor outcome. Ulcers arising over violaceous indurated plaques on the trunk with or without indurated papules were reported to be more frequent in adults with DM who developed a malignancy. Necrotic/ulcerative skin disease is thought to an unfavorable prognostic feature overall. The mechanic's hand lesion has been suggested to be associated with an increased risk for interstitial lung disease in classic DM.

Prognosis in both adults and children with classic DM is associated with the types of autoantibodies produced. The presence of antisynthetase autoantibodies (Jo-1, PL-7, PL-12) has been correlated with incomplete response to therapy and interstitial lung disease. As noted earlier (see Antibodies) SRP antibodies have been found in patients with acute-onset, severe, and treatment-resistant forms of disease with frequent cardiac involvement. Autoantibodies to Mi-2 are associated with more treatment-responsive forms of DM. PM-SCL has been associated with overlapping features of DM and systemic sclerosis. The presence of the 155-kd autoantibody might possibly indicate a significantly increased risk for occult malignancy.

The causes of death in DM vary depending on the age of onset of disease. In juvenile-onset classic DM, death is more commonly seen with complications of vasculopathy (e.g., bowel perforation, central nervous system involvement) and severe widespread dystrophic calcification (ulceration with sepsis). In adult-onset classic DM, death is more common from occult malignancy, cardiac involvement, and pulmonary involvement or complications (aspiration pneumonia related to esophageal dysfunction, restrictive ventilatory insufficiency due to involvement of muscles of breathing, interstitial lung disease). Patients with both juvenile-onset and adult-onset DM can also die of complications of prolonged systemic immunosuppressive therapy (e.g., opportunistic infection with viruses, bacteria, mycobacteria, and fungi).

Clinically Amyopathic Dermatomyositis

Data are not available to allow adequate discussion of mortality in either adult-onset or juvenile-onset CADM. Individual reports of death from occult malignancy and interstitial lung disease in adult-onset CADM have appeared.[24]

Insufficient long-term follow-up data are available to assess prognosis and clinical course in adults or children with CADM. All six patients in one cohort with adult-onset disease who initially had only skin disease and who were treated conservatively ultimately developed muscle disease.[89] In another cohort, none of the five adults with CADM treated aggressively with high-dose systemic glucocorticoids developed clinical evidence of myositis.[90] Both of these small case series could have suffered from case selection/publication bias.

A systematic review of adult-onset CADM identified 291 cases among which there was a 13 percent incidence of interstitial lung disease and 14 percent incidence of associated internal malignancy.[24] However, this compilation of individual case reports and small case series is likely to have also been affected by reporter bias. Population-based studies of the epidemiology and management of CADM are greatly needed to address this and other clinical issues relating to this sub-type of DM.

One study has suggested that patients with juvenile-onset DM who have only the cutaneous manifestations are usually not treated aggressively and may frequently develop pathologic calcifications.[60] This report is contrary to the findings of other studies of CADM in both children[59] and adults,[20,57] which have indicated that this mode of presentation is usually not associated with a high rate of subsequent dystrophic calcification. One study, indicating that both rheumatologists and dermatologists tend to be conservative in treating patients with CADM,[59] also reported that a high percentage of patients with juvenile-onset CADM enjoy spontaneous remission without systemic immunosuppressive treatment.

TREATMENT

A search of the Cochrane Library revealed a single systematic review of the efficacy of steroid-sparing immunosuppressant and immunomodulatory treatments for DM and PM.[91] This review identified seven potentially relevant randomized controlled trials, none of which had DM skin disease activity as the primary endpoint. Therefore, by necessity, the following discussion of the clinical management of DM skin disease is the product of published anecdotal observation by others, expert opinion by others, and the personal clinical experience of the authors.

The treatment of CADM patients differs from that of classic DM patients only in the absence of the need to treat symptomatic inflammatory myositis. The cutaneous manifestations of classic DM and CADM respond similarly to aggressive systemic immunosuppressive therapy; however, this therapy is difficult to justify in cases of CADM when nonimmunosuppressive topical and systemic measures might be of benefit.

Local Treatment

Patients with either classic DM or CADM should avoid excessive sun exposure and use effective broad-spectrum sunscreens. An in-depth discussion of practical and theoretical photoprotection and local therapy for autoimmune connective tissue skin disease such as DM has been presented elsewhere.[92] However, efforts should be made to insure that vitamin D deficiency does not occur, especially in growing children.

Topical glucocorticoids (classes I and II) can dampen cutaneous inflammation and pruritus, and such agents can be used safely for prolonged periods of time when administered cyclically (2 weeks of daily treatment followed by 2 weeks off treatment). However, these agents alone usually cannot fully suppress DM skin disease activity. Daily use of a medicated shampoo followed by application of a topical class I and II glucocorticoid solution, gel, spray, or foam to the affected areas can provide relief for scalp pruritus. Xerosis is often present, especially in the elderly, and effective moisturization regimens can be of value in managing the pruritus often experienced by patients with DM. Topical antipruritic agents such as combinations of menthol/phenol/camphor, pramoxine, and doxepin can provide short-term relief.

Pulsed dye laser therapy has been advocated for the cosmetic treatment of the residual poikilodermatous skin changes that can follow in the wake of active cutaneous DM.[93]

Systemic Treatment

When nonimmunosuppressive systemic therapy is possible, its use should be maximized. Non-sedating or sedating antihistamines can be used during the day as appropriate. Doxepin, a tricyclic antidepressant, is a potent H_1 and H_2 receptor–blocking antihistamine. When given at bedtime in doses of 10 to 50 mg titrated to the degree of somnolence the next morning, this long-acting antihistamine can ameliorate the pruritus and excoriation that often occur during sleep. The addition of cimetidine 200 to 400 mg four times daily for its histamine H_2 receptor–blocking ability can also be helpful. With the appropriate precautions, oral naltrexone and mirtazapine may be used to treat the intractable pruritus and burning sensations that can be seen in this setting.

ANTIMALARIALS Hydroxychloroquine sulfate (6 mg/kg given as two divided doses per day) has been used to treat DM skin disease. Some experienced clinicians have reported that hypersensitivity reactions to hydroxychloroquine occur at higher frequencies in DM patients than in other patient groups.[94]

Some DM patients will respond better to a combination of hydroxychloroquine and quinacrine, 100 mg/day, or to chloroquine (3.5 mg/kg/day) and quinacrine (100 mg/day)[95] than to hydroxychloroquine alone (see Fig. 157-3). However, even combination antimalarial therapy will not adequately control the cutaneous symptoms of many DM patients. Precautions should be taken to minimize the risk of retinal toxicity with hydroxychloroquine or chloroquine and of hematologic toxicity with quinacrine. If extrapolation from the experience gained from patients with cutaneous LE is valid, patients with DM who smoke cigarettes may be less responsive to antimalarial therapy than those who do not smoke. It should be remembered that on rare occasion antimalarials can contribute to muscular weakness by causing a toxic vacuolar myopathy. Other nonimmunosuppressive systemic therapies that have been suggested to be of benefit in cutaneous DM include dapsone[96,97] and anti-estrogen therapy.[98]

SYSTEMIC GLUCOCORTICOIDS Systemic glucocorticoids remain the traditional first-line therapy for classic DM. Early intervention with systemic glucocorticoids is associated with a better overall prognosis. In adults, prednisone (prednisolone for those with decreased liver function) is given orally in divided doses of 1.0 to 1.5 mg/kg/day, whereas in children the dosage is 1 to 2 mg/kg/day. Significant improvement of muscle strength, normalization of muscle enzyme levels, and improvement in cutaneous inflammation are the endpoints of therapy. Most patients require 1 to 3 months of full-dose treatment with prednisone. When symptoms improve, the dose can be consolidated from a divided dose to a single daily dose given in the morning to reduce the risk of adrenal suppression and other glucocorticoid side effects. The glucocorticoid dosage can then be progressively decreased. Treatment should be continued for 12 to 24 consecutive months to minimize the chance for recurrence. Attention should be paid from the outset to managing the side effects of long-term systemic glucocorticoid use such as osteoporosis. Calcium loss from bones starts within the first 3 months after initiation of systemic corticosteroid therapy.

In acutely ill patients, intravenous pulse therapy with methylprednisolone can be

used. This approach has become increasingly popular in the management of juvenile DM. Alternate-day glucocorticoid administration usually does not provide adequate relief during active phases of the disease. The cutaneous lesions of DM can be refractory to high-dose, long-term glucocorticoid therapy in some patients. Other patients have recrudescent disease activity only in the skin after complete suppression of muscle disease with systemic immunosuppressive therapy.

Systemic glucocorticoids and other systemic immunosuppressives can be used to treat disabling skin disease activity in patients with CADM. However, it remains to be determined whether early aggressive immunosuppressive treatment of CADM might prevent the subsequent development of clinically significant myositis in the minority of CADM patients in whom this occurs.

Approximately 25 percent of patients with classic DM do not respond adequately to systemic glucocorticoids within the first 2 months of treatment. Azathioprine (2 to 3 mg/kg/day), cyclophosphamide (1 to 2 mg/kg/day), methotrexate (7.5 to 50 mg/week), chlorambucil (2 to 6 mg/day), cyclosporine (3 to 5 mg/kg/day), and mycophenolate (1 to 3 g/day) have been used in this setting in patients who cannot tolerate the side effects of prolonged high-dose glucocorticoid therapy.

METHOTREXATE, CYCLOSPORINE, AND CYCLOPHOSPHAMIDE Methotrexate (7.5 to 25.0 mg) given once weekly by mouth has been successful in the treatment of patients with classic DM and some patients affected primarily by the cutaneous manifestations of DM. Higher dosages can be given subcutaneously or intravenously; administration by the intramuscular route may cause spurious elevation of muscle enzyme levels. Cyclosporine and cyclophosphamide have each been reported to be of benefit in treating severe complications of interstitial lung disease in patients with CADM, especially when started before frank respiratory failure has developed.[99,100] In children, oral cyclophosphamide (2 to 4 mg/kg/day) has traditionally been used in cases that could not be managed satisfactorily with systemic glucocorticoids. High-dose intravenous γ globulin therapy has been used in both children and adults in this setting and has the advantage of low toxicity. Plasmapheresis and leukapheresis appear to have little additional value in the management of IIDM.

ANTI–TUMOR NECROSIS FACTOR-α AND OTHER IMMUNOBIOLOGIC AGENTS Based on experimental evidence indicating a role for TNF-α in the pathogenesis of the muscle inflammation in classic DM, anti–TNF-α therapy has been used anecdotally to treat both the muscular and cutaneous manifestations of DM. A small number of cases of severe, therapy-resistant DM have been successfully treated with etanercept (Enbrel) or infliximab (Remicade).[101] More systematic study is needed to define the value of this treatment. Such therapy would have to be used with caution because of the possibility of its uncovering other patterns of systemic autoimmunity (e.g., SLE). In addition, anecdotal reports have appeared suggesting benefit from the use of efalizumab, an inhibitor of T-cell co-stimulation, and rituximab, a depletor of memory B cells, in patients with therapeutically refractory DM.[102,103] B cells have also been implicated in the pathophysiology of DM. Studies of therapy with rituximab (a CD20 B cell–depleting antibody) have provided encouraging results in patients whose disease responded poorly to other treatments.[103,104]

Because levels of enzymatic indicators of muscle inflammation tend to normalize quite quickly after systemic therapy is begun, other surrogate markers of DM systemic disease activity are used by some to guide therapy. Such markers include the von Willebrand factor antigen, $CD19^+$ B cells, and neopterin (reviewed in ref. 29). Serum levels of KL-6 have also been suggested to reflect DM interstitial lung disease activity.

Additional Management

Medical treatment of dystrophic calcification in DM is very challenging. Aluminum hydroxide antacids and diltiazem are currently used to treat this problem with less than ideal results. Other agents that can be tried include probenecid (250 mg/day), potassium para-aminobenzoic acid (15 to 25.0 g/day), warfarin (1 mg/day), ethylenediaminetetraacetic acid, and colchicine (1.2 to 1.8 mg/day). The bisphosphonates, such as alendronate, might be of value.[105] The surgical removal of symptomatic cutaneous or subcutaneous calcium deposits can be considered as a last resort. There is a theoretical basis for considering therapies such as sodium thiosulfate chelation[106,107] and extracorporeal lithotripsy[108,109] for the management of calcinosis cutis.

Passive range-of-motion exercise should be provided early in the disease course to prevent disabling joint contractures, especially in children. Once disease activity is suppressed medically, an active exercise program can facilitate the return of normal strength.

Surveillance for the detection of occult malignancy was discussed earlier in Internal Malignancy. In addition, changes in the clinical status of the respiratory, cardiovascular, and gastrointestinal systems should be evaluated carefully for the possibility of systemic disease activity in these target organs.

Treatment of Clinically Amyopathic Dermatomyositis

Current approaches to the treatment of adults and children with CADM are based on anecdotal observations of individual cases or a relatively small case series. One approach has been to treat patients with CADM aggressively from the outset with systemic glucocorticoids in the hope that progression to systemic involvement might be delayed or prevented.[90] This approach is supported by studies of patients with both juvenile- and adult-onset classic DM, which indicate that early systemic immunosuppressive treatment can lessen long-term disability from muscle dysfunction and complications such as calcification. However, in the large majority of published reports to date, a more conservative approach has been taken to the treatment of CADM.[24,26,110] This approach is validated by reports of patients with CADM who go 10 to 28 years and longer without any sign of disease activity or damage other than in the skin.[1,57,58,111]

Until it is confirmed that adult patients with CADM do not have a significantly increased risk of internal malignancy, they should be evaluated for this potential complication in a manner similar to for patients with classic DM. Because internal malignancy has not been reported to be associated with juvenile-onset classic DM or CADM, it can be assumed that routine evaluation for internal malignancy is not indicated in this population.

PREVENTION

Predicting and preventing the initial clinical manifestation of DM, whether it is skin disease or muscle weakness, is not feasible at this time. However, because many DM patients exhibit worsening of their skin disease activity with

ultraviolet light exposure, physical protection from sunlight and artificial sources of ultraviolet light as well as the regular uses of broad-spectrum sunscreens with a sun protection factor of 30 or higher should be encouraged.

It has been suggested that once the initial features of classic DM have become clinically manifested, early aggressive systemic immunosuppressive therapy can minimize subsequent complications, such as calcinosis and muscle atrophy, and thereby decrease morbidity and mortality. In this context, it has been questioned whether early systemic immunosuppressive therapy in patients with CADM might decrease or eliminate the risk of subsequently development of clinically significant muscle weakness. However, to date, only a minority of CADM patients have been observed to develop muscle weakness after 6 months. Therefore, most authorities currently think that, because of the risks associated with early aggressive systemic immunosuppressive therapy, its use in CADM patients is unwarranted.

CHAPTER 158

Scleroderma (Systemic Sclerosis)

Christopher P. Denton
Carol M. Black

Systemic sclerosis (SSc) is a prototypic multisystem disease that has hallmark cutaneous manifestations but which has the highest case-specific mortality of any of the autoimmune rheumatic diseases. This high mortality and an associated severe morbidity make diagnosis important. SSc also serves as a valuable model for organ-specific fibrotic processes and disease. The clinical diversity of SSc makes classification important. Although not curable, there have been substantial advances in therapy for organ-based complications of SSc, and this represents a major therapeutic advance. The sporadic nature of complications that affect only a minority of cases has stimulated interest in risk-stratification. In addition to being of clinical importance, this also may have impact on studies of pathogenesis and genetics, as distinct pathogenic mechanisms may be predominant in different organ systems.

It is important to distinguish SSc from the localized forms of scleroderma (lcSSc) and also from scleroderma-like conditions, including fasciitis and scleromyxedema. Formal diagnostic criteria are not well established, although the clinical features that lead to the diagnosis of SSc are clear. Classification criteria have mostly focused on the differentiation of SSc from other forms of connective tissue disease. With this in mind, it is important to note that up to 20 percent of cases of SSc may have overlap features.

SCLERODERMA AT A GLANCE

- A multisystem disease characterized by sclerosis of skin in which high mortality and an associated severe morbidity make diagnosis important.
- Clinical features that are almost always present include Raynaud phenomenon and skin sclerosis.
- The extent of skin sclerosis defines each major disease subset.
- It is important to distinguish systemic sclerosis from the localized forms of scleroderma and also from scleroderma-like conditions, including fasciitis and scleromyxedema.

EPIDEMIOLOGY

SSc is an uncommon disease that has proven difficult to ascertain in epidemiologic studies. Estimated prevalence is between 1 and 2 cases per 10,000 of the population, with an annual incidence of new cases approximately 10-fold less than this. Contrasting estimates of frequency in population-based surveys are likely to reflect methodologic challenges of assessing a rare and clinically diverse disease. Although there have been substantial differences between estimates of frequency of SSc in different populations, this may well reflect methodology of individual studies. There is likely to be particular bias in hospital-based series in which more severe cases are likely to be over-represented. This may explain the lower frequency of lcSSc

cases in hospital-based series compared with population-based estimates.

Although a genetic component to etiopathogenesis is likely and evidence supports genetic factors in severity and susceptibility, there is also strong evidence supporting environmental factors as triggers for the disease. This probably underlies the clusters that have been reported in Italy and associated with the mining industry in North America and South Africa.

A major advance for SSc epidemiology has been the recruitment of large cohorts of cases in multicenter registries in a number of different countries. These registries may provide a valuable tracking tool to identify SSc cases and facilitate population-based analysis of environmental and genetic factors influencing the disease phenotype and outcome in SSc.

ETIOLOGY AND PATHOGENESIS

SSc is a complex disease. The pathogenesis involves multiple cell types interacting through a variety of mechanisms that are dependent on microenvironment and key mediators. Major facets of the disease include inflammation, vasculature, and connective tissue–producing cells. Genetic factors are likely to be important, as in other complex disease. However, few genetic factors have been robustly described. The clinical heterogeneity of SSc makes it likely that distinct pathogenetic mechanisms predominate in particular patients or subsets of disease. Similarly, it is likely that the balance of different mechanisms differs at different stages of SSc.

Genetic Factors

The best evidence for a genetic contribution to SSc comes from studies that report familial clustering and from the limited twin studies that have been undertaken. Some support is provided from genetic association studies that have usually used a candidate gene approach. Most success has been observed in genetic analysis of individual components of the disease such as autoantibody profiles. These appear to have a strong genetic determinant, and this may underlie the apparent mutual exclusivity of the SSc hallmark reactivities. It has been demonstrated that the ability to mount an immune response to a particular SSc-associated antigen is restricted by major histocompatibility complex haplotype. Observation from a large number of studies examining genetic markers has identified a number of candidate genes. However, as with other complex diseases, in very many instances, it has not proven possible to replicate initially promising data. Studies of genetically homogeneous populations have been especially informative, including those of the Choctaw nation of Native Americans. It is, however, of interest that some of the associations are very plausible in terms of molecular pathogenesis. It is likely that epistasis and the effect of multiple modifier genes confound simple genetic association studies in SSc, just as in other complex diseases.[1] Reported genetic associations are summarized in Table 158-1.

TABLE 158-1
Summary of Recent Genetic Association Studies in Systemic Sclerosis (SSc)

POLYMORPHISM	CLINICAL ASSOCIATION	REFERENCE

ACE = angiotensin-converting enzyme; CXCR = chemokine receptor 2; SPARC = secreted protein, acidic and rich in cysteine; TGF = transforming growth factor.

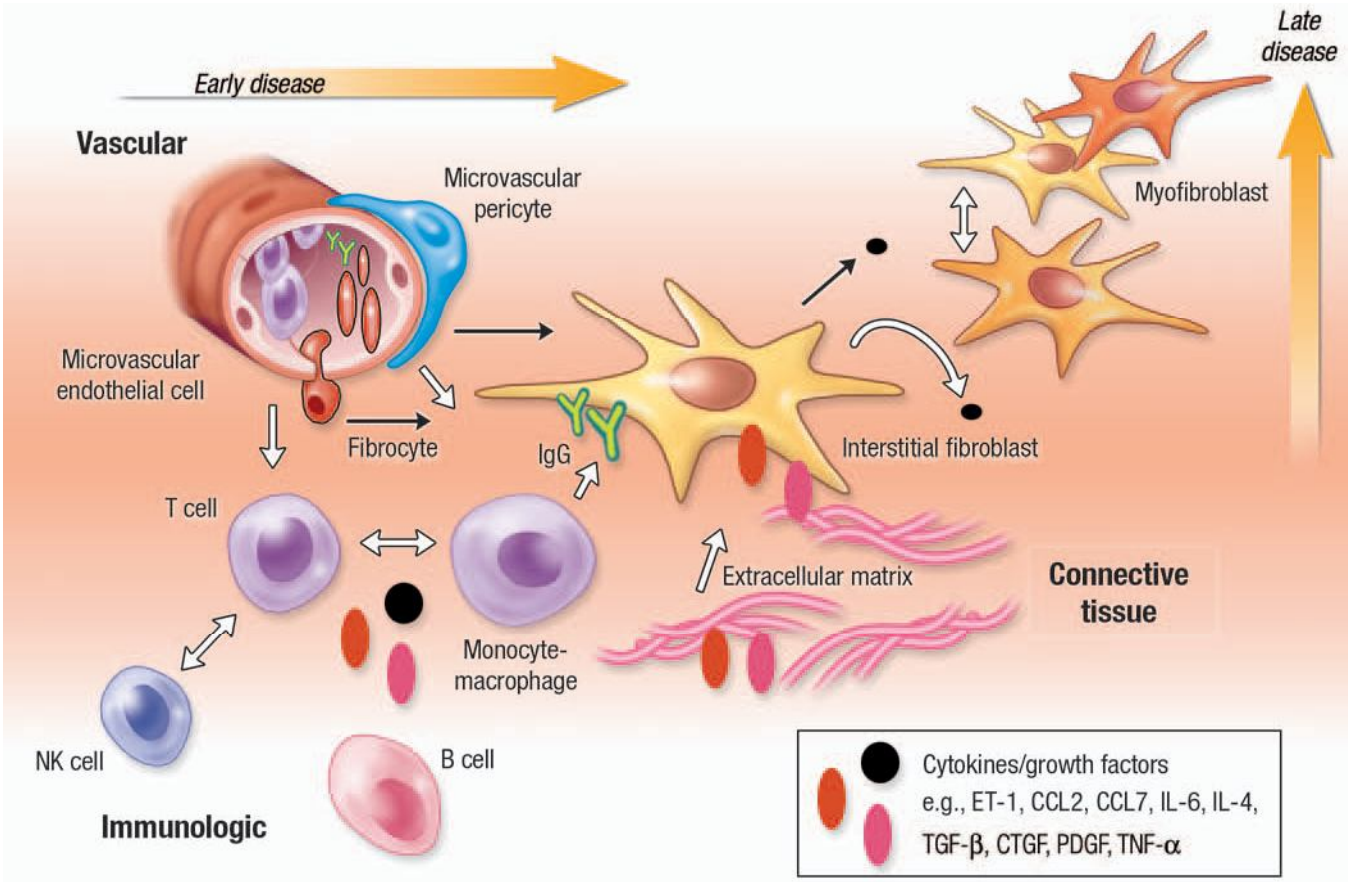
Immune Events

There is substantial evidence of inflammatory change in the skin and lung of cases of SSc. One example is the presence of highly specific hallmark autoantibodies. These are summarized in Table 158-2. The first inflammatory infiltrates in lesional skin are predominantly cells of the monocyte lineage. Later, T lymphocytes predominate, and these demonstrate sub-populations of memory cells. The potential role of autoantibodies in pathogenesis is a fascinating and exciting area. The majority of SSc cases have positive anti-nuclear antibodies. These include a number of hallmark reactivities as well as autoantibodies that occur in other autoimmune rheumatic diseases (e.g., anti-cyclic citrullinated peptide, rheumatoid factor) and antibodies that may have functional significance that are directed against cell surface antigens. Functional impact of these antibodies remains an area of investigation. Several studies suggest that antigens recognized by hallmark SSc autoantibodies may be

TABLE 158-2
Clinical Association of Hallmark Autoantibodies in Systemic Sclerosis (SSc)

REACTIVITY	TARGET ANTIGEN	FREQUENCY	CLINICAL ASSOCIATION
Centromere	CENP proteins	60% lcSSc, 2% dcSSc	Limited skin sclerosis, severe gut disease, isolated pulmonary arterial hypertension
Scl-70	Topoisomerase-1	40% dcSSc, 15% lcSSc	Diffuse skin sclerosis, pulmonary fibrosis
RNAP	RNA polymerase III	25% dcSSc, 2% lcSSc	Diffuse skin sclerosis, hypertensive renal crisis
nRNP	U1-RNP	15% SSc	Overlap features of SLE, arthritis
PM-Scl		l5% SSc	Myositis-systemic, sclerosis overlap

dcSSc = diffuse cutaneous systemic sclerosis; lcSSc = localized cutaneous systemic sclerosis; SLE = systemic lupus erythematosus.



▲ **FIGURE 158-1** Pathogenesis of systemic sclerosis. The schematic shows how the development of systemic sclerosis results from a complex interplay between cells within the immune system, including adaptive and innate compartments, the vasculature, and the connective tissue. Cell-matrix interactions are also potentially important. Early vascular events lead to later development of a relatively autonomous population of activated fibroblasts and myofibroblasts that contract soft tissue and deposit excessive extracellular matrix. These cells may develop from resident connective tissue fibroblasts; transdifferentiation from other cell types, including activated microvascular pericytes; and recruitment of circulating progenitor cells (fibrocytes). The contribution of each lineage to the fibrotic lesion is unclear. Many growth factors and cytokines are implicated as mediators of this process, and complex reciprocal networks may lead to a profibrotic microenvironment. Potential disease-modifying therapies could target individual mediators alone or in combination [e.g., tumor growth factor-β (TGF-β), endothelin (ET-1), connective tissue growth factor (CTGF), platelet-derived growth factor (PDGF)] or modulate immune cells (e.g., cyclophosphamide) or the endothelial cell (e.g., prostacyclin analogues). The extracellular matrix may be an important repository for mediators that are later released and play a key role in pathogenesis. CCL = CC chemokine ligand; Ig = immunoglobulin; IL= interleukin.

expressed on the cell surface. The best evidence of functional significance is for anti-endothelial cell autoantibodies and for anti-fibroblast–reacting antibodies. Recent reports suggest the presence of anti-fibrillin autoantibodies and stimulatory autoantibodies reacting with platelet-derived growth factor receptors, although this observation requires further confirmation. Microchimerism and graft-versus-host disease mechanisms have been suggested in some cases, although the relatively high frequency of microchimerism in healthy individuals or other disease states suggests that this may be contributory rather than causal if it has a role in SSc.

Vasculopathy

Vascular abnormalities are universal in SSc—they manifest as changes in the microcirculation evidenced by structural damage to the nail fold capillaries and as vasospastic responses in Raynaud phenomenon. Vascular change underlies some of the major complications of SSc, including pulmonary arterial hypertension (PAH), scleroderma renal crisis (SRC), and digital vasculopathy.

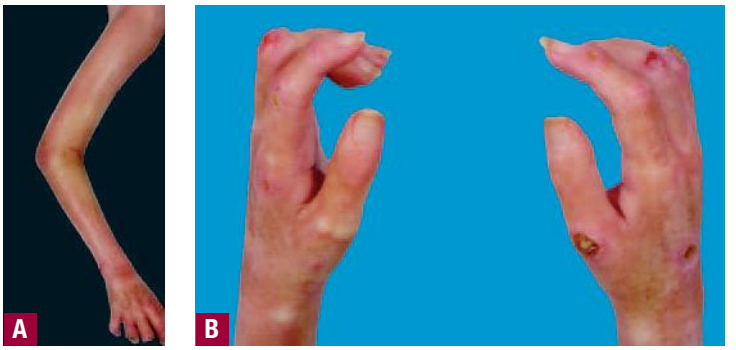
Fibrosis

SSc is a prototypic multisystem fibrotic disease. Deposition of excessive extracellular matrix in specialized organs is responsible for much of the morbidity and mortality of the disease. Fibrous connective tissue is deposited by activated fibroblasts and myofibroblasts. From an early stage in the disease, there appears to be established an autonomous population of fibroblasts that produce excessive extracellular matrix. The initiators of this process include a number of key cytokines and growth factors that may represent logical therapeutic targets.

A schematic summarizing pathogenetic mechanisms in SSc is shown in Fig. 158-1.

CLINICAL FINDINGS

The heterogeneity of SSc arises from the range of disease manifestations that vary in extent and severity between patients. However, some clinical features that are almost always present, including Raynaud phenomenon (see Chap. 171) and skin sclerosis. The extent of skin sclerosis defines each major disease subset. Each subset has particular features, although there are common features to both. It is also important to consider cases in which there are features of



▲ **FIGURE 158-2** **A,B.** Diffuse cutaneous systemic sclerosis. Skin sclerosis in diffuse cutaneous systemic sclerosis extends proximal to the elbows and knees, and often involves the chest and abdominal wall. Severe soft-tissue contractures may arise, and ulceration occurs, especially over extensor surfaces. Skin sclerosis score typically is maximum within the first 18 months of disease. Raynaud phenomenon may develop after onset of skin changes.

one or more additional autoimmune rheumatic diseases; these cases are designated *overlap syndromes*. The two major subsets of SSc are illustrated in Figs. 158-2 to 158-5, and features are summarized in Table 158-3.

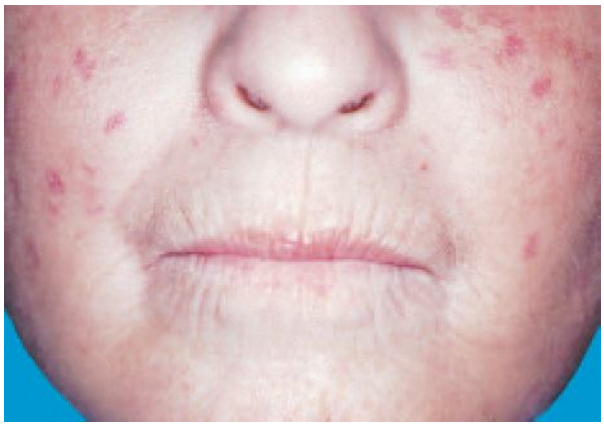
Although the two major subsets of SSc are classified according to the presence or absence of proximal skin involvement, in practice, many other clinical differences exist. This includes the duration of Raynaud phenomenon at onset of the other clinical features of SSc. This is typically only a few months in diffuse cutaneous systemic sclerosis (dcSSc) but often spans several years in lcSSc. In addition, the frequency and timing of different visceral manifestations of SSc differs between major subsets. There is, however, some overlap between subsets in terms of organ-based disease, and the extent and severity of skin sclerosis, assessed by modified Rodnan skin score, varies such that lcSSc may have only minor sclerodactyly or may have severe sclerotic changes extending to the elbows. An intermediate subset has been proposed but is not generally recognized. It is also important to recognize that proximal skin involvement can occur in morphea (see Chap. 62).

Autoantibody-based classification of SSc has been proposed, and there is evidence from association studies that this may be clinically meaningful, as indicated in Table 158-2. Moreover, genetic association analysis using a candidate gene approach has demonstrated association between serologically based subsets of SSc that are more strong than with SSc overall. The significance of this remains uncertain, and it should be noted that a genetic basis for autoantibody reactivity has been well described, leading to the suggestion that the serologic subsets may be more genetically homogeneous than unselected SSc cases or clinically defined subsets of SSc.

▲ **FIGURE 158-3** **A–D.** Localized cutaneous systemic sclerosis. Skin sclerosis in localized cutaneous systemic sclerosis is confined to the face, neck, and extremities. Vascular changes are prominent, including telangiectasis. Raynaud symptoms often pre-date skin sclerosis by several years. Skin score tends to slowly rise but does not exceed 18 based on the maximal number of sites involved. Vascular abnormalities that occur include critical ischemia, digital ulceration, and gangrene, ultimately leading to autoamputation.

▲ **FIGURE 158-4** Localized cutaneous systemic sclerosis showing involvement of the face that has a mask-like appearance, with inability of opening the mouth, sclerodactyly, and ulcerations.

The clinical manifestations of SSc depend to a large extent on the subset and stage of disease. Typical constellations exist for the two major subsets and form the basis for discriminating between lcSSc and dcSSc. Thus, most cases of lcSSc occur after a substantial pre-existing period of Raynaud phenomenon. Typical presenting features are those of oesophageal reflux and dysmotility and swelling or skin textural changes in the extremities. Other manifestations reflect individual patterns of internal organ disease. A very small proportion of cases develops vascular, immunologic, and organ-based fibrotic features of SSc but do not show skin sclerosis. These cases constitute approximately 1 percent of SSc cases and are termed *SSc sine scleroderma*. In all other patients, the extent and severity of skin sclerosis can be assessed by the modified Rodnan skin score. Usually, 17 sites are assessed and skin thickness is categorized to grade 1, 2, or 3, corresponding to mild, medium, and severe, according to palpation of the



▲ **FIGURE 158-5** Radial furrowing around the mouth and mat-like telangiectases are prominent on the cheeks in a patient with scleroderma.

TABLE 158-3
Clinical Features of the Major Systemic Sclerosis (SSc) Subsets

- Localized cutaneous SSc
  - Long pre-existing history of Raynaud phenomenon
  - Skin sclerosis spares proximal sites
  - Often anti-centromere antibodies–positive (but any reactivity possible)
  - Includes classic CREST (*c*alcinosis cutis, *R*aynaud phenomenon, *e*sophageal dysfunction, *s*clerodactyly, and *t*elangiectasia) syndrome
  - High frequency of visceral disease including isolated pulmonary arterial hypertension
  - Pulmonary fibrosis and gastrointestinal tract involvement common
  - Low frequency of scleroderma renal crisis
- Diffuse cutaneous SSc
  - Proximal skin sclerosis (upper arms, thighs, chest and abdomen)
  - Close temporal relationship between onset of Raynaud and skin sclerosis
  - Prominent inflammatory features during first 24 mo of disease
  - High frequency of pulmonary fibrosis, cardiac involvement, and scleroderma renal crisis
  - Often Scl-70 or anti-RNAPIII positive (but any reactivity can occur)
- Overlap SSc
  - Features of scleroderma together with those of another autoimmune rheumatic disease
  - Poly- or dermatomyositis
  - Systemic lupus erythematosus
  - Sjögren syndrome
  - Vasculitis
  - Polyarthritis
  - Anti-nuclear antibody testing often shows speckled nucleolar staining with specificity for nRNP, fibrillarin, or PM-Scl
  - May demonstrate additional serologic features of systemic lupus erythematosus, rheumatoid arthritis, Sjögren

skin by a trained examiner. Skin score at baseline correlates with disease severity and outcome in dcSSc.

Cases of dcSSc have a more abrupt onset, with major inflammatory symptoms including swelling of the extremities. Typically, the vascular manifestation of Raynaud phenomenon is delayed compared with lcSSc and may occur simultaneous with the onset of other features of the disease or at a later time point. The first presentation is typically with arthralgia, stiffness, and swelling of the extremities that may reflect increased vascular permeability. Later, the features of skin sclerosis develop. For classification purposes, any involvement of the proximal limbs or trunk defines the case as dcSSc. In addition to Raynaud and skin sclerosis of the extremities, other common features of early stage dcSSc are weight loss, constitutional symptoms, and gastrointestinal manifestations, including oesophageal reflux and dysmotility, and postprandial bloating.

The clinical features of established SSc are diverse and reflect the multiple patterns of internal organ involvement and the consequences of progression of the underlying pathologic processes of vasculopathy, inflammation, and fibrosis. Particular consideration must be given to the hallmark complications of hypertensive SRC, PAH, pulmonary fibrosis (PF), and gastrointestinal dysmotility. Overlap syndromes have especially variable clinical features reflecting the underlying pathology of these conditions. Many of the symptoms and signs are seen to a lesser extent in isolated SSc but are more severe.

Some symptoms are especially common in SSc and raise important differential diagnostic questions. These are considered in Table 158-4.

TABLE 158-4
Cardinal Symptoms in Systemic Sclerosis: Potential Mechanisms Underlying Morbidity in Systemic Sclerosis

- Chest pain
  - Reflux esophagitis
  - Esophageal spasm
  - Pericarditis
  - Cardiac arrhythmia
  - Pulmonary arterial hypertension
  - Miscellaneous—chest infection, chest wall inflammation
- Breathlessness
  - Interstitial pulmonary fibrosis
  - Pulmonary arterial hypertension
  - Pleural or pericardial effusion
  - Cardiac involvement
  - Anemia (e.g., from gastric antral vascular ectasia)
  - Physical deconditioning due to reduced activity
  - Miscellaneous—chest infection, myositis
- Altered bowel habit
  - Constipation with overflow
  - Small intestinal bacterial overgrowth
  - Pancreatic exocrine insufficiency
  - Pseudo-obstruction
  - Obstruction due to inspissated feces
  - Sigmoid volvulus
- Impaired exercise capacity
  - Cardiorespiratory complications
  - Physical deconditioning due to reduced activity
  - Contractures of skin and soft tissue
  - Lower extremity ulcers
  - Muscle weakness/myositis

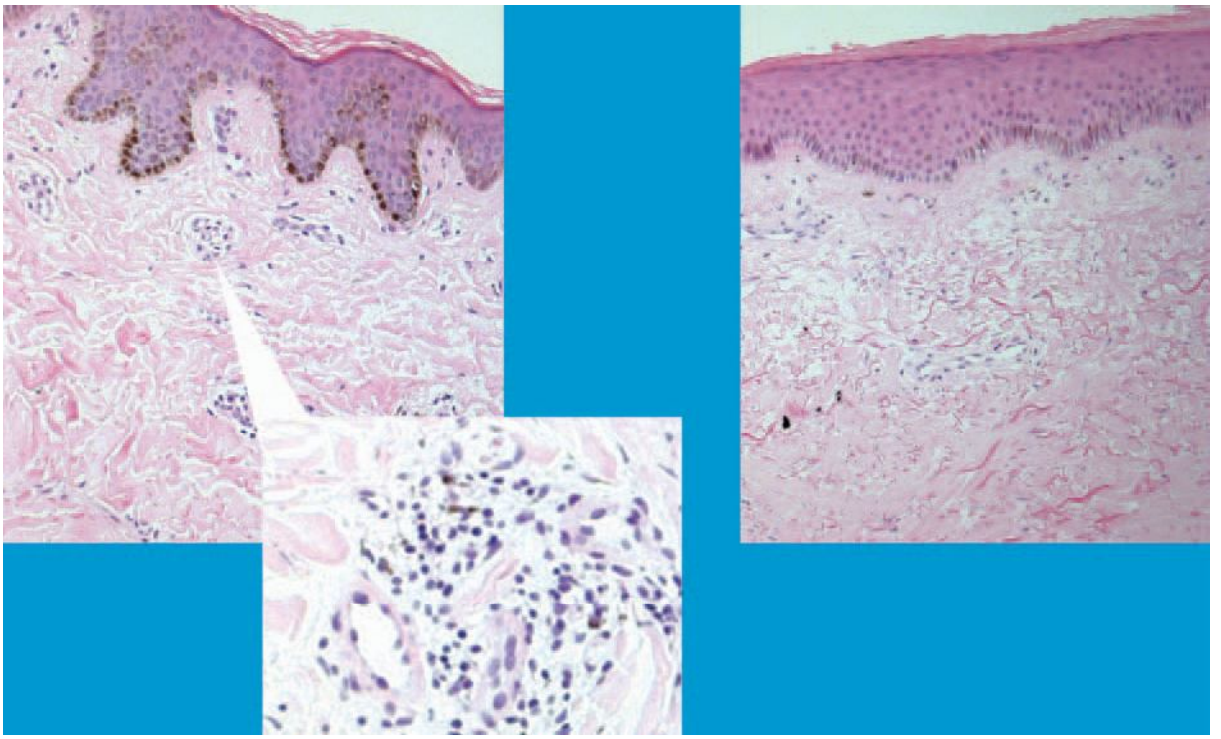
HISTOPATHOLOGY

The histopathology of SSc shows fibrosis of the lower two-thirds of the dermis and the subcutaneous fibrous trabeculae (Fig. 158-6). Panniculitis may also be a prominent feature in the early stages, whereby subcutaneous fat is replaced by a fibrous connective tissue. In the dermis, the collagen bundles appear pale, homogenous, and swollen, and there may be a sparse perivascular lymphocytic infiltrate. In later stages, pilosebaceous units and eccrine glands disappear, and there may be an effacement of the rete ridges.

Vessels of all sizes may be involved in SSc. In the early stages, there may be only dilatation of capillaries, then endothelial proliferation and complete occlusion of vessels.

DIFFERENTIAL DIAGNOSIS

The diagnosis of SSc is clinical. Although there are classification criteria that were developed to facilitate distinction of SSc



▲ **FIGURE 158-6** Histologic appearance of skin in early and late-stage diffuse cutaneous systemic sclerosis (dcSSc). In dcSSc there is perivascular mononuclear cell infiltrate at the early stages of disease. This precedes the development of skin sclerosis. Perivascular changes are shown at high power in the left panel. Later stage disease is accompanied by skin sclerosis and a low density of blood vessels and absence of inflammatory cells. At this stage, there may be associated epidermal changes with thickening and loss of secondary skin structures, including hair follicles and sweat glands. Absence of the rete ridges is also characteristic at the later stages of dcSSc. Similar changes are predicted in localized cutaneous SSc, but this is rarely biopsied due to limited skin sclerosis and concerns about healing.

from other connective tissue diseases, no formal diagnostic criteria have been developed. The main differential diagnosis is with other conditions within the scleroderma spectrum and with the scleroderma overlap syndromes. In addition it is critical to distinguish other causes of skin sclerosis. Box 158-1 summarizes important differential diagnosis for SSc. In cases of established SSc, the most important aspects of differential diagnosis relate to differentiation of the diverse manifestations of SSc. For example, there are multiple SSc-related causes for dyspnea, chest pain, or gastrointestinal symptoms that need to be correctly diagnosed.

COMPLICATIONS AND COURSE

See the section Organ-Based Treatment Strategies.

TREATMENT

Disease-Modifying Treatment

The three facets of SSc are potentially amenable to therapeutic modulation, and this raises the possibility of true disease-modifying treatment. At present, vascular therapies and immunomodulation have the widest range of candidate therapies. These approaches are summarized in Tables 158-5 and 158-6. Antifibrotic treatment remains much more of a challenge. Some encouragement is provided by recent clinical trials of idiopathic PF. However, at present there is no proven antifibrotic agent. Further details about possible treatment approaches are provided in Table 158-7. A simplified schematic for integrating putative disease-modifying therapy with programs of screening and surveillance that permit timely intervention in SSc is shown in Fig. 158-7 with organ-based strategies that currently form the basis of the majority of SSc therapeutics. Possibilities for targeted disease modifying therapy depend on the availability of therapeutic agents and a clear understanding of their role in pathogenesis.[2]

Organ-Based Treatment Strategies

There has been much more success in the field of organ-based therapeutics in SSc. The individual complications together with an overview of treatment options are listed below.

DIGITAL VASCULOPATHY AND ITS COMPLICATIONS Approximately 50 percent of patients with SSc are troubled by digital ulceration associated with vasculopathy at some point in their disease history. This is the major external feature of structural vessel disease. Other complications include critical digital ischaemia, paronychia, and finger pulp loss. Tender and painful pitting scars are very frequent and may, on occasion, progress to ulcers. Raynaud phenomenon per se does not lead to these structural and trophic changes that serve to distinguish cases with underlying connective tissue disease. Treatment requires optimal therapy for Raynaud, including agents that may have the potential for vascular remodeling, such as angiotensin receptor–blocking drugs. Parenteral prostacyclin derivatives are widely used. These help to heal digital ulcers and may prevent recurrent lesions. Prostacyclin derivatives by continued intravenous infusion are the mainstay of therapy for critical digital ischaemia. Anti-platelet agents such as aspirin or clopidogrel are used especially in critical digital ischaemia. Nebulized iloprost has been reported to be beneficial in some cases, but formal trial data are not available. More recently, there has been enthusiasm about use of therapies that are effective for PAH in digital vasculopathy. Thus bosentan, an oral

dual specificity endothelin receptor antagonist, has been demonstrated in two large controlled trials to significantly reduce the number of new digital ulcers occurring, compared with placebo.[3] No positive effect on healing of established ulcers has been demonstrated. Other agents, such as phosphodiesterase type 5 inhibitors sildenafil and tadalafil, have also been used for treatment of Raynaud, and digital ulcers but prospective clinical trial data are not available. Surgical treatments include digital microarteriolysis, which can benefit single fingers with refractory ulcers. Whenever possible, surgical amputation of digits is avoided, and prolonged treatment with parenteral prostacyclin and potent analgesia may help with this. Lumbar sympathectomy may be helpful for lower

Potential Antifibrotic Strategies for Treatment of Systemic Sclerosis

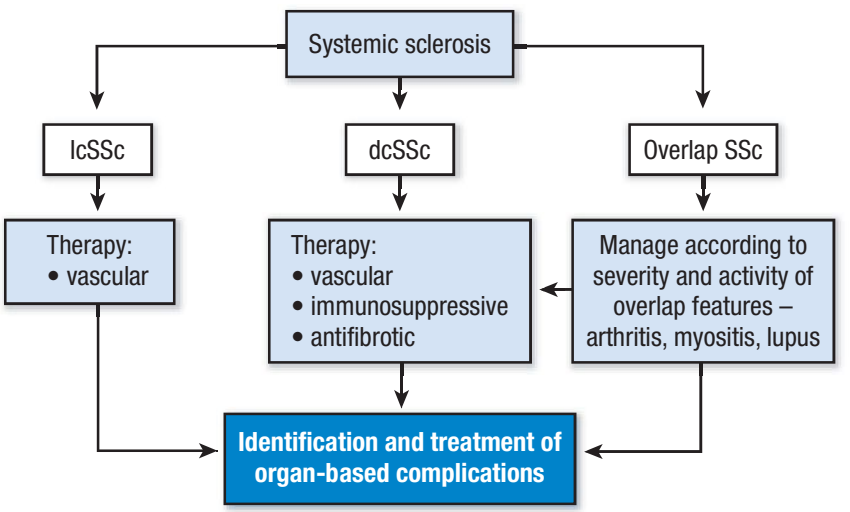
AGENT	CLINICAL TRIAL DATA	REFERENCE
D-Penicillamine	High- vs. low-dose study in United States. 134 patients, no apparent benefit.	Clements et al. 1999
Relaxin	Placebo-controlled dose-escalation study (30 patients stable scleroderma) encouraging. Improved global assessment score. Large phase III study negative. Considered ineffective.	Seibold et al. 2000
Interferon-γ	Open study (44 patients) showed minor improvements in skin sclerosis.	Grassegger et al. 1998
Anti–TGF-β strategies	Pilot studies of anti–TGF-β1 antibodies (44 patients) showed no efficacy. No high-dose toxicity observed. Anti–TGF-β1–3 in development as blocking single isoform unlikely to be effective. Other strategies being considered, including anti–connective tissue growth factor and small molecule inhibitors.	Denton et al. 2007

TGF = tumor growth factor.

limb Raynaud or ulceration. Generally, a temporary procedure is performed initially to determine likely benefit from a definitive sympathectomy. In cases of critical digital ischemia, anti-platelet therapies are often given, with anecdotal reports of the benefit of clopidogrel in preventing digital infarction.

SCLERODERMA RENAL DISEASE Although hypertensive SRC is the most devastating renal complication of SSc, there are other patterns of disease. Studies suggest that a chronic vasculopathy with reduced glomerular filtration rate is frequent. In addition, there is evidence of an increase in fibrillar collagen deposition within the renal interstitium in SSc. Finally, cases with overlap SSc may manifest inflammatory glomerular disease, including glomerulonephritis or vasculitic changes. These are usually associated with serologic features of these diseases.

However, SRC remains the most devastating renal manifestation. It occurs overall in 10 percent to 15 percent of dcSSc and 1 percent to 2 percent of lcSSc cases during the course of disease. Many cases occur within the first 12 months of disease, and in up to one-fourth of patients with SRC the diagnosis of SSc is made at the time of the renal presentation. Typically, cases present with accelerated phase hypertension and progressive renal impairment. End-organ damage can result in encephalopathy with generalized seizures or flash pulmonary edema. Microangiopathic anemia is common, and sometimes disseminated intravascular coagulation develops. Overall, approximately two-thirds of cases of SRC presenting to a specialist center require renal replacement therapy. Of these, approximately one-half of cases eventually recover sufficiently to discontinue dialysis. This can occur over 24 months after the crisis, and so decisions about renal transplantation should be postponed until that time. The possibility of late recovery distinguishes SRC from other causes of end-stage renal failure. These outcomes are possible through the use of angiotensin-converting enzyme inhibition as routine therapy for SRC. Before their availability, the mortality from established SRC was more than 90 percent at 12 months; this is dramatically improved, but outcome still has room for improvement. Patient and physician education forms an important part of this.



▲ **FIGURE 158-7** Algorithm summarizing current approach to management of systemic sclerosis (SSc). The principles of therapy for SSc include accurate diagnosis and treatment according to the disease subset, the presence of overlap features, and the likely predominant pathologic process according to the stage of disease. In all cases, screening for and treatment of organ-based complications has a major role in successful management. Education of patients and a multidisciplinary team, including specialist nurses, physiotherapists, occupational therapists and many subspecialty physicians, and surgeons, are central to providing appropriate care for severe cases of SSc. dcSSc = diffuse cutaneous systemic sclerosis; lcSSc = localized cutaneous systemic sclerosis.

PULMONARY ARTERIAL HYPERTENSION PAH is currently the most common cause of disease-related death in SSc. It occurs in both limited and diffuse cutaneous subsets, although the most typical cases are those of lcSSc associated with isolated PAH. This condition has substantial similarities to idiopathic PAH. Current classification of pulmonary hypertension is shown in Table 158-8. Thus, two patterns of disease occur in SSc. Most cases have PAH, but there are some patients with late-stage extensive interstitial lung fibrosis in SSc that develop a true secondary PH. It is increasingly appreciated that a group of cases with some lung fibrosis [that can be detected by high-resolution computed tomography (HRCT) in up to 50 percent of SSc cases] have predominantly PAH and that this group may respond to standard PAH therapies. There have been substantial advances in the treatment of PAH over the past decade.[4] This has significantly increased the options for therapy of SSc-associated PAH, and this, in turn,

TABLE 158-8
Revised World Health Organization Classification of Pulmonary Hypertension

- Group I: Pulmonary arterial hypertension
  - Idiopathic
  - Familial
  - Related conditions: Connective tissue disease, congenital left-right shunt, portal hypertension, human immunodeficiency virus infection, drugs/toxins, other diseases
  - Associated with significant venous or capillary involvement
    - Pulmonary venoocclusive disease
    - Pulmonary-capillary hemangiomatosis
    - Persistent pulmonary hypertension of the newborn
- Group II: Pulmonary venous hypertension
  - Left-sided atrial or ventricular disease
  - Left-sided valvular heart disease
- Group III: Pulmonary hypertension associated with hypoxemia
  - Chronic obstructive pulmonary disease
  - Interstitial lung disease
    - Chronic exposure to high altitude
- Group IV: Pulmonary hypertension due to chronic thrombotic and/or embolic disease
  - Proximal pulmonary thromboembolic obstruction
  - Distal thromboembolic obstruction
- Group V: Miscellaneous
  - Sarcoidosis, vascular compression

Adapted from Simonneau et al: Clinical classification of pulmonary hypertension. *J Am Coll Cardiol* **43**:5, 2004.

has raised the profile and priority of PAH in SSc. Most cases are treated with oral agents: either bosentan (an endothelin receptor antagonists) or sildenafil (a phosphodiesterase 5 inhibitor) once they are significantly functionally limited (New York Heart Association class III). Later, if progression takes place, combination oral treatment or introduction of parenteral prostacyclin is used, by either intravenous or subcutaneous route. Inhaled delivery systems for iloprost are available.

PULMONARY FIBROSIS Although PAH is probably responsible for more deaths that lung fibrosis in SSc, lung fibrosis remains an important complication. Most cases fall histologically into the classification of non-specific interstitial pneumonia. Interestingly even those cases that have a usual interstitial pneumonia histologic or HRCT pattern have a much more favorable outcome than cases of idiopathic PF. Treatment of SSc-PF remains challenging.[5] Adding to a substantial body of uncontrolled or retrospective data suggesting benefit for cyclophosphamide in SSc-PF, the results of two randomized double-blind placebo-controlled trials have recently been reported. Both show a modest placebo-subtracted benefit for cyclophosphamide.[6] For change in forced vital capacity (percent predicted), this was statistically significant for the Scleroderma Lung Study comparing oral cyclophosphamide with placebo, and was a strong trend ($p = 0.06$) in the trial of intravenous cyclophosphamide followed by oral azathioprine. At present, most centers use cyclophosphamide as treatment for severe or progressive SSc-PF, defining the extent and severity by pulmonary function tests and HRCT. Extent of disease by HRCT and a history of progressive restrictive abnormality on pulmonary function tests is the best predictor of future decline in lung function and generally used to make decisions about therapy. Other therapies that are in use include carbocysteine and low dose corticosteroids. The place of other immunosuppressive strategies remains uncertain and requires evaluation in prospective multicenter clinical trials. It is noteworthy that despite strong theoretic rationale as a treatment for lung fibrosis, the endothelin receptor antagonist bosentan was not superior to placebo in a recent large multicenter study of SSc-PF cases. Recent trials in idiopathic PF of pirfenidone, etanercept, and interferon-γ that have shown some signals of efficacy and are under further evaluation for this disease.

GASTROINTESTINAL COMPLICATIONS Involvement of the gastrointestinal tract is very frequent in SSc. More than 90 percent of cases have esophageal involvement with dysmotility and reflux. This can respond very well to proton pump inhibitors and agents that increase lower oesophageal sphincter tone such as domperidone. Mid-gut involvement takes many forms. Pseudo-obstruction requires conservative management initially but may require parenteral nutritional supplementation. Small intestinal bacterial overgrowth can be treated using broad-spectrum antibiotics, and pancreatic insufficiency may require enzyme supplements. Large bowel involvement is a major challenge. Anorectal incontinence sometimes responds well to an implanted sacral nerve stimulator or to less elaborate approaches such as bioplastic injection to increase the internal anal sphincter bulk. Associated rectal prolapse may require additional surgical intervention. Chronic constipation, sometimes with overflow diarrhea, is a common problem. An adjustment to diet and judicious use of stimulating, softening, or bulking aperients is recommended, but an individualized approach with substantial patient involvement is generally the most successful approach. On occasion, defunctioning colostomy is needed, but this is only appropriate in a very limited number of cases.

MYOSITIS One of the challenges of treating myositis is the need to balance the risk and benefit of corticosteroid therapy in SSc and the definition of the pathologic basis for muscle involvement in SSc. Fibrosis, atrophy, and inflammation can all occur. Steroid doses should be minimized. Imaging and electromyogram can be helpful in distinguishing different patterns of pathology.

CARDIAC COMPLICATIONS Cardiac involvement from SSc is an important contributor to mortality but remains one of the least well understood and poorly recognized of the internal organ complications of SSc. A large number of studies confirm that radionuclide imaging, electrophysiologic, and functional abnormalities are frequent in SSc, but the significance of these findings is uncertain. Hemodynamically significant cardiac involvement occurs in up to 10 percent of cases of dcSSc. An inflammatory component of myocarditis may respond to immunosuppression, and so an operational approach to management of cardiac scleroderma is indicated in Fig. 158-7. This is not based on data but could form the basis for prospective evaluation of the significance of impaired left ventricular ejection fraction and elevated circulating troponin levels in SSc. Cardiac magnetic resonance imaging, tissue Doppler, and assessment of diastolic dysfunction by conventional two-dimensional echocardiography are all potential strategies for assessing cardiac involvement in SSc.

There have been many advances in SSc, including a better appreciation of the diversity of the condition, improved understanding of the underlying pathologic mechanisms, and major progress in treating organ-based complications. This includes the accumulation of robust clinical trial data that demonstrate effectiveness or lack of benefit of individual therapies and in validation of measures of disease assessment.[7] Furthermore, there have been major steps forward in developing effective patient organizations and

in the development of networks to better understand this disease.

SCLERODERMA-LIKE DISORDERS

Scleroderma-like disorders have been reported in association with numerous environmental toxins and drugs. These agents include solvents (vinyl chloride, benzene, toluene, epoxy resins), drugs (bleomycin, cardiopa, pentazocine, cocaine, docetaxel, metaphenylenediamine), and miscellaneous substances.

SSc was reported to occur in underground coal and gold miners. In male patients with silicosis who are older than 40 years of age, the likelihood of developing SSc is approximately 190 times greater than in males not exposed to silica, and 50 times greater than in males without silicosis but exposed to silica dust.[8] Most epidemiologic studies have failed to show a significant association between silicone gel implants and other silicone products and the development of scleroderma.[9]

An unusual form of scleroderma characterized by Raynaud phenomenon, morphea-like skin changes, capillary abnormalities of the nail fold (similar to those in SSc), osteolysis of the distal phalanges, and hepatic and PF may occur in workers exposed to polyvinyl chloride. Bleomycin also produces PF, Raynaud phenomenon, and cutaneous changes indistinguishable from those of SSc.[10] The development of these changes appears to be dose dependent and is reversible on discontinuation of the drug.

Collectively, chemical exposures account for a small fraction of scleroderma cases. Large epidemiologic studies have not yet revealed a significant role for toxins and drugs in scleroderma.

Scleroderma-like skin changes may also be associated with scleromyxedema, porphyria cutanea tarda, and graft-versus-host disease. Similar skin changes, primarily in the legs, have been described in the carcinoid syndrome, but these entities are clearly separable from scleroderma per se.

Other syndromes that cause scleroderma-like skin changes, such as eosinophilic fasciitis (Shulman syndrome), the eosinophilia myalgia syndrome, and toxic oil syndrome are discussed in Chap. 35. Scleromyxedema is discussed in Chap. 159.

CHAPTER 159

Scleredema and Scleromyxedema

Roger H. Weenig
Mark R. Pittelkow

Disorders characterized by excessive mucin deposition, increased collagen production, and fibrocyte hyperplasia are historically categorized as mucinoses, sclerosing disorders, and fibrosing disorders, respectively. The fibrocyte (fibroblast) is central in the pathogenesis of each of these conditions. Thus, shifting the focus from products and consequences of disordered fibroblast activity (e.g., mucin, collagen, fibrosis) to the cell of origin, the fibroblast, and the mechanisms that stimulate specific fibroblast dysfunction provides a better understanding of the histopathogenesis of these diseases and also lays a foundation for the development of more effective treatments for these incapacitating conditions. In some disorders, a singular fibroblast activity predominates, such as excessive mucin or collagen production [pretibial myxedema (see Chap. 152) and sclerodermoid disorders (see Chap. 158) respectively]. In others, a combination of excessive mucin and collagen production occurs (scleredema, this chapter) or excessive mucin production and fibrocyte hyperplasia ensues [scleromyxedema (this chapter) and nephrogenic fibrosing dermopathy (see Chap. 151)].

Fibroblasts are derived from CD34-positive hematopoietic precursors that originate in the bone marrow and populate the skin during development and wound repair. The chief role of the skin fibroblast is to deposit collagen, elastin, and ground substance, the major constituents of the dermis and pannicular septae and the substrates to which the epidermis and skin appendages attach and integrate (see Chap. 61).

The stimuli that cause fibroblasts to overproduce mucin or collagen, or to proliferate or aberrantly immigrate into skin are varied. Infectious triggers, inflammatory states, diabetes mellitus, drugs, genetic mutations, and toxins as well as specific mediators such as eicosanoids, growth factors, cytokines, chemokines, immunoglobulins-paraproteins, and other circulating factors have been implicated, but the precise mechanisms that result in fibroblast pathology (fibropathy) are poorly characterized. Some of these stimuli may recruit bone marrow–derived fibroblast precursors to the skin; others may act directly on fibroblasts already residing in the skin.

This chapter discusses scleredema and scleromyxedema. Other diseases relevant to cutaneous fibrocytes are discussed separately in other chapters and are listed in Table 159-1.

SCLEREDEMA

Scleredema was described by Buschke in 1902[1] and is also designated as *scleredema of Buschke* or *scleredema adultorum*, although the latter is a misleading term because children or adolescents can develop the condition.

Epidemiology

Scleredema is rare, although the precise incidence and prevalence are unknown. Men and women are affected with

SCLEREDEMA AT A GLANCE

- Acute skin induration characterized by dermal mucinosis and mild sclerosis.
- Disease associations:
  - Post-infectious scleredema of youth.
  - Diabetes mellitus–associated scleredema of adulthood.
  - Paraproteinemia-associated scleredema.
  - In rare cases, hyperparathyroidism, connective tissue disease, human immunodeficiency virus infection.
- Histopathology: pan-dermal thickening with broad collagen bundles separated by mucin deposits, chiefly hyaluronate.
- Clinical course:
  - Post-infectious: usually resolves in 1 to 2 years.
  - Diabetes mellitus associated: may improve with better control of diabetes, but a prolonged course is expected.
- Treatment: therapy for underlying disease, ultraviolet A1 light; psoralen plus ultraviolet A light.

equal frequency. More than half of cases of scleredema occur in childhood or adolescence, most commonly after an upper respiratory tract infection.[2] Streptococcal infection is most commonly identified, but other infectious agents have also been implicated. Disease development in adulthood in association with adult-onset diabetes mellitus is the second most common presentation of scleredema. Uncommonly, scleredema occurs in association with paraproteinemia or multiple myeloma, and this association possibly is becoming more common as other causes diminish in frequency with better treatment and management of underlying disease.

Pathogenesis

Type I collagen and hyaluronate appear to be the major fibroblast products whose production is increased in scleredema-affected skin.[3–5] The precise mechanism(s) for increased collagen and glycosaminoglycan production in scleredema is not known. Stimulation of fibrocytes by immunoglobulin may be related to the pathogenesis of scleredema, particularly in cases associated with infectious agents or a paraproteinemia. Serum from a patient with scleredema associated with paraproteinemia was able to increase collagen production by cultured fibroblasts in vitro.[6] However, the factor(s) involved has not been elucidated. Other soluble circulating cytokines and small molecule mediators likely also play critical roles.

Clinical Findings

The clinical findings of scleredema are distinctive. An acute onset of non-pitting induration of neck, shoulders, and upper back skin may be followed by involvement of the face and arms. Characteristically, the affected skin appears smooth and waxy, with tense dermal induration and prominent follicular ostia, at times imparting a *peau d'orange* appearance (Fig. 159-1). In general, however, skin changes are better felt on palpation than seen. The skin of the upper trunk (especially the back) is a favored site for scleredema, but more widespread involvement may be observed. The affected and unaffected skin blend imperceptibly. Scleredema involving the esophagus, bone marrow, nerve, liver, or salivary glands has been described rarely.[7,8] Patients may report symptoms of restricted motion of joints, the tongue, or eyes, as well as muscular weakness or tenderness. However, investigations to identify internal organ involvement by scleredema are infrequently pursued.

Histopathology

Punch biopsy specimens of affected skin have a non-tapered (square) appearance on low-power microscopic examination. The proportion of dermis is very significantly increased in comparison to adjacent non-affected skin (Fig. 159-2A). There is a decreased number or higher placement of eccrine units. Fibroblasts are normal in number and morphology.

• Generalized myxedema	152
• Localized myxedema	152
• Reticular erythematous mucinosis and plaque-like mucinosis	147
• Connective tissue disease	156, 157, 158, 162
• Degos disease	172

▲ **FIGURE 159-1** Scleredema showing waxy, non-pitting induration of back skin.

The collagen bundles are slightly thickened and separated from each other by subtle deposits of mucin. Stains for mucin (Alcian blue, colloidal iron) are recommended to identify the mucin deposits (see Fig. 159-2B).

Prognosis and Clinical Course

Post-infectious scleredema usually abates in 1 to 2 years. Scleredema associated with adult-onset diabetes tends to be protracted, although some patients appear to improve with better glucose control. Gammopathy-associated scleredema is more chronic and can be resistant to many therapies.

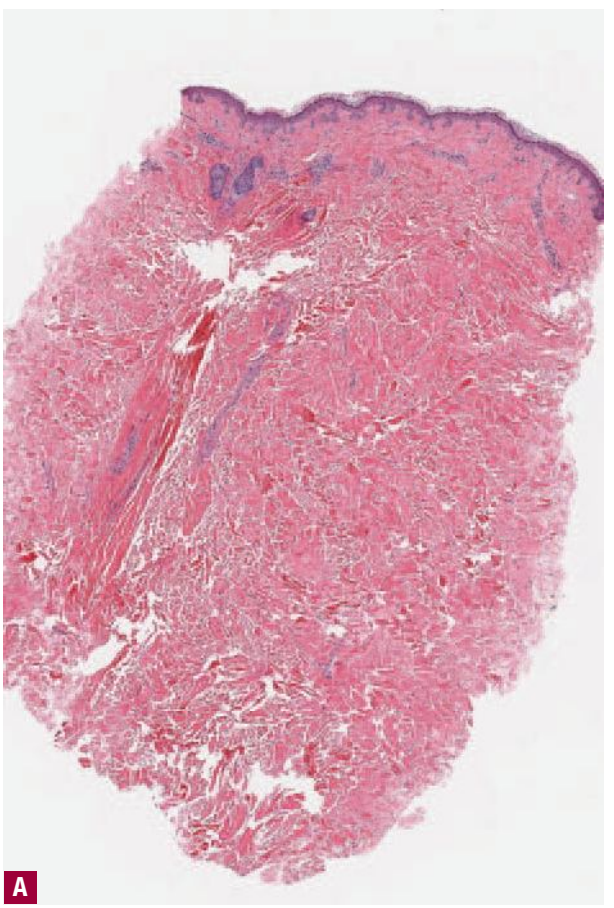
Treatment

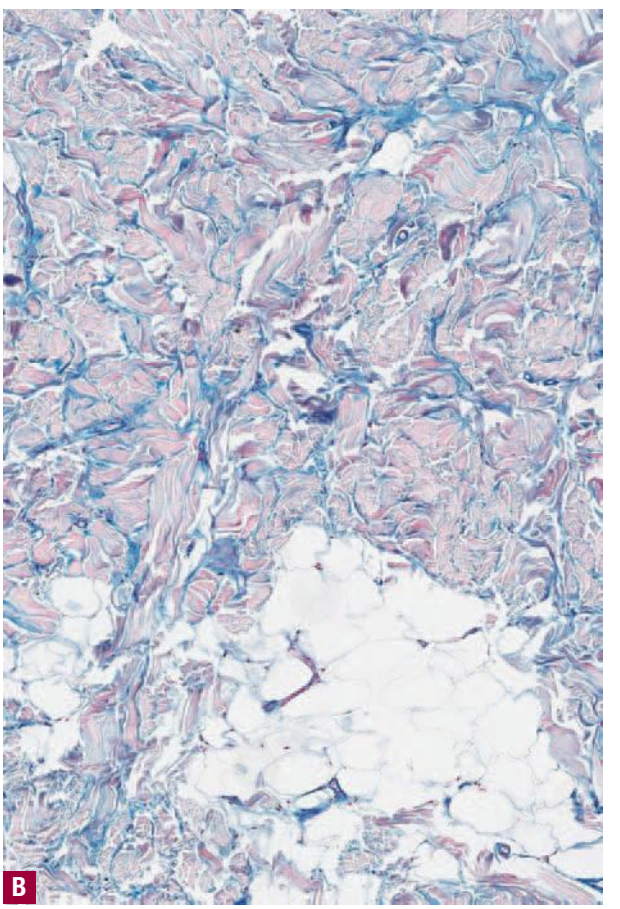
Antibiotics do not appear to affect the course of post-infectious scleredema. Treatment of the associated disease (e.g., improved glucose control or treatment of paraproteinemia) may lead to improvement. Ultraviolet A1 phototherapy has been reported effective in a few adult patients,[9,10] as has bath–psoralen plus ultraviolet A phototherapy.[11] Treatment with methotrexate did not provide benefit in a series of cases of scleredema. Scleredema has responded to local radiotherapy or electron-beam irradiation. Scleredema associated with monoclonal gammopathy has responded to extracorporeal photopheresis.

SCLEROMYXEDEMA

Historical Aspects

Lichen myxedematosus/scleromyxedema and scleredema are related conditions characterized by dermal fibroplasias and excess mucin production. Lichen myxedematosus presents with scattered small, whitish cream to red papules on the trunk and extremities, whereas confluent papules forming large areas of thickened, indurated skin typify scleromyxedema. A monoclonal paraproteinemia, usually of immunoglobulin G κ, is frequently associated with lichen myx-





▲ **FIGURE 159-2** Photomicrograph of scleredema showing a mild increase in the thickness of dermal collagen bundles separated by clear spaces (**A**), and mucin deposition identified in clear spaces by Alcian blue stain (**B**).

SCLERO-MYXEDEMA AT A GLANCE

- Chronic, progressive condition characterized by dermal fibrosis and mucinosis with normal thyroid function.
- Usually associated with paraproteinemia.
- Clinical variants:
  - Generalized, confluent lichenoid eruption (scleromyxedema).
  - Discrete papular (rarely nodular) eruption on the trunk or extremities (lichen myxedematosus).
    - Papular mucinosis of infancy.
    - Papular mucinosis of adulthood.
    - Self-healing papular mucinosis.
    - Acral persistent papular mucinosis.
    - Nodular variant.
  - Localized or generalized lichenoid plaques (but distinct from plaque-like mucinosis/reticulated erythematous mucinosis).
  - Urticarial plaques.
- Histopathology: superficial to mid-dermal fibroplasia and mucinosis.
- Clinical course: chronic progressive course and poor outcome in generalized cases; localized and self-healing forms have a better prognosis.
- Treatment: correction of paraproteinemia through melphalan therapy, bone marrow transplantation.

edematosus and almost universally observed in scleromyxedema.

Epidemiology

Lichen myxedematosus/scleromyxedema constitutes a rare spectrum of disease that affects men and women with equal frequency and shows an onset of symptoms in mid to later life.

Pathogenesis

The pathogenesis of scleromyxedema is unknown. Most patients with scleromyxedema have a monoclonal gammopathy (paraproteinemia), usually of the immunoglobulin G κ type and defined as being of "undetermined significance." Excessive hyaluronate production and fibroblast proliferation are observed, but support for a direct effect of the monoclonal protein on fibroblasts is lacking.[15,16] Indirect mechanisms of development appear to include circulating cytokines, inflammatory mediators, and fibroblast precursor cell lineages that migrate from the blood, take up residence in the dermis and, in more extensive cases, in other tissues, and synthesize mucin.

▲ **FIGURE 159-3** Scleromyxedema showing marked nodular induration of facial skin with accentuated skinfolds.

Clinical Findings

Several distinct clinical presentations, and hence nosologic designations, have been recognized. Although there is considerable clinical overlap and patients may show progression from limited to widespread involvement, it is useful to distinguish localized from generalized disease as well as presentation with discrete papules from presentation with confluent plaques. The generalized lichenoid eruption consists of numerous minute (1- to 3-mm) papules scattered on the extremities and the trunk. Scleromyxedema presents with confluent lichenoid plaques. Individual lesions and plaques may exhibit marked erythema or hyperpigmentation. The face is involved in most cases, which leads to significant deformity (Fig. 159-3). The trunk and extremities are usually affected (Fig. 159-4A), and the result is often decreased flexibility and range of motion in the involved areas (see Fig. 159-4B).

A monoclonal paraproteinemia of undetermined significance, usually of immunoglobulin G κ, is identified in most patients. Paraproteinemia is less common in localized variants. Progression to multiple myeloma occurs rarely.

Muscle weakness, contractures, restrictive lung disease, upper airway involvement, pulmonary hypertension, esophageal dismotility, and neurologic disorders (seizures, motor impairment, carpal tunnel syndrome, depression, memory loss, aphasia, peripheral neuropathy, and psychosis) have been reported in association with scleromyxedema.[17] Thyroid function is normal.

Histopathology

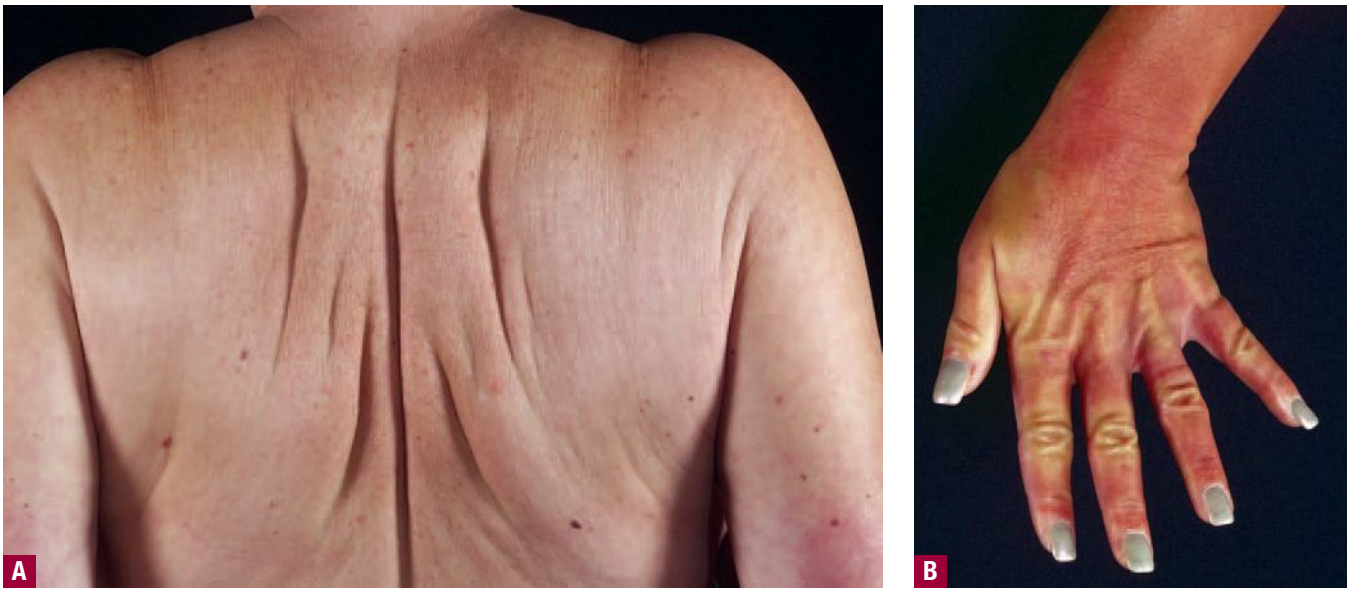
Regardless of the clinical presentation, the histopathologic findings of lichen myxedematosus/scleromyxedema are identical and demonstrate superficial to mid-dermal mucin deposition with admixed fibroblast proliferation (Fig. 159-5). The disease spectrum of scleromyxedema is histologically distinct from other mucinoses as well as sclerosing and fibrosing conditions. Nephrogenic fibrosing dermopathy (see Chap. 151) shows close histologic resemblance to scleromyxedema. The pannicular septa are the focus for histologic distinction: they are always involved in nephrogenic fibrosing dermopathy and never involved in scleromyxedema. Moreover, scleromyxedema tends to be restricted to the upper half of the dermis, whereas nephrogenic fibrosing dermopathy becomes more prominent in the lower dermis then extends to the pannicular septa.

Prognosis and Clinical Course

Localized, self-healing variants are usually confined to the skin and self-limiting. However, prospective follow-up and caution is advised, because some cases fitting the criteria for localized disease have been associated with internal organ involvement or progression to more generalized disease (so-called *atypical papular mucinosis*). Scleromyxedema usually follows a chronic and progressive clinical course, and the outcome is poor. Respiratory failure, cerebral disease, and infection usually lead to a gradual decline and death.

Treatment

Melphalan has been used for decades to treat scleromyxedema with variable efficacy.[18–20] Other therapies directed



▲ **FIGURE 159-4** Scleromyxedema. **A.** Thickened, bound-down skin of the back. **B.** Confluent lichenoid papules and indurated skin of the hand and wrist.

toward quantitatively reducing or ameliorating the effects of the paraproteinemia have shown variable results. Agents or therapies with reported efficacy include glucocorticoids,[21] intravenous immunoglobulin,[22] thalidomide,[23] interferon-α,[24] retinoids, psoralen plus ultraviolet light,[25] electron-beam radiation, plasmapheresis, and extracorporeal photopheresis.[21–26] Autologous peripheral blood stem cell transplantation has resulted in dramatic remission of scleromyxedema in a number of patients with severe disease.[27,28]

CHAPTER 160

Relapsing Polychondritis

Camille Frances

RELAPSING POLYCHONDRITIS AT A GLANCE

- Relapsing polychondritis is a rare multisystem autoimmune disease with both autoantibodies and cellular immune reactions to different cartilage proteins.
- More than 30 percent of patients have an associated disease, mainly of autoimmune or hematologic origin.
- Recurrent episodes of chondritis lead to progressive destruction of cartilaginous structures.
- Other proteoglycan-rich structures such as eyes, blood vessels, or inner ear may be affected.
- Dermatologic manifestations occur frequently, especially in association with myelodysplasia.

EPIDEMIOLOGY

The incidence of relapsing polychondritis (RP) has been estimated to be 3.5 per 1 million in Rochester, Minnesota.[1] The peak age for disease onset is the fifth decade; however, development of the disease may occur in young children and in the elderly.[2] The male-female ratio has been estimated to be from 1.1:1.0 to 1.3:1.0.[3] Although most cases have been reported in Caucasians, there is no evidence supporting a role for ethnic or geographic factors.

ETIOLOGY AND PATHOGENESIS

Several lines of evidence have been accumulated that suggested the role of autoimmunity in RP. More than 30 percent of patients have an associated disease, mainly of autoimmune origin.

The role of the humoral immune response was based on the presence of antibodies to collagen type II in the acute phase of RP. Antibody titers seemed to correlate with the severity of symptoms. Other antibodies were also detected in patients with RP: antibodies to type IX and type XI collagen, minor collagens which represent 5 percent to 10 percent of cartilage collagens, antibodies to matrilin-1, an extracellular matrix protein, predominantly expressed in upper respiratory tract cartilage; and antibodies to cartilage oligomeric matrix protein, another cartilage protein. Several animal models have been described in which immunization with these various cartilage proteins induced a variety of chondritis manifestations that mimic those seen in patients.[4] A role for immune complexes and subsequent activation of the complement system is suggested by examination of tissue lesions, which usually shows the presence of granular deposits of immunoglobulins and the C3 component of complement associated with $CD4^+$ lymphocytes and plasma cells. A role for T cells in RP pathogenesis, although less well studied, has also been demonstrated in patients and in animal models with specificity against the same cartilage proteins. T-cell clones isolated from a RP patient were found to be specific for a peptide corresponding to residues 261 to 273 of the type II collagen and were restricted to either the DRBI*0101 or the DRBI*0401 allele.[5] A significant near twofold increase in DR4 antigen frequency was found in RP patients as compared to that in healthy controls, but the genotyping of DR-4 positive patients and controls did not show predominance of any DR4 sub-type. Genetic susceptibility was also confirmed by animal models.

CLINICAL FINDINGS

Disease onset is usually sudden with characteristic chondritis, with arthritis or ocular inflammation occurring less frequently. Non-specific initial symptoms, such as fever or weight loss, are rare.

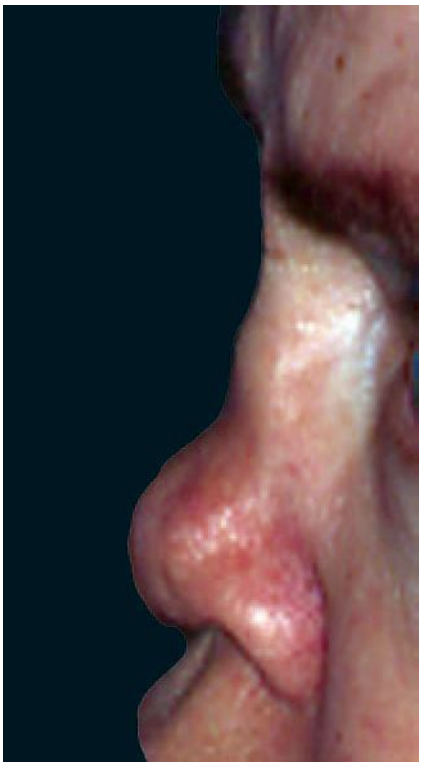
Attacks of chondritis usually occur in a relapsing and remitting pattern. Inflammatory episodes generally last a few days or weeks and may subside spontaneously or with treatment; recurrences after weeks or months occur and subsequently result in cartilage destruction. Auricular chondritis is the most frequent sign, occurring in 85 percent of patients, causing pain, redness, and swelling of the cartilaginous portion of the pinna, sparing the non-cartilaginous lobe (Fig. 160-1). Biopsy of the auricular cartilage is not needed to make a correct diagnosis. After several attacks, the pinna may become soft and floppy, looking like a cauliflower (Fig. 160-2); sometimes it is stiff due to calcifications. Nasal chondritis (65 percent) is less inflammatory, presenting with nasal pain, stuffiness, rhinorrhea, and, sometimes, epistaxis. The characteristic saddle-nose deformity (Fig. 160-3) may appear with or without previous clinical inflammatory episodes.

▲ **FIGURE 160-1** Relapsing polychondritis. Painful inflammation of the cartilaginous portion of ear.

OTHER ORGAN INVOLVEMENT

Respiratory tract chondritis, though uncommon at presentation, occurs in up to 50 percent of patients, and may be lethal. The respiratory involvement results in complaints of hoarseness, nonproductive persistent cough, dyspnea, and wheezing. Complications include

▲ **FIGURE 160-2** Relapsing polychondritis. Soft and floppy ear with a "cauliflower" appearance.



▲ **FIGURE 160-3** Relapsing polychondritis. Saddle nose deformity.

upper airway collapse, obstructive respiratory insufficiency, and secondary infections. Costochondritis (35 percent) causes parietal pains that may also compromise respiration.

Joint pain is a common presenting feature in RP (30 percent). Large and small joints of the peripheral or axial skeleton may be affected (> 70 percent). Arthritis is intermittent, migratory, asymmetric, seronegative, and usually nonerosive.

Nearly 60 percent of patients develop ocular inflammation. Episcleritis and scleritis (see eFig. 160-3.1 in on-line edition) are the most common manifestations, followed by keratoconjunctivitis sicca, iritis, retinopathy, keratitis. Rarely corneal perforation, retinal vasculitis, and optic neuritis lead to blindness.

Conductive hearing loss is secondary to stenosis of the external auditory canal, eustachian tube chondritis, or serous otitis media, while perception hearing loss may occur as a consequence of sensorineural involvement. Symptoms of vestibular dysfunction, such as dizziness, ataxia, nausea, and vomiting, are usually acute and improve with time.

The spectrum of cardiovascular manifestations is wide, including different cardiac tissues (aortic and/or mitral regurgitation, impairment of the conduction system, pericarditis) and all types of vessels (thoracic and abdominal aortitis leading to aneurysms, Takayasu-like aortic arch syndrome, medium and large vessels vasculitis, leukocytoclastic vasculitis, thrombophlebitis). Lesions are inflammatory and/or thrombotic. Some, but not all, thrombotic manifestations have been linked to anti-phospholipid syndrome. Large vessel vasculitis tends to occur after several years of smoldering and often, occult disease, despite immunosuppressive therapy.

Dermatologic manifestations are sometimes the presenting feature of RP (12 percent), and ultimately become apparent in more than one-third of patients.[6] They are non-specific including nodules on the limbs (see eFig. 160-3.2 in on-line edition), purpura (see eFig. 160-3.3 in on-line edition), oral or complex aphthosis (see eFig. 160-3.4 in on-line edition), papules, sterile pustules (see eFig. 160-3.5 in on-line edition), superficial phlebitis, livedo reticularis, ulcerations on the limbs, and distal necrosis (see eFig. 160-3.6 in on-line edition). They appear concomitantly or in the absence of attacks of chondritis. Pathologic features include inflammatory or thrombotic vascular lesions, neutrophil infiltrates as in neutrophilic dermatoses, and inflammation of the dermis or subcutis. Patients with and without dermatologic manifestations have similar clinical manifestations of RP. However, the frequency of dermatologic manifestations (> 90 percent), age of onset of chondritis, and male-female ratio seems higher when RP is associated with myelodysplasia.[6]

LABORATORY FINDINGS

Histopathology

Histopathology of affected cartilage shows perichondrial inflammation and the loss of the normal cartilaginous basophilia.

Other Laboratory Tests

Laboratory findings in RP are nonspecific, consistent with acute or chronic inflammation. Urinalysis may be abnormal in the presence of renal involvement (mesangial expansion, immunoglobulin A nephropathy, tubulointerstitial nephritis, or necrotizing glomerulonephritis).

Pulmonary function tests, including inspiratory and expiratory flow volume curves, should be performed systematically to detect occult pulmonary involvement, which may be confirmed by computed tomography of the respiratory tract. Three-dimensional or spiral magnetic resonance imaging may provide better resolution. Although not routinely available, autoantibodies to type II, IX, and XI collagen and to matrilin I can be found in patients with RP. Urinary type II collagen neoepitope measurement may be a useful tool to follow the evolution of disease.[7]

Box 160-1

Empirical Diagnostic Criteria[a]

- Bilateral auricular chondritis
- Non-erosive seronegative inflammatory polyarthritis
- Nasal chondritis
- Ocular inflammation
- Respiratory chondritis
- Audiovestibular damage

[a]For the diagnosis of relapsing polychondritis, patients must have one of the following: at least three of the above clinical criteria, one or more of the above clinical criteria and biopsy confirmation of cartilage inflammation, or chondritis at two or more separate anatomic locations with response to steroids and/or dapsone.
Data from Michet CJ et al: Relapsing polychondritis—Survival and predictive role of early disease manifestations. *Ann Intern Med* **104**:74, 1986.

DIAGNOSIS (Box 160-1)

DIFFERENTIAL DIAGNOSIS (Box 160-2)

PROGNOSIS AND CLINICAL COURSE

The clinical course of RP is progressive with intermittent flares. The number of different organs involved, the severity of involvement, and the response to treatment are unpredictable. Common causes of death are respiratory or cardiovascular complications and secondary infections. Patients have an increased risk of developing lethal myelodysplastic malignancies.

TREATMENT

Because of the highly variable course of RP, individualized therapy is the key to optimum management. General therapeutic guidelines are based on retrospective analyses of series of patients or isolated case reports. Nonsteroidal anti-inflammatory drugs, colchicine, or dapsone may be useful for patients with mild auricular or nasal chondritis, arthralgia, or mild arthritis. More serious mani-

festations require oral corticosteroids in doses of 0.3 to 1.0 mg/kg of body weight according to the severity of disease. Pulse intravenous steroids are prescribed for acute airway obstruction, and/or before surgical intervention (tracheostomy, aortic aneurysm repair, cardiac valve replacement). Long-term corticosteroids decrease the frequency and severity of recurrences although it does not prevent vital organ involvement. Many kinds of immunosuppressants have been used with some success as disease-modifying and steroid-sparing agents. Methotrexate, azathioprine, cyclophosphamide, and cyclosporine A are most commonly used. The beneficial effects of new biologic therapies such as anti-CD4 monoclonal antibodies, antitumor necrosis factor agents, and of autologous stem cell transplantation have been reported in isolated cases. One child was successfully treated with daily oral fetal bovine type II collagen.

CHAPTER 161

Rheumatoid Arthritis, Rheumatic Fever, and Gout

Christina L. Haverstock
Joseph L. Jorizzo

This chapter discusses common rheumatologic diseases that have predominantly musculoskeletal presentations; however, all of these conditions have cutaneous manifestations.

RHEUMATOID ARTHRITIS

Rheumatoid arthritis (RA) is a systemic inflammatory autoimmune disease that is characterized by a debilitating chronic, symmetric polyarthritis with significant extra-articular manifestations, which include rheumatoid nodules, pyoderma gangrenosum, granulomatous dermatitis, vasculitis, and internal organ involvement. The disease process is often progressive, resulting in limitation of joint function. Ultimately there may be a resultant decline in functional status, possibly leading to premature death. Permanent remission is unusual.

Epidemiology

Approximately 1 percent of the adult population in North America and Northern Europe are affected with RA, with great variation in prevalence in other parts of the world.[1] Approximately 70 percent of patients follow a chronic disease course with exacerbations and remissions, 25 percent have intermittent disease with brief attacks of inflammation followed by remissions, and approximately 5 percent have an aggressive, malignant form with multiple extra-articular manifestations.[2] RA is more common in females than males, ratio from 2:1 to 3:1, and has a peak onset at 50 years of age.[1]

Etiology and Pathogenesis

The exact etiology of RA remains unknown. The initial onset of joint symptoms is likely multifactorial. Genetics plays at least some role in the development, severity, and outcome of the disease in certain patients.[3] Furthermore, an association between extra-articular disease and HLA-DR1 and -DR4 genes has been noted in some populations.[4]

Mechanical stress on joints may initiate an inflammatory response creating an imbalance between the rapid response to trauma and the need to pro-

RHEUMATOID ARTHRITIS AT A GLANCE

- Affects roughly 1 percent of the world population.
- Chronic disfiguring inflammatory condition.
- Genetics and environment play a role in etiology.
- Symmetric arthritis of the proximal interphalangeal and metacarpalphalangeal joints.
- Skin findings include: Granulomatous dermatitis, vasculitis, rheumatoid nodules, pyoderma gangrenosum, and Bywaters lesions.
- Treatment based on severity of disease.

TABLE 161-1
1987 American College of Rheumatology Revised Criteria for the Classification of Rheumatoid Arthritis (Modified)

CRITERION	DEFINITION
Morning stiffness	Morning stiffness in and around the joints, lasting at least 1 h before maximal improvement.
Arthritis of three or more joint areas	At least three joint areas simultaneously afflicted with soft-tissue swelling or joint fluid observed by a physician. The possible areas are (right or left): PIP, MCP, wrist, elbow, knee, ankle, and MTP joints.
Arthritis of hand joints	At least one area swollen in a wrist, MCP, or PIP joint.
Symmetric arthritis	Simultaneous involvement of the same joint areas on both sides of the body (bilateral involvement of PIP, MCP, or MTP acceptable without perfect symmetry).
Rheumatoid nodules	Subcutaneous nodules over bony prominences or extensor surfaces or in juxta-articular regions (observed by a physician).
Serum rheumatoid factor	Abnormal amount of serum rheumatoid factor by any method while the result has been positive in 5% of control subjects.
Radiographic changes	Erosions or unequivocal bony decalcification localized in or most marked adjacent to the involved joints.

MCP, metacarpophalangeal; MTP, metatarsophalangeal; PIP, proximal interphalangeal.
From Arnett FC et al: The American Rheumatism Association 1987 revised criteria for the classification of rheumatoid arthritis. *Arthritis Rheum* **31**:315, 1988.

tect self from damage. Patients with seropositive RA (positive rheumatoid factor) have circulating and tissue-bound immune complexes. B cells produce autoantibodies in some RA patients. After binding to antigen, these autoantibodies result in complement fixation and recruitment of polymorphonuclear leukocytes, which result in joint destruction. Possible antigens in RA include heat shock proteins, collagen, and cyclic citrullinated peptides.[5]

Patients with seronegative RA (negative rheumatoid factor) may not create autoantibodies, but other immune mechanisms are involved. This theory led to the recognition that T cells are important players in the etiology of this disease. In the SKG mouse model, autoreactive T cells are preferentially selected, leading to inflammatory arthritis similar to RA. T cells also activate other cells via cytokines, including osteoclasts, which play a major role in the bone resorption seen in RA. Effector cytokines of the T cell include interferon-γ, interleukin 1, interleukin 17, and tumor necrosis factor (TNF)-α, many of which have been, or are being, used as therapeutic targets to treat RA.[2,5]

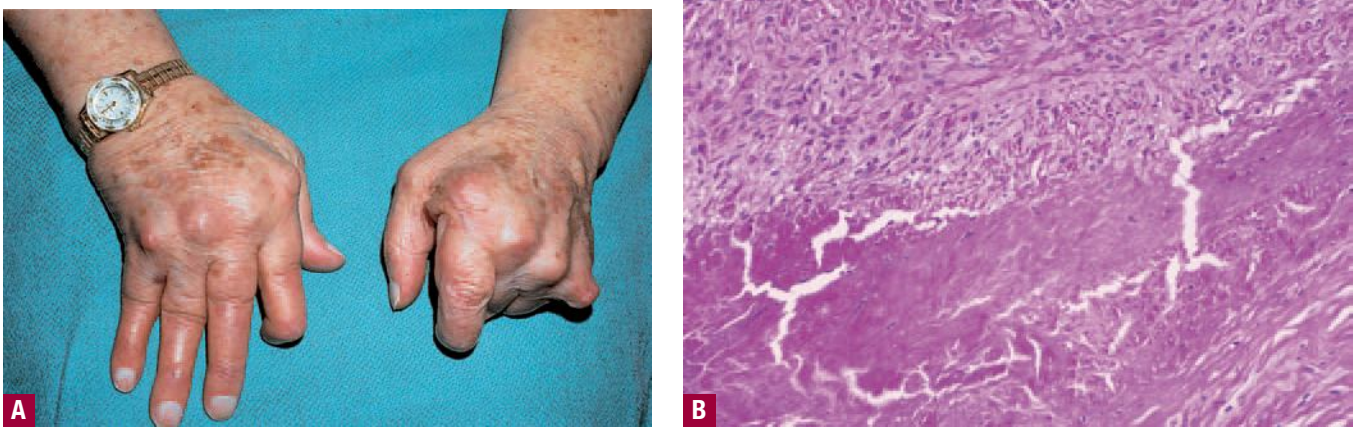
Lastly, joints have unique anatomic and physiologic qualities that render them targets for immune and inflammatory assault. Cartilage is subject to repetitive mechanical stress, retains antigens and pro-inflammatory cytokines, and has a limited capacity for regeneration. Once proteolytic enzymes cause erosions, narrowing of the joint space, and mechanical instability, rheumatoid inflammation may become self-sustaining.[6]

Clinical Features

RA often begins with general constitutional symptoms such as fatigue, anorexia, vague musculoskeletal complaints, and generalized weakness. It may be weeks or months before the characteristic synovitis presents. It is in these early stages that definite diagnosis is most difficult, despite a thorough patient evaluation. However, early diagnosis and treatment are essential because most of joint damage is thought to occur early in the disease process. The American College of Rheumatology has guidelines for the diagnosis of RA (Table 161-1).[7] For a patient to be diagnosed with RA, four of the seven criteria must be present, and the first four criteria listed must be present for at least 6 weeks. Extra-articular manifestations may help to delineate the disease process early and may signify a more serious disease process requiring the initiation of aggressive therapy.[8,9]

ARTICULAR MANIFESTATIONS The articular manifestations of RA relate to an inflammatory synovitis that can affect the synovial lining of joints, tendons, and bursae. Synovial inflammation usually results in warmth but not erythema of the affected area. There is significant pain in association with stretching of the joint capsule. Hand and foot involvement forms the basis of the disease in most patients. Although the initial manifestations in the hand may be asymmetric, the clinical course subsequently takes on a symmetric and diffuse pattern. There is characteristic involvement of the proximal interphalangeal (PIP) and metacarpophalangeal joints with sparing of the distal interphalangeal (DIP) joints. The pattern of joint involvement is highly suggestive of the diagnosis.

Chronic inflammation may result in irreversible structural damage of the joint, including cartilage destruction and bony erosion. Late structural deformities may result from soft-tissue contractures or from bony ankylosis. Characteristic deformities include radial deviation of the hand with ulnar deviation of the digits, the "swan neck" deformity from hyperextension of the PIP joint and compensatory flexion of the DIP joint, and the boutonnière deformity from flexion contracture of the PIP joint and extension of the DIP joint. Similar structural deformities can occur in the feet, and all can be debilitating. Involvement of the thoracic and lumbar spine in RA is exceptional. Although the shoulder joint is often affected, it is soft-tissue structures, which include the ro-



▲ **FIGURE 161-1** Rheumatoid nodules. **A.** Severely affected joints of a patient with rheumatoid arthritis with overlying rheumatoid nodules. **B.** Histopathologically, rheumatoid nodules are palisaded granulomas in the deep reticular dermis surrounding degenerated collagen.

tator cuff tendons and muscles and the subacromial bursa, that are usually involved in the patient's symptomatology.

DERMATOLOGIC MANIFESTATIONS Extra-articular manifestations occur in more aggressive or extensive forms of RA.[8,9] The most common dermatologic finding in RA is the rheumatoid nodule. The classic rheumatoid nodule is a subcutaneous nodule that occurs in approximately one-fourth of patients with RA (Fig. 161-1A). More than 90 percent of patients with rheumatoid nodules have seropositive RA. The usual location is over pressure points such as the olecranon, the extensor surface of the forearms, and the Achilles tendon; but they have been described in almost every location, including viscera.[9] The main histologic findings (see Fig. 161-1B) are palisaded granulomas in the deep dermis or subcutaneous tissues with fibrinoid degeneration of collagen, a multitude of neutrophils, and neutrophilic dust, with surrounding fibrosis and proliferation of vessels. The main differential diagnoses histopathologically include subcutaneous granuloma annulare, necrobiosis lipoidica, foreign body or infectious granulomatous reaction, and epithelioid sarcoid.[10]

Though rheumatoid nodules are benign, they can lead to complications, including ulceration, infection, joint effusion (rheumatoid chyliform bursitis), and fistulas (fistulous rheumatism). All conditions may lead to the need for surgical excision.[9]

Rheumatoid vasculitis has an estimated annual incidence of less than 1 percent, most often affects patients with seropositive disease, and is believed to affect 1 in 8 males with RA, versus 1 in 38 females.[11] Small- to medium-sized vessels are primarily affected, often with associated peripheral neuropathy (including motor), digital gangrene, nail fold infarcts, and palpable purpura (see Chap. 164).[9,12] Some patients may have nail fold telangiectasias, with minute digital ulcerations or petechiae and digital pulp papules (Bywaters lesions) (Fig. 161-2). These papules are a manifestation of mild vasculitis and typically occur without systemic signs of vasculitis. Histopathology of skin biopsy specimens usually shows leukocytoclastic vasculitis with neutrophilic infiltration of the vessel wall, fibrinoid necrosis, and hemorrhage without palisaded granulomatous reaction.[10] Cutaneous small vessel vasculitis mostly involves postcapillary venules and may affect arterioles and larger vessels of the viscera, heart, and central nervous system. The spectrum of clinical lesions reported in rheumatoid vasculitis is wide and varies with the size and location of the vessels involved and with the extent of the disease (see Chaps. 164 and 165). Unfortunately, the presence of vasculitis, especially at the onset of the disease, portends a poor outcome.[13] Patients with evidence of vasculitis affecting the skin should be started on aggressive therapy and followed closely for other organ involvement.[6]

Rheumatoid vasculitis can present as lower-extremity ulcers; however, pyoderma gangrenosum (see Chap. 32) should be suspected if deep liquefying ulcers with a characteristic purple, undermined border occur in patients with RA. The ulcers may occur at any site but are most common on the lower extremities and abdomen. Pyoderma gangrenosum occurs more frequently and more severely in females and may take years to heal. Leg ulcers may also appear in patients with Felty syndrome, a combination of chronic RA, hypersplenism, and leukopenia (Fig. 161-3).[9]

Rheumatoid neutrophilic dermatosis is a very rare cutaneous manifestation in patients with severe RA. First described by Ackerman in 1978, these lesions are

▲ **FIGURE 161-2** Bywaters lesions. Note the purpuric papule on the dorsal finger.

▲ **FIGURE 161-3** Felty syndrome. A refractory ulcer on the foot of a patient with rheumatoid arthritis and hypersplenism.

usually chronic, erythematous, and urticaria-like plaques and papules that are sharply marginated (Fig. 161-4A). Histopathologically, these lesions have a dense infiltrate of neutrophils without leukocytoclasia, in the setting of a mixed infiltrate and papillary edema (see Fig. 161-4B).[10] It may be difficult to differentiate rheumatoid neutrophilic dermatosis from acute febrile neutrophilic dermatosis (Sweet syndrome) (see Chap. 31).

Other vasculitis syndromes, such as erythema elevatum diutinum (see Chap. 166) and livedo vasculitis (segmental hyalinizing vasculitis), have also been described in patients with RA. Skin manifestations such as palmar erythema, erythromelalgia, autoimmune bullous diseases such as epidermolysis bullosa acquisita (see Chap. 58), yellow nail syndrome (see Chap. 87), erythema multiforme (see Chap. 38), erythema nodosum (see Chap. 68), and urticaria (see Chap. 37) also have been reported in patients with RA.[8]

NON-DERMATOLOGIC EXTRA-ARTICULAR MANIFESTATIONS In addition to systemic vasculitis, which can affect numerous organ systems, there are multiple non-dermatologic extra-articular manifestations of RA. Table 161-2 lists the more common ones.

TABLE 161-2
Non-Dermatologic Extra-Articular Manifestations of Rheumatoid Arthritis

TYPE	MANIFESTATIONS
Ocular	Keratoconjunctivitis sicca, scleritis, episcleritis, scleromalacia
Renal	Amyloidosis and vasculitis
Hematologic	Anemia, thrombocytosis, lymphadenopathy, Felty syndrome
Neurologic	Entrapment neuropathy, cervical myelopathy, mononeuritis multiplex (vasculitis), peripheral neuropathy
Lung	Pleural effusions, pulmonary fibrosis, bronchiolitis obliterans, rheumatoid nodules, vasculitis
Cardiac	Pericarditis, premature atherosclerosis, vasculitis, nodules, aortic root dilatation

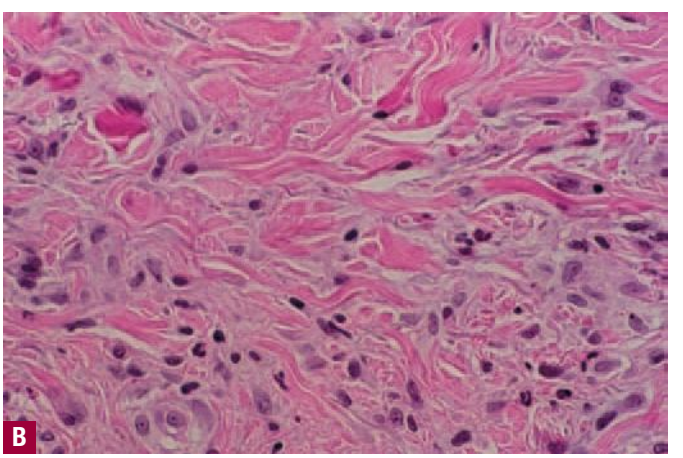
Differential Diagnosis (Box 161-1)

Laboratory Findings

There is no one specific histologic, radiographic, or laboratory test that conclusively permits the diagnosis of RA. Rheumatoid factor, an autoantibody that reacts with the Fc portion of immunoglobulin G (IgG), is found in sera of 85 percent of patients with RA. Rheumatoid factor should not be used as a definitive screening tool because it can be found in other disease processes (sarcoidosis, liver diseases, pulmonary fibrotic processes, and cryoglobulinemia). It is also found in approximately 5 percent of the unaffected population.[12] A false-positive rheumatoid factor can be caused by many factors, including chronic bacterial infections such as infective endocarditis, tuberculosis, and Lyme disease, as well as by viral diseases such as rubella and infectious mononucleosis.[6]

Treatment

Because the exact cause of RA is unknown, treatment has been directed against various components of the in-



▲ **FIGURE 161-4** Rheumatoid neutrophilic dermatosis. **A.** Lesions are erythematous urticarial papules often coalescing into plaques in a patient with rheumatoid arthritis. **B.** Histopathologically, there is an interstitial mixed dermal infiltrate predominated by neutrophils without leukocytoclasis. This is often accompanied by papillary edema.

Box 161-1

Differential Diagnosis of Rheumatoid Nodules

Consider

- Subcutaneous granuloma annulare
- Foreign body granuloma
- Infectious granuloma
- Sarcoid granuloma
- Myxoid cyst
- Traumatic epidermal cyst
- Xanthoma

Rule Out

- Epithelioid sarcoma
- Fibromatous nodules in Lyme borreliosis

flammatory process. No single therapy is the treatment of choice. In the past, most patients with early disease were started on nonsteroidal anti-inflammatory drugs until joint erosions were evident.

These medications are useful to alleviate symptoms. They do not alter disease progression.

Furthermore, new understanding of disease mechanism and the chronic disabling nature of RA has resulted in a shift to earlier use of disease-modifying anti-rheumatic drugs (DMARDs). New guidelines released by the American College of Rheumatology in 2002[13] advocate this switch.[14] DMARDs decrease inflammation (confirmed by a reduction in acute phase reactants), reduce or prevent joint damage, and modify the disease process.[2] The use of DMARDs is now recommended early in the disease course, when joint damage has already occurred or is imminent. Multiple medications fall into this category (Table 161-3). They may be used alone or in combination, but their use may be limited by loss of efficacy or systemic toxicity. Medications are often used in combination, but the decision about which drug to use is often individualized and determined by the clinical severity and loss of function and resultant disability, along with concerns about the safety profile of each given patient.

TABLE 161-3
Disease-Modifying Anti-Rheumatic Drugs

- Methotrexate
- Hydroxychloroquine
- Gold salts
- Sulfasalazine
- Azathioprine
- Cyclosporine
- Cyclophosphamide
- Leflunomide
- D-Penicillamine

Systemic glucocorticoids are potent anti-inflammatory agents but have a serious side-effect profile when used in large doses over long periods of time. They are not a good option alone for RA, but are sometimes used in a low dose with other DMARDs. Methotrexate has been used as a very effective DMARD for many years.

The newest additions to the anti-rheumatic armamentarium are the biologic response modifiers, which act to inhibit the pro-inflammatory cytokines that play a role in RA. The best known commercially available members of this category are the anti–TNF-α agents. TNF-α is a pro-inflammatory agent released by macrophages and T cells contributing to synovitis and joint destruction.

There are three anti–TNF-α drugs currently approved by the U.S. Food and Drug Administration for the treatment of RA: etanercept, infliximab, and adalimumab. Etanercept is a recombinant human TNF dimeric receptor fusion protein consisting of the ligand-binding portion of the human 75-kd TNF receptor linked to the Fc portion of human IgG1. This treatment is given as a subcutaneous injection twice per week. Infliximab is a chimeric (mouse/human) IgG1 monoclonal antibody to TNF-α. It is given intravenously every 6 to 8 weeks. Last, adalimumab, the newest of these agents, is a human IgG1 monoclonal antibody that binds membrane bound and soluble TNF-α.[15] Etanercept, infliximab, and adalimumab render TNF-α biologically inactive, thereby significantly decreasing the synovitis and retarding the progression of joint destruction.[16]

There are a number of limitations to the use of biologic response modifiers. They are expensive, ranging between 18,000 to 30,000 dollars per year, and both etanercept and adalimumab require the patient to self-administer injections. Not all patients are willing to do this. Infliximab, on the other hand, is an infusion, which inherently requires that the patient have more time from work/home and lends itself to the possibility of infusion reactions. In addition, there needs to be an infusion center nearby where the patient can receive therapy. Most patients receiving TNF-α blocking agents have failed therapy with one or a combination of the previously mentioned DMARDs. Inhibiting the normal host immune response has led to concern about re-activation of tuberculosis, increased susceptibility to other infections, and predisposition to the development of malignancy. The true risk of malignancy is difficult to establish because patients with RA are thought to have a higher incidence of lymphoid malignancy than the normal population and some have shown that the incidence of lymphomas may in fact be increased in patients taking anti–TNF-α drugs.[17] As with all medications, knowing your patient's medical history is the key to proper use of these medications. They should not be used in patients with concurrent serious infection or in those predisposed to serious infections (patients with poorly controlled diabetes). Extreme caution and consultation with the hematologist-oncologist should be used before prescribing these medications to patients with a recent history of malignancy.

In conclusion, the dermatologist and rheumatologist must function as a cohesive team in the treatment of patients with cutaneous manifestations of RA, which often present during phases of intense disease activity. Patients need their underlying rheumatic disease to be treated aggressively, but proven treatments for these associated dermatologic processes, such as pyoderma gangrenosum, cryoglobulins, vasculitis, and others, should not be forgotten. These specific treatment regimens are beyond the scope of this chapter.

RHEUMATIC FEVER

Acute rheumatic fever (ARF) is a delayed sequel to group A β-hemolytic streptococcal (GAS) infection of the oropharynx. It is an inflammatory disease that can affect the heart, joints, central nervous system, skin, and subcutaneous tissues. There are no specific diagnostic tests, rather it is a clinical diagnosis made on the basis of certain criteria. Treatment of the underlying infection leads to prevention of rheumatic fever.

Epidemiology

ARF is rare and most commonly occurs in children 5 to 15 years of age after clinically severe tonsillopharyngeal infections. However, it has been reported in patients of all ages and in those with asymptomatic disease. The incidence of rheumatic fever has dropped precipitously since the 1950s with widespread recognition of disease and treatment with penicillin. It has been nearly eradicated from the developed world but remains a serious health problem in developing countries.[2] The World Health Organization es-

timates that 15.6 million people worldwide are affected by rheumatic heart disease, and that 233,000 people die annually either from rheumatic heart disease or acute renal failure as a result of complicated GAS infection.[18]

Pathogenesis

The exact mechanism by which ARF results from an infection with group A streptococcal bacteria is unclear, but it is thought to be an exaggerated immune response to infection. Some strains of streptococcus are more likely to cause ARF than others. For instance, pharyngeal strains are much more likely to cause ARF than extrapharyngeal strains responsible for impetigo or cellulitis. Molecular mimicry has also been implicated in the etiology of ARF. M protein has structural similarity to cardiac myosin. Studies have demonstrated that rats immunized with streptococcal M protein develop myocarditis. Oddly, however, the morbidity and mortality of rheumatic fever results from valvular disease rather than acute carditis.[18] Familial clustering of disease, and the linkage of HLA-DR4 and -DR2 to ARF in Caucasian and African American patients demonstrates that host properties also affect the susceptibility of individual patients in the development of disease.[2]

Clinical Features

The clinical features of ARF vary widely and are largely outlined in the Jones criteria used to aid in diagnosis of the disease. The Jones criteria, updated in 1992,[19] emphasize five characteristic major manifestations: polyarthritis, carditis, chorea, subcutaneous nodules, and erythema marginatum (Box 161-2). Non-specific signs of systemic inflammation are considered minor criteria and include arthralgia, fever, elevated acute phase reactants, and a prolonged P-R interval by echocardiogram.

Diagnosis is based on the presence of two major criteria and one minor criteria plus evidence of preceding infection with group A streptococcus. If, however, chorea and carditis are present then demonstration of antecedent strep infection is not required to make the diagnosis.[19]

Rheumatic carditis usually involves the endocardium, myocardium, and pericardium and almost always is associated with a murmur, either mitral or aortic regurgitation.[18] Carditis, if present, usually presents in the first 3 weeks of the illness. There has been much debate about the use of echocardiography to aid in diagnosis of rheumatic heart disease without clinical evidence of a murmur; however, thus far its routine use has not been advocated. Its use has been accepted in patients with polyarthritis where other diagnostic criteria have not yet been met and in indistinguishable heart murmurs.[18]

Migratory polyarthritis can affect any joint but most often involves the large joints. Early administration of anti-inflammatory medications does mitigate the arthritis and may therefore mask it. In addition, post-streptococcal reactive arthritis exists and can confound the picture.[18] The diagnosis of chorea is based entirely on clinical signs, which include fleeting local muscular weakness, emotional lability, personality changes, and erratic, jerky, purposeless movements. Chorea does not occur in adult men.

The dermatologic manifestations of ARF are characteristic but rare. Subcutaneous nodules are small, painless, and localized over bony prominences and in tendon sheaths. Typically, they last for 1 to 2 weeks and spontaneously resolve. Erythema marginatum begins as an erythematous macule or papule extending outward while the central skin returns to normal. The border is pink and serpiginous, is not indurated, and blanches with pressure (Fig. 161-5). Patients are often unaware of its presence.[6] Histopathologically, there is a sparse superficial perivascular infiltrate of lymphocytes and neutrophils.[10]

Treatment

Treatment is directed at eradication of GAS from the oropharynx. Penicillin is the antibiotic of choice, is inexpensive, and can be administered orally or intramuscularly. Oral therapy should be continued for at least 10 days.[6] Penicillin-allergic patients can be treated with cephalosporins or macrolide antibiotics.[20] Due to the high rate of recurrence in previously affected people, antibiotic prophylaxis is recommended, especially in endemic areas.

The acute inflammatory process is largely treated symptomatically. Anti-inflammatory medications including salicylates and nonsteroidal agents are effective for the arthritis, fever, and arthralgia. However, salicylates alone have not been shown to be effective in decreasing the incidence of rheumatic heart disease after ARF. Corticosteroids are believed to be beneficial in the treatment of carditis; though this has never been shown in a randomized controlled trial. Lastly, intravenous Ig has also been tested but not shown any benefit.[18] Approximately 80 percent of patients who fulfill the criteria for this disorder recover spontaneously.

Box 161-2

The Jones Criteria for Rheumatic Fever, Updated 1992

MAJOR CRITERIA
- Carditis
- Migratory polyarthritis
- Sydenham chorea
- Subcutaneous nodules
- Erythema marginatum

MINOR CRITERIA
- Clinical
  - Fever
  - Arthralgia
- Laboratory
  - Elevated acute phase reactants
  - Prolonged P-R interval

plus

Supportive evidence of a recent group A streptococcal infection (e.g., positive throat culture or rapid antigen detection test; and/or elevated or increasing streptococcal antibody test)

GOUT

Gout is a clinical syndrome caused by a group of heterogeneous diseases characterized by deposition of monosodium urate crystals in synovial fluid and joints with or without hyperuricemia, renal disease, and nephrolithiasis. Classically, the presentation is that of an acute lower extremity peripheral joint inflammatory synovitis. The most commonly affected sites are the first metatarsophalangeal joint and the ankle.[6]

Epidemiology

Gout affects approximately 5 million Americans and has historically been described as a disease that affects men; however, it also affects women. Recent epidemiologic studies demonstrate that on average, women develop gout a decade later than men, and that female patients with gout are more likely to have renal insufficiency or to be taking diuretics.[21] Obesity has been linked to gout, and both diseases have increased in incidence over the past two decades. Alcohol has long been recognized as a risk factor for gout, but only recently has consumption of purine rich foods such as meat and seafood has been shown to correlate positively with serum urate levels and gout. It has also been shown that eating low fat dairy products may be protective.[22] Gouty attacks in children are so uncommon that this diagnosis should prompt an evaluation for a malignant or genetic cause.

Pathogenesis

Hyperuricemia is a risk factor for gout, but acute gouty arthritis can occur in patients with normal serum uric acid levels. Patients with serum uric acid levels greater than 7 mg/dL have a 22 percent chance of developing gout over a 5-year period, demonstrating that many patients with elevated serum uric acid levels may never have gouty arthritis.[6]

Uric acid is the end product of purine catabolism. Humans lack the enzyme uricase, which breaks down uric acid into a more water-soluble product. When the plasma monosodium urate level exceeds its limit of solubility, it is more likely to precipitate in tissues. Hyperuricemia results from either overproduction or underexcretion of uric acid. Ninety percent of affected patients are underexcreters.[6]

Table 161-4 presents a classification of hyperuricemia. Less than 10 percent of patients with hyperuricemia or gout excrete excessive quantities of uric acid in a 24-hour urine collection. It is usually in this group that identifiable and inherited derangements in mechanisms regulating protein nucleotide synthesis, specifically a deficiency of hypoxanthine-guanine phosphoribosyltransferase, glucose-6-phosphatase, or fructose-1-phosphatase, either partial or complete, can be found. These are genetically inherited by X-linked and autosomal recessive means (in the latter two); therefore, family history or early presentation may be a clue. The Lesch-Nyhan syndrome, well described but very rare, is an extremely severe form of hypoxanthine-guanine phosphoribosyltransferase deficiency associated with mental retardation, gout, and self-mutilation.[6]

TABLE 161-4
Classification of Hyperuricemia

- Overproduction of uric acid
  - Primary hyperuricemia
    - Idiopathic
    - Hypoxanthine-guanine phosphoribosyltransferase deficiency
    - Phosphoribosylpyrophosphate synthetase superactivity
  - Secondary hyperuricemia
    - Excessive dietary purine intake
    - Increased nucleotide turnover (e.g., myeloproliferative and lymphoproliferative disorders, hemolytic disease, psoriasis)
- Diminished excretion of uric acid
  - Primary hyperuricemia
    - Idiopathic
  - Secondary hyperuricemia
    - Diminished renal function
    - Inhibition of tubular urate secretion by competitive anions (e.g., keto- and lactic acidosis)
  - Enhanced tubular urate reabsorption
    - Dehydration, diuretics
  - Miscellaneous
    - Hypertension
    - Hyperparathyroidism
    - Certain drugs (e.g., cyclosporine, pyrazinamide, ethambutol, low-dose salicylates)
    - Lead nephropathy

Uric acid underexcretion is idiopathic in patients with hyperuricemia. The anatomic appearance and physiologic function of the kidney appear normal; however, alteration of renal tubular function in these patients by many drugs can precipitate gouty attacks. These pharmacologic agents include loop diuretics, low-dose cyclosporine, and salicylates.

Precipitating causes of an acute gouty attack are not well understood. Studies have shown the presence of intracellular monosodium urate crystals in synovial fluid of asymptomatic patients, suggesting that inflammation in gout is chronic. There must be an unidentified trigger in the acute attack that incites a more robust inflammatory response. Monocytes are present and secrete cytokines, including TNF-α, interleukin 1, interleukin 6, and interleukin 8. Neutrophils are then attracted to the site as well, ingest the crystals, and release multiple inflammatory mediators, initiating further inflammation and tissue damage.[6]

Clinical Manifestations

It is felt that gout occurs in four stages: asymptomatic hyperuricemia, acute gouty arthritis, intercritical gout (between gouty attacks), and chronic tophaceous gout.[6]

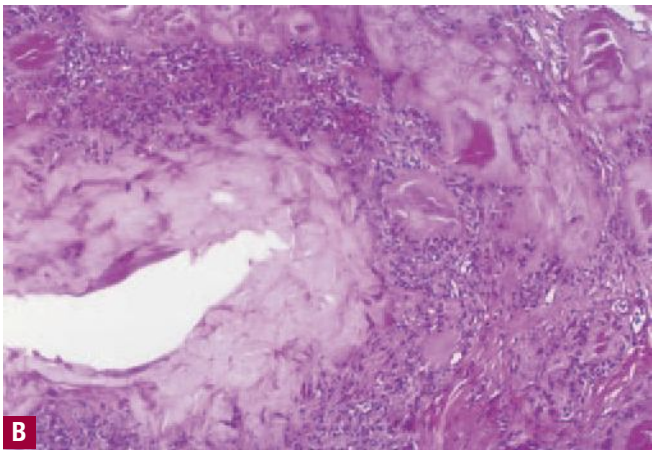
Patients are often asymptomatic for years, requiring no therapeutic intervention in the absence of other evidence of disease (for example, nephrolithiasis or renal insufficiency).

Acute gouty arthritis usually occurs in middle age and primarily affects a single joint in the lower extremities, the first metatarsophalangeal being the most common site of initial involvement (podagra). Clinically, the affected joint is erythematous and exquisitely tender to palpation. This may be confused with a sprain, a septic joint, or cellulites. Cytokine release can lead to fever and systemic symptoms, confounding the picture further. Further differential diagnoses include other forms of arthritis (psoriatic, reactive arthritis osteoarthritis, or RA) and pseudogout (chondrocalcinosis).[6]

Intercritical gout describes the interval that occurs between attacks of gout, an interval of between 6 months to 2 years. As attacks continue, they tend to be polyarticular, more severe, and of longer duration. Chronic tophaceous gout describes gout where patients rarely have asymptomatic periods. Urate crystals may be found in the soft tissues, cartilage, and tendons (Fig. 161-6A).[6] They have been reported in a variety of unusual places as well, including the nasal dorsum.[23] They may be confused with rheumatoid nodules, and aspiration or biopsy may prove useful.

Laboratory Presentation and Pathology

Laboratory analysis may reveal elevated uric acid levels, but this finding is not necessary for the diagnosis. Leukocytosis and



▲ **FIGURE 161-6** Gouty tophi. **A.** Tender nodules overlying joints and tendons, which may drain chalky white material. **B.** Histopathology shows granulomatous "fluffy" appearing infiltrate surrounding radially arranged needle-like spaces.

elevated sedimentation rate are often seen during acute arthritic attacks. Accurate diagnosis rests on the demonstration of intracellular, negatively birefringent, needle-shaped crystals by polarized microscopy. Histopathologic examination of a gouty tophus reveals granulomatous inflammation surrounding yellow-brown urate crystals or needle-like spaces in a radial arrangement, representing crystals dissolved during processing (see Fig. 161-6B; Fig. 161-7).[10]

Treatment

The goal of therapy in acute gouty attacks is analgesia and reduction in inflammation. The main options to choose from are the nonsteroidal anti-inflammatory drugs, colchicine, and corticosteroids. Indomethacin has been shown in randomized controlled trials to decrease pain, as has colchicine; however, the adverse gastrointestinal side effect of colchicine is often a deterrent for its use. Indomethacin can precipitate acute renal failure in patients with underlying renal disease. Corticosteroids, both oral and intra-articular, are also believed to be effective. Because patients with gout are older and often have many co-morbidities, therapy should be individualized. Treatment should continue for 7 to 10 days after the acute attack, and prophylactic therapy may be continued for 3 to 6 months.[6]

▲ **FIGURE 161-7** Gouty tophi on helix.

In patients with only one gouty attack, a conservative management approach can be used. This includes avoidance of drugs that decrease the excretion of uric acid such as thiazide or loop diuretics, aspirin, pyrazinamide, or niacin. Patients should maintain adequate hydration, lose weight, control hypertension and hyperlipidemia, and make diet adjustments by decreasing purine intake. Effectiveness of limiting cholesterol, fat, meat, and alcohol has never been studied, but should be advocated to avoid the need for lifelong oral therapy.[6,24]

Uric acid–lowering therapy is probably necessary in patients in whom the diagnosis of gout has been established, and who have had more than one gouty attack or are suffering from chronic tophaceous gout. It is also indicated in patients with history of gout and renal calculi, extremely high values of serum uric acid, high serum uric acid levels in the setting of a known familial history of gout (for example, where there is a known deficiency of one of the relevant enzymes previously described), and prophylaxis for patients receiving acute courses of chemotherapy.

The goal of urate-lowering drugs is to maintain the serum urate level consistently at less than 6 mg/dL. Uricosuric therapy is ideal in younger patients (age less than 60 years) with normal kidneys who are underexcreters of uric acid. Uricosurics include probenecid and sulfinpyrazone. The major risks associated with these medicines include hypersensitivity reactions and increased risk of uric acid nephrolithiasis (avoided by alkalinizing the urine). Unfortunately, most patients with gout do not fit this "ideal" situation.

For all other patients, the xanthine oxidase inhibitor allopurinol is used. It decreases production of uric acid, and is indicated for patients with nephrolithiasis, renal impairment, those who failed uricosuric agents, with myeloproliferative disorders on chemotherapy, and patients with hyperuricemia due to enzyme abnormalities. Dosages must be reduced in patients with renal failure. Twenty percent of patients taking allopurinol report side effects, and 5 percent discontinue medication as a result. Side effects include dyspepsia, headache, diarrhea, a pruritic papular eruption, thrombocytopenia, and hepatic function abnormalities. Allopurinol hypersensitivity syndrome is rare and includes fever, urticaria, leukocytosis, eosinophilia, interstitial nephritis, acute renal failure, granulomatous hepatitis, and toxic epidermal necrolysis.

CHAPTER 162

Sjögren Syndrome

Stamatina Danielides
Gabor Illei

EPIDEMIOLOGY

Sjögren syndrome (SS) is one of the most common rheumatic autoimmune diseases. SS affects predominantly women with a female to male ratio of 9:1. Women are most commonly diagnosed in their fifth or sixth decade, but it can affect individuals of any age and sex.

SS has a worldwide distribution. In most studies the estimated prevalence rate in the adult general population is between 0.1 percent and 0.8 percent in mainly Caucasian populations. However, one study in the United Kingdom showed a prevalence rate of 3.3 percent, whereas another study in Japan showed only a 0.02 percent prevalence rate. The estimated annual incidence rate was consistently approximately 0.005 percent in several studies.[1]

PATHOGENESIS

The pathogenesis of SS is still largely unknown. In a genetically predisposed individual, various environmental factors, such as viral infections, may lead to epithelial cell activation and a protracted inflammatory response with features of autoimmunity. Autoreactive lymphocytes and autoantibodies are considered important in this process, although the pathogenic role of any particular autoantibody is still undefined. Abnormal apoptosis may be important in several ways. First, increased apoptosis of epithelial cells may lead to functional defects and provide autoantigens, whereas the prolonged survival of B and T cells through upregulation of anti-apoptotic signals may be involved in sustaining a self-perpetuating autoimmune process. Decreased apoptosis of lymphocytes may also contribute to the increased frequency of lymphoma in SS patients.

Immunogenetic Factors

The role of genetic factors in SS was recognized in family studies where first degree relatives of patients had an increased prevalence of SS.[2] Such family clustering was further observed among first-degree relatives of individuals with anti-Ro/SSA antibodies regardless of their clinical diagnoses [SS or systemic lupus erythematosus (SLE) or even healthy controls].[3] There is a well-established association between SS or anti-Ro/SSA and anti-La/SSB antibodies with HLA class II genes.[4] The first HLA class II associations described with primary SS were with DR3 and DR2 in European populations.[5] This genetic association predominantly involves antibody-positive but not antibody-negative Sjögren patients. Several small studies suggested an association between anti-Ro/SSA and anti-La/SSB antibodies and molecularly defined HLA-DR and HLA-DQ alleles, especially DRB1*0301, DRB1*15, and DQB1*0201.

Genes other than those of the HLA loci may also be associated with an increased risk of disease. Associations with a number of cytokine gene polymorphisms, such as interleukin (IL) 6, IL-10, tumor necrosis factor (TNF)-α and the IL-1 receptor antagonist, have been reported, but none of these have been confirmed to date.[4]

Environmental Factors

The inciting event in the pathogenesis of SS is not known, and it may not be a single event. The strong predominance of females suggests gender-specific predisposing factors. Although sex hormones are obvious targets, there is no conclusive proof yet that the difference in the pathogenesis between males and females is due to sex hormones alone. Viral infections have also been proposed as inciting events. This theory is strongly supported by the fact that chronic inflammation of the salivary glands has been observed with chronic hepatitis C and human immunodeficiency virus infections, and such infections cause a disease with a clinical spectrum very similar to SS. The fact that some viruses, such as Epstein-Barr virus (EBV), are known to replicate in oropharyngeal and lacrimal glands led to the hypothesis that these viruses may be involved in Sjögren pathogenesis. In fact, genetic material from EBV was detected by DNA hybridization in SS salivary tissue, but it was also found in normal individuals. Further experiments have identified an unusual strain of EBV containing a deletion in the genome in salivary gland specimens from Chinese SS patients.[6] Similarly, in a Japanese cohort, defective human T-lymphotropic virus-I genome was isolated from salivary gland tissue.[7] Other viruses, such as coxsackievirus[8] or endogenous retrovi-

SJÖGREN SYNDROME AT A GLANCE

- Chronic autoimmune disease characterized by chronic inflammation involving the exocrine glands.
- Salivary and lacrimal glands are predominantly affected leading to dry mouth and dry eyes.
- May occur alone (primary Sjögren syndrome), or may co-exist with other systemic connective tissue disorders (secondary Sjögren syndrome).
- Systemic manifestations, such as fatigue, arthritis, vasculitis, interstitial pulmonary disease, peripheral or central neuropathy, and autonomic nervous dysfunction may accompany glandular involvement.
- Patients with systemic manifestations are at higher risk of lymphoma.
- Treatment of sicca symptoms is mainly symptomatic, whereas management of extraglandular manifestations is similar to other autoimmune diseases.

ruses have also been proposed as causative agents. However, there is no proof, to date, that any of these viruses play a pathogenic role in SS.

Epithelial Cell Activation and Chronic Inflammation

Sections of salivary and lacrimal glands in SS are characterized by periductal mononuclear infiltrates. The majority of the infiltrating cells are $CD4^+$ T lymphocytes, whereas $CD8^+$ cytotoxic T cells are found in smaller numbers. Activated B lymphocytes are also present, including immunoglobulin-secreting cells.

Inflammation seems to target glandular epithelial cells, and recent research has demonstrated the central role of epithelial cell activation in initiating the recruitment of the inflammatory infiltrate.[9] In animal models, changes in epithelial cells occur before the appearance of lymphocytes in the salivary glands. Initial events include the expression of HLA class II molecules and various activation markers, such as the costimulatory molecules CD80 and CD86, on the surface of acinar and ductal[10] salivary epithelial cells. These molecules are crucial in regulating the interaction between antigen-presenting cells and lymphocytes. Their expression in acinar and tubular[11,12] epithelial cells suggests that epithelial cells in SS act as antigen-presenting cells and actively participate in lymphocyte activation. Another important step is the upregulation of adhesion molecules and chemokines, all of which contribute to the recruitment of inflammatory cells, such as T and B lymphocytes, macrophages, and dendritic cells. The activation of lymphocytes leads to abnormal cytokine and chemokine expression, perpetuating the chronic inflammatory process characterized by a complex interaction between activated epithelial cells, the innate and acquired immune system. Extraglandular manifestations occur as a result of similar lymphocytic infiltrations at other organs. This is described by some as *autoimmune epithelitis* to better reflect the systemic nature of the disease. Some epithelial cells express Fas and Fas ligand[13] and as a consequence undergo apoptosis; others may be destroyed by perforin, granzymes, and other cytotoxins produced by lymphocytes. However, in most patients, only partial destruction of the glands is noted. Local production of cytokines, autoantibodies, metalloproteinases, and other inflammatory mediators may contribute to the dysfunction of the remaining epithelial cells by various mechanisms. For example, it has been shown that TNF interferes with the intracellular trafficking of aquaporin-5, one of the water channels required for saliva production.

Autoantibodies

Autoantibodies are the hallmarks of systemic autoimmune diseases, including SS. The best-defined autoantibodies in SS are the anti-Ro/SSA and anti-La/SSB antibodies.[14] Both are targeted against ribonucleoprotein antigens. Anti-Ro/SSA recognizes two RNA binding proteins (the 52-kd or the 60-kd protein), whereas anti-La/SSB antibodies recognize RNA polymerase III. Anti-Ro/SSA antibodies are found in over 70 percent of patients with SS, but are not specific for SS and are frequently found in SLE and other autoimmune diseases even when there are no symptoms or signs of oral or ocular dryness. Anti-La/SSB is more specific; it is present in 50 percent of patients with primary SS or SS/SLE but is rarely seen in other diseases. The pathogenic role of these antibodies is not yet defined, but, because Ro and La are expressed on the surface of apoptotic epithelial cells, it is possible that an immune response against these antigens contributes to inflammation in the gland. The most compelling in vivo evidence for a pathogenic role of these autoantibodies comes from newborns with fetal heart block born to women with anti-Ro/SSA and/or anti-La/SSB antibodies. These antibodies can cross the placenta and bind to Ro and La antigens located on the cell surface of fetal myocardial tissue, leading to fetal heart block. Other autoantibodies, such as anti-nuclear antibodies and rheumatoid factor, are frequently present in patients with both primary and secondary SS. Although they lack specificity, they are markers of a systemic autoimmune response and thus can help distinguish SS from other causes of salivary or lacrimal gland dysfunction.

In recent years, research has focused on identifying antibodies more specific for SS, such as anti-α-fodrin and anti-muscarinic acetylcholine receptor antibodies, but the results have been controversial. The major stimulus for saliva production is the binding of acetylcholine to muscarinic acetylcholine receptors. The hypothesis that oral and ocular dryness could result from antibodies antagonizing the muscarinic acetylcholine receptor-3, is intriguing. These antibodies have been demonstrated to play an essential role in eliciting glandular dysfunction in the NOD mouse model of SS, possibly through an inhibitory effect on the receptor.[15] In humans, however, results are still contradictory as multiple attempts to detect these antibodies with conventional immunologic methods have been fruitless.[16]

CLINICAL MANIFESTATIONS

Exocrine Gland Involvement

The dominating feature of SS is exocrine gland dysfunction, leading to the classic sicca symptoms of xerostomia (oral dryness) and xerophthalmia or keratoconjunctivitis sicca (dry eyes).

XEROSTOMIA Oral dryness is the principal symptom of SS. Before attributing dry mouth to SS, other possible common causes, such as dehydration, diabetes, viral infections, or drug treatment, should be excluded. In SS, hyposalivation is persistent and continuous throughout day and night and can significantly compromise quality of life. The oral manifestations of SS result from the loss of lubricating and antimicrobial properties of saliva. Patients with SS often have increased incidence of caries, even with excellent oral hygiene leading to increased number of decayed, missed, and filled teeth. A characteristic feature of caries in SS is that it is primarily located at the cervical and incisal regions of the teeth. Oral mucosal surfaces are dry and ulcerations may be evident; ulcerations are particularly common in SS patients with dentures, in proximity to the mucosal surface that makes contact with the denture. Physical examination may reveal a red, dry, and fissured tongue with a characteristic atrophy of the filiform papillae or angular cheilitis. Reduced salivation causes difficulty in chewing and swallowing dry foods; dryness of the tongue and oral mucosa leads to an altered sense of taste and at times produces a burning discomfort, especially when eating acidic or spicy foods.

Reduction of saliva flow can lead to an increased susceptibility to infections. Fungal infections, especially oral candidiasis of the oral cavity, are common and can be manifested as pseudomembranous or erythematous mucosal lesions. They can be asymptomatic or present as burning pain.

Bilateral salivary gland enlargement may occur in the parotid glands of SS patients. It is usually non-tender, and it

Box 162-1

Differential Diagnosis of Parotid Gland Swelling

Unilateral	Bacterial infections	
	Neoplasms	Mainly lymphomas
	Sialothithiasis	

can be recurrent or chronic (Box 162-1). Painful, unilateral parotid enlargement should raise the suspicion of an infection (Fig. 162-1) or a salivary gland stone. In cases of persistent unilateral parotid gland enlargement, the presence of lymphoma should be excluded (see Box 162-1).

KERATOCONJUNCTIVITIS SICCA Ocular dryness is the other dominant feature of SS. A burning and itching sensation in the eyes, commonly exacerbated by smoke, is caused by lack of tear production. Patients frequently complain of intolerance to contact lenses. Paradoxically, the quantity of tears produced during crying may not be affected. Physical evaluation shows corneal injection and mucous discharge in the lower fornix. Enlarged lachrymal glands have been described in Sjögren patients, but occur less commonly than enlarged salivary glands. The constellation of symptoms and signs indicating dry eyes constitutes keratoconjunctivitis sicca.

▲ **FIGURE 162-1** Acute infectious parotitis. Note the asymmetric swelling of the left parotid gland.

OTHER SICCA MANIFESTATIONS *Cutaneous xerosis*, a term used to describe dryness of the skin, is very common in SS, with a frequency varying between 23 percent to 68 percent. The most common symptoms of xerosis are non-specific pruritus, burning sensation and a pin-prick–like feeling. Physical examination reveals roughness, fine scaling, and loss of elasticity of the skin. The pathogenesis of xerosis is unknown. Impairment of the sweat glands is considered an important factor because decreased sweating has been reported in SS patients. A recent study has indicated that xerosis may be related to increased epidermal proliferation with disturbed epidermal differentiation.[17]

Dryness of the upper respiratory tract can cause epistaxis, hoarseness, and bronchial hyper-responsiveness. Another common complaint in women with SS is vaginal dryness, which may lead to an increased incidence of vaginal infections and dyspareunia.

Non-Exocrine Gland Involvement

SKIN INVOLVEMENT Cutaneous manifestations common extraglandular features of SS (Table 162-1).[18] They are generally divided as vasculitic and nonvasculitic lesions.

Vascular Lesions. Raynaud phenomenon is probably the most common abnormality. It can be seen in 15 percent to 35 percent of patients and can precede sicca symptoms by many years. Although Raynaud is usually mild in SS, it is a marker of a subgroup with increased risk of extraglandular manifestations.[19]

TABLE 162-1
Cutaneous Manifestations of Sjögren Syndrome

Vascular	• Raynaud phenomenon
	• Cutaneous vasculitis
	  • Non-palpable purpura
	  • Palpable purpura
	  • Urticarial vasculitis
	  • Necrotizing vasculitis
	• Annular erythema
	• Erythema multiforme
	• Erythema perstans
	• Erythema nodosum

Nonvascular	• Oral
	  • Dry mucous membranes
	  • Papillary atrophy of the tongue
	  • Candidiasis
	  • Angular cheilosis
	• Eyelid dermatitis
	• Alopecia
	• Vitiligo

Cutaneous vasculitis (CV) in SS presents most commonly as flat or palpable purpura (Fig. 162-2). CV appears as recurrent crops of round, pink, macular, or patchy lesions. After a few days, the lesions turn dull purple, then brown, finally leaving a pale brown stain. Flat purpura is most commonly seen in patients with hyperglobulinemia, whereas palpable purpura represents dermal vasculitis and typically involves the lower extremities and buttocks (see Chap. 164). In contrast to simple purpura, palpable purpura does not blanch when pressure is applied to the skin. Histopathologically, CV can be divided in two groups. Neutrophilic inflammatory vascular disease is characterized by a predominantly neutrophilic infiltrate, fibrinoid necrosis, occlusion of the lumen and extravasation of red blood cells and is indistinguishable from the classical leukocytoclastic vasculitis (see Chap. 164). On the other hand, mononuclear inflammatory vascular disease is characterized by a mononuclear inflammatory infiltrate with invasion of the blood vessel walls. Fibrinoid necrosis is present but less prominent. The clinical presentation of these two forms are indistinguishable, but neutrophilic inflammatory vascular disease is associated more strongly with markers of systemic au-

▲ **FIGURE 162-2** Cutaneous vasculitis in primary Sjögren syndrome. Biopsy showed leukocytoclastic vasculitis.

toimmunity, such as anti-nuclear antibodies and anti-Ro/SSA and anti-La/SSB antibodies, hypergammaglobulinemia, rheumatoid factor, and hypocomplementemia. Cryoglobulinemic vasculitis can also be seen among Sjögren patients and has the same cutaneous manifestations (see Chap. 170).

Urticarial vasculitis is the second most frequent form of CV in SS and presents as pruritic wheals with erythema (see Chap. 37). In contrast to true urticaria, individual lesions last for more than 24 hours and often resolve with hyperpigmentation. Biopsy of the skin lesions demonstrates a perivascular neutrophilic infiltrate accompanied by leukocytoclasia. Cutaneous purpura is an important marker of more severe disease in SS because it has been associated with an increased risk of lymphoma development and mortality.

Necrotizing vasculitis initially presents as palpable purpuric lesions of the lower extremities, which may ulcerate, finally resolving within 1 to 4 weeks. They heal with atrophy or scar tissue formation. This form of CV has been observed more frequently among patients with more active disease; it has been associated with arthritis, Raynaud phenomenon, peripheral neuropathy, fever, and pulmonary or glomerular involvement.

Annular erythema is found among Asian patients who have anti-Ro/SSA antibodies. Characteristic lesions are annular erythematous plaques with elevated borders and central clearing. They are localized on the face, arms, back, trunk, and proximal thighs. Lesions are similar to subacute cutaneous lupus but seem to represent a distinct clinical and histopathologic entity.

A painful nodular eruption of the anterior surface of the lower extremities, suggesting erythema nodosum (see Chap. 68) may occur in patients with sicca manifestations. Because erythema nodosum in SS patients is rare, its presence should raise suspicion for sarcoidosis. Erythema multiforme–like lesions and superficial ill-defined patches (erythema perstans) have also been described in SS.

Nonvascular Cutaneous Manifestations. Xerostomia predisposes to angular cheilitis, which presents as recurrent, symmetric, itching fissures. Eyelid dermatitis is defined by the presence of erythematous, infiltrated and lichenificated lesions of the eyelids associated with itching and foreign body sensation. Alopecia and vitiligo can also be seen in SS, albeit infrequently. Despite multiple case reports describing cutaneous B- and T-cell lymphomas in SS patients, they are, in fact, rare.

NON-CUTANEOUS EXTRAGLANDULAR MANIFESTATIONS

Musculoskeletal. A symmetric non-erosive polyarthritis can frequently be seen in primary SS. The distinction from rheumatoid arthritis may be difficult; the absence of rheumatoid factor and anti-CCP antibodies would favor SS over RA. Arthralgias and myalgias are common complaints but true myositis is rare in primary SS.

Visceral Manifestations. Tracheobronchitis sicca and interstitial pneumonitis are the most common lung manifestations of SS. Patients may also develop mucosa-associated lymphoid tissue (MALT) lymphoma in the lungs. Genitourinary manifestations include interstitial cystitis, renal tubular acidosis, interstitial nephritis, and, rarely, glomerulonephritis. Dysphagia due to xerostomia and esophageal dysmotility is common. *Helicobacter pylori* is associated with an increased risk of MALT lymphomas, therefore, SS patient with gastritis should be checked for *H. pylori* and treated if found positive. SS is associated with various other diseases, such as celiac disease, primary biliary cirrhosis, and hypothyroidism. Because of these associations, a high index of diagnostic suspicion is warranted to identify and treat these conditions.

Neurologic Manifestations. Nervous system involvement is reported in approximately 20 percent of patients with SS. The most common manifestations are peripheral axonal or ganglionic polyneuropathies and autonomic dysfunction. Sensorimotor neuropathies present with symmetric anesthesia and dysesthesia of the extremities in a glove and stocking distribution, whereas motor dysfunction is usually minor. Less frequently, patients may also present with a pure sensory neuropathy. Another entity that has been described to occur frequently among SS patients is a ganglionopathy involving the sensory ganglia of the posterior column. This starts with unilateral peripheral paresthesias evolving over months to years to deep sensory impairment, positive Romberg's sign, generalized areflexia, and ataxia.[20] An asymmetric motor and sensory neuropathy can signal vasculitis of small- and medium-sized vessels. Cranial neuropathies are also frequent among SS patients. The most common form is unilateral trigeminal neuropathy; it usually spares the ophthalmic division, thus preserving the corneal reflex. Other cranial neuropathies may lead to Bell palsy (facial nerve), neural deafness and vestibular dysfunction (vestibule-cochlear), and diplopia (oculomotor, trochlear, abducent nerve).

Lymphoproliferative Disease. The incidence of lymphoma in Sjögren patients is increased 15- to 44-fold, according to various studies,[21] and 4 percent to 8 percent of SS patients develop lymphoma. Most of these are indolent, extra-nodal, marginal-zone, B-cell lymphomas of MALT, but higher grade lymphomas are also seen.

A variety of clinical and laboratory features have been correlated to an increased risk of lymphoma development. Recurrent or persistent salivary gland swelling, palpable purpura, low complement levels, low CD4 counts, and persistently elevated inflammatory markers indicate an increased disease activity and increased risk for lymphoma development.[25]

DIAGNOSIS

The diagnosis of SS is based on the clinical constellation of xerostomia, keratoconjunctivitis sicca, and features of autoimmunity, such as anti-nuclear antibodies and/or anti-Ro/SSA and anti-

TABLE 162-2
Revised International Classification Criteria for Sjögren Syndrome

I. Ocular symptoms: A positive response to at least one of the following questions:
1. Have you had daily, persistent, troublesome dry eyes for more than 3 mo?
2. Do you have a recurrent sensation of sand or gravel in the eyes?
3. Do you use tear substitutes more than three times a day?

II. Oral symptoms: A positive response to at least one of the following questions:
1. Have you had a daily feeling of dry mouth for more than 3 mo?
2. Have you had recurrently or persistently swollen salivary glands as an adult?
3. Do you frequently drink liquids to aid in swallowing dry food?

III. Ocular signs—that is, objective evidence of ocular involvement defined as a positive result for at least one of the following two tests:
1. Schirmer's test, performed without anaesthesia (≤5 mm in 5 min)
2. Rose bengal score or other ocular dye score (≥4 according to van Bijsterveld's scoring system)

IV. Histopathology: In minor salivary glands (obtained through normal appearing mucosa) focal lymphocytic sialoadenitis, evaluated by an expert histopathologist, with a focus score ≥1, defined as a number of lymphocytic foci (which are adjacent to normal appearing mucous acini and contain more than 50 lymphocytes) per 4 mm^3 per glandular tissue

V. Salivary gland involvement: Objective evidence of salivary gland involvement defined as a positive result for at least one of the following diagnostic tests:
1. Unstimulated whole salivary flow (< 1.5 mL/15 min)
2. Parotid sialography showing the presence of diffuse sialectasias (punctuate, cavitary or destructive pattern), without evidence of obstruction in the major ducts
3. Salivary scintigraphy showing delayed uptake, reduced concentration and/or reduced excretion of tracer

VI. Autoantibodies: Presence in the serum of the following autoantibodies: antibodies to Ro/SSA, La/SSB or both

Modified from Vitali C et al: Classification criteria for Sjögren's syndrome: A revised version of the European criteria proposed by the American-European Consensus Group. *Ann Rheum Dis* **61**:554, 2002.

La/SSB antibodies. In patients with severe symptoms the diagnosis is straightforward, but in patients with milder symptoms, or those without the typical autoantibody profile, the diagnosis can be difficult. Moreover, several sets of diagnostic criteria were developed and used by various groups, adding to the confusion. Recently, an international consensus group agreed on a set of criteria, and this revised American-European classification system has been widely accepted (Table 162-2).[26] Six features are taken into consideration: subjective complaints, objective evidence of dry eyes or dry mouth, objective evidence of salivary gland involvement, and the presence of specific autoantibodies in the serum. For the diagnosis of primary SS, at least four criteria should be present, and at least one of them should be either evidence of lymphocytic infiltration or the presence of autoantibodies. Patients with a co-existing connective tissue disease are labeled secondary SS. Exclusions include other diseases and medications that may cause sicca symptoms.

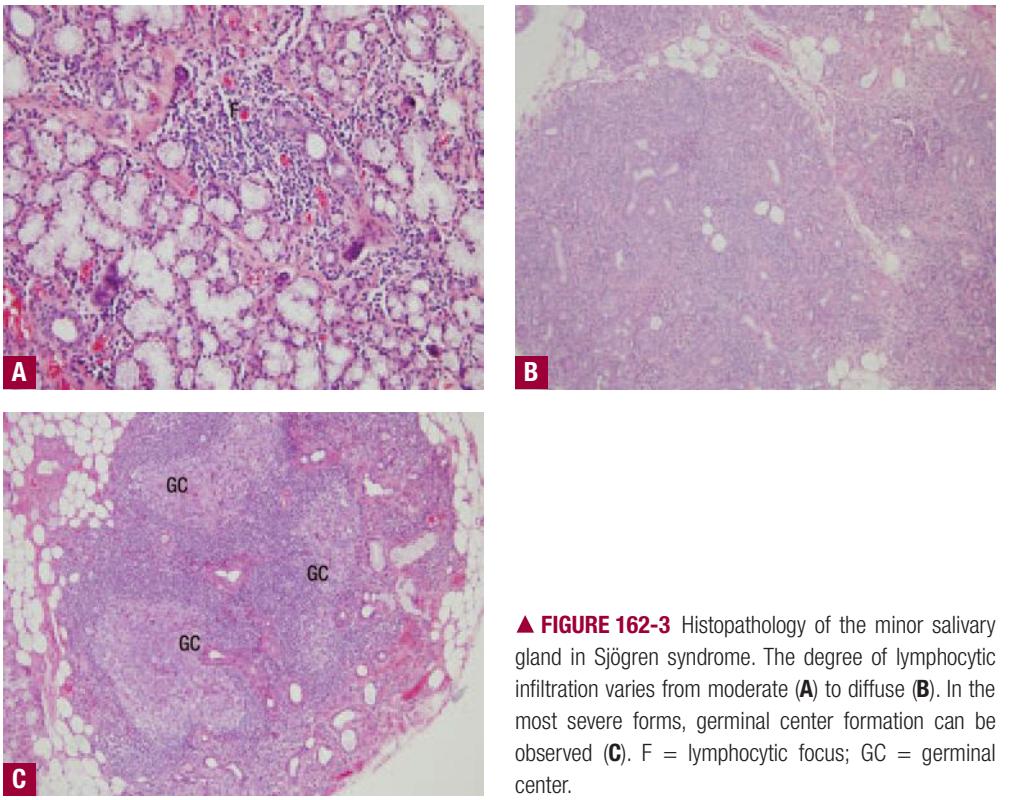
To establish subjective symptoms of dry eyes and dry mouth, a validated uniform questionnaire is used. A variety of non-invasive methods can be used to diagnose reduced salivary flow in clinical practice. The most commonly used method is sialometry, which involves measurement of the total unstimulated and stimulated saliva produced from salivary glands in a time period of 15 minutes (unstimulated or stimulated whole salivary flow). The whole unstimulated salivary flow is considered abnormal if it is less than 1.5 mL in 15 minutes. Salivary gland scintigraphy assesses saliva production by measuring the secretion of a radioisotope (99m technetium-sodium pertechnetate) into the oral cavity. Salivary scintigraphic changes correlate significantly with sialometric values and provide the same functional information.[27] Given the high cost and the exposure to radiation, their routine use is not justified. Sialography is an imaging method based on retrograde injection of contrast media into the parotid duct. Dilatations of salivary ducts and sialolithiases are the most common findings.

However, none of the above diagnostic procedures is specific for SS. The most reliable objective diagnostic feature is seen on biopsy of the minor salivary gland. A small incision is made on the inner surface of the lip, and a minor salivary gland tissue sample is collected. Evidence of a focal, periductal infiltrate composed of T and B lymphocytes and few plasma cells is the histologic hallmark of SS (Fig. 162-3). The degree of lymphocytic infiltration is evaluated semi-quantitatively by means of a focus scoring system. Evidence of more than one focus is considered indicative of SS, and a focus is considered a conglomeration of at least 50 lymphocytes per 4 mm^3 of glandular tissue. Atrophy and fat tissue are other findings that may be present in SS patients, but are also present among healthy, elderly individuals. Although salivary gland biopsy provides important clues that may lead to definitive diagnosis, some controversy still exists regarding its sensitivity and specificity. Some patients with primary SS diagnosed on the basis of reduced salivary flow and evidence of anti-SSA and anti-SSB antibodies have no lymphocytic infiltration in biopsy specimens of minor salivary glands. In addition, some healthy individuals may demonstrate lymphocytic foci in their salivary glands.

The diagnosis of keratoconjuctivitis sicca is based on the demonstration of decreased tear production, corneal damage, or both. Tear production is measured by Schirmer's test. This is performed by placing a standardized paper strip in the inferior fornix of each eye and measuring the length of filter paper that becomes wet after 5 minutes. The European-American classification system uses a cut-off value of 5 mm in 5 minutes, below which the diagnosis of dry eyes is made. An alternative method is staining with a dye (rose bengal or lissamine green) that preferentially stains the devitalized cornea and conjunctiva. This staining is evaluated through the van Bijsterveld's scoring system; a score of 4 or more indicates keratoconjunctivitis sicca. These tests have a high sensitivity but low specificity; they identify ocular dryness, but cannot attribute abnormal findings to SS.

PROGNOSIS

There are two patterns of primary SS that define two distinct disease categories with very different clinical risks. Patients with low C4 levels and/or palpable purpura early in their disease course may be classified as a high-risk disease syndrome (type I). This group comprises approximately 20 percent of the primary SS diagnoses and carries a significantly increased risk of lymphoproliferative disease and also has an increased mortality rate. Most severe extraglandular manifestations also occur in this group. Patients without these two predictors (80 percent of all primary SS diagnoses) may be reassured that they have a low-risk ("type II") form of primary SS that carries no in-



▲ **FIGURE 162-3** Histopathology of the minor salivary gland in Sjögren syndrome. The degree of lymphocytic infiltration varies from moderate (**A**) to diffuse (**B**). In the most severe forms, germinal center formation can be observed (**C**). F = lymphocytic focus; GC = germinal center.

creased risk of death and in general has a more benign course dominated by sicca symptoms.[25]

TREATMENT

Treatment of Dry Mouth (Table 162-3)

The treatment of oral dryness is largely symptomatic.[28] Although various artificial saliva preparations are available, the mainstay of replacement therapy consists of frequent sips of water or other sugar-free fluids. Patients should be encouraged to use sugar-free candies and chewing gums to increase saliva production. Sugar-containing foods should be avoided because they contribute to the increased risk of dental caries and oral candidiasis. Meticulous dental hygiene is essential for SS patients to prevent or treat dental caries. The mainstay of prevention is the use of various fluoride applications including prescription-strength toothpaste, fluoride gels, and oral rinses. Oral candidiasis is treated with oral and systemic antifungal therapy. To prevent candidiasis, patients should not wear dentures at night, and the dentures should be soaked in 2 percent chlorhexidine. Nystatin or clotrimazole cream can be used to treat angular cheilitis.

If dry mouth is not adequately controlled with replacement methods, pharmacologic therapy with secretagogue drugs is an option. Two drugs are approved for this indication: pilocarpine (5 mg four times a day) and cevimeline (30 to 60 mg three times/day). Both act on muscarinic receptors and increase exocrine gland secretion. They are contraindicated in narrow-angle glaucoma and uncontrolled asthma. Cholinergic side effects, such as excessive sweating, urinary frequency, flushing, and headaches, are common for both agents. Tolerability can be increased if treatment is started at a lower dose, which is then gradually increased (see Table 162-3).

Treatment of Dry Eyes (See Table 162-3)

Many tear substitutes are available and are commonly used by patients to alleviate ocular dryness. Preservative-free preparations are preferred, especially if used more than four times a day. Methylcellulose-containing ointments may provide longer relief, but their use is limited to nighttime use by the risk for blurred vision. Cyclosporin ophthalmic solution (0.05 percent, one drop every 12 hours) has recently been approved for the treatment of keratoconjunctivitis sicca. Topical corticosteroids are rarely needed and should only be prescribed by ophthalmologists. Infections may present with aggravation of symptoms or increased mucus secretion, and should be promptly treated with topical antibiotics.

A frequently used surgical option is the occlusion of the puncta to block tear

TABLE 162-3
Management of Sicca Symptoms in Sjögren Syndrome

Xerostomia	• Frequent water • Mechanical stimulation of salvia secretion (sugar-free gum and candies) • Artificial saliva • Meticulous oral hygiene • Caries prevention with fluoride-containing toothpaste and rinses • Aggressive treatment of candidiasis with topical and systemic antifungals • Sialogogues: pilocarpine (5 mg orally three times/day) or cevimeline (30–60 mg orally three times/day)
Xerophthalmia	• Frequent use of preservative-free artificial tears • Nighttime use of moisturizing ointments • Topical cyclosporine A ophthalmic solution (0.05%, one drop every 12 h) • Surgical: Punctual plug placement • Sialogogues

drainage and consequently increase moisture. The occlusion can be transient by the insertion of collagen or silicone plugs, or permanent by electrocautery.

Pilocarpine and cevimeline can be effective for dry eyes, too, especially in patients with the most severe dryness.[29]

Treatment of Extraglandular Manifestations

The treatment of musculoskeletal manifestations of SS is similar to those of other systemic rheumatologic diseases.[28] Because of reduced saliva production and esophageal dysmotility, these patients have reduced tolerance to nonsteroidal anti-inflammatory drugs. Antimalarial drugs, such as hydroxychloroquine, are effective for arthralgia/arthritis, myalgia, and fatigue.[30] They also decrease erythrocyte sedimentation rate, serum γ globulin, and C-reactive protein values. Dryness of eyes and mouth may also improve slightly in some cases.[31] Visceral manifestations such as vasculitis, pneumonitis, glomerulonephritis, and neurologic manifestations are treated with corticosteroids and immunosuppressive drugs, in doses similar to those used in systemic lupus erythematosus. Steroid-sparing immunosuppressive drugs include methotrexate, leflunomide, and azathioprine. Pulse cyclophosphamide is reserved for the most severe manifestations. Primary biliary cirrhosis should be treated with ursodeoxycholic acid.

Treatment of lymphoma in SS is the same as in the general population. Most SS-associated lymphomas are low-grade B-cell lymphomas localized to the exocrine glands. For these, watchful waiting may be the most appropriate approach. Higher grade lymphomas require more aggressive treatment with a cytotoxic regimen and/or radiation therapy.

Targeted Therapy

Several randomized case-control studies have focused on therapy for SS using biologic agents, such as the TNF-blocking agents infliximab[32]and etanercept,[33] but none of the studies showed clinical benefit. There is increasing interest in therapies targeting B cells, such as monoclonal antibodies against CD20 (rituximab) or CD22 (epratuzumab).[34] Other potential targets for biologic therapy include cytokines such as IL-6 and BlyS (BAFF), interferons, adhesions molecules, and chemokines. However, even if effective, systemic immunomodulatory therapy may be associated with unwanted side effects and may not be justified in patients with primary SS whose disease is limited to exocrine glands. An alternative approach is to develop a localized form of immunotherapy by using gene therapy restricted to the salivary and lacrimal glands. This approach would most likely alter the abnormal immune response locally but may avoid the systemic side effects.[35]

SECTION 28

THE SKIN IN INFLAMMATORY AND OTHER VASCULAR DISORDERS

CHAPTER 163

Endothelium in Inflammation and Angiogenesis

Peter Petzelbauer
Lisan S. Peng
Jordan S. Pober

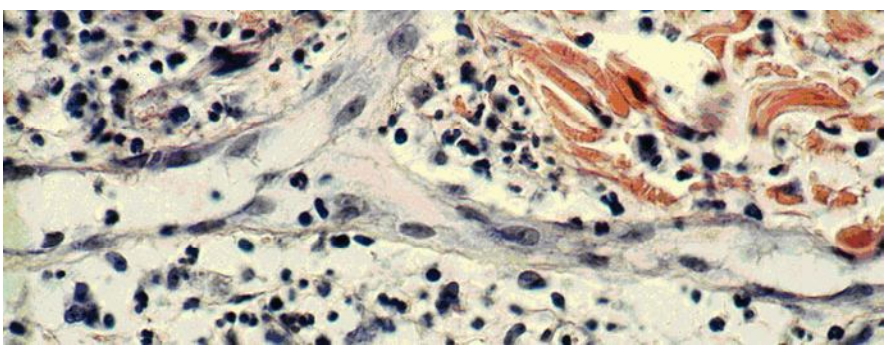
OVERVIEW OF THE VASCULAR SYSTEM

The blood vascular system is formed by a continuous series of hollow tubes that carry blood from the heart to the tissues and back again. Blood exits the heart through the aorta, a large elastic artery, which gives rise to a series of diverging, progressively narrower muscular arteries and arterioles that deliver the blood to all organs of the body. The terminal arterioles arborize into an interconnecting network of microvessels, mostly capillaries, which nourish and cleanse the peripheral tissues. The capillary network empties into a series of converging venules and progressively larger veins that ultimately return the blood to the heart. All segments of this vascular system, as well as the heart itself, are lined by a simple, one-cell-thick layer of epithelium-like cells called *endothelium* (Fig. 163-1). All of these endothelial cells (ECs) share common features and functions, and hence may be collectively described as one cell type. However, endothelia from one segment of the vascular system may differ in significant ways from the endothelia at other anatomic sites. Blood vessel ECs also differ in a number of ways from lymphatic ECs, which are not discussed in this chapter.

All blood vessel ECs must perform three important constitutive functions. First, vascular ECs must maintain homeostasis of the blood, which consists of roughly equal volumes of fluid (plasma) and cellular elements (erythrocytes, leukocytes, and platelets). The plasma contains the proteins of the coagulation system, which have the capacity to self-assemble into an insoluble matrix of fibrin (i.e., to form an intravascular thrombus or an extravascular clot) when placed in contact with tissue cells or extracellular matrix. In addition, both the leukocytes and the platelets have membrane receptors that trigger cellular activation on contact with the extravascular environment. The EC lining acts to prevent intravascular activation both of the coagulation system and of these responsive cellular elements, yet it keeps both systems poised to appropriately respond to wounding or infection.

The second function that must be performed by ECs is to form a barrier that separates circulating blood from the tissues. The barrier formed by ECs permits limited passage of fluid and solutes, allowing the blood to nourish the tissues while displaying "permselectivity" for macromolecules and presenting a virtually impenetrable barrier for blood cells (except at specialized sites of high permeability and leukocyte trafficking). In other words, vascular ECs regulate rather than completely prevent interactions between blood and tissues.

The third constitutive function performed by ECs is to regulate the extent of local blood flow. Because ECs are arranged in alignment with flow, their contraction is a mechanism of opening gaps between cells, which thus enhances permeability but does not alter flow (see Fig. 163-1). However, ECs indirectly regulate flow by acting on smooth muscle cells, which are arranged radially around the vessels. Their contraction narrows the vessel lumen, reducing flow. ECs control smooth muscle cell tone (i.e., the degree of contraction of smooth muscle cells), which regulates the size of the vessel lumen and flow. ECs do so principally by the generation of smooth muscle cell relaxants [i.e., vasodilators like nitric oxide (NO), prostaglandin E_2 or prostaglandin I_2 (PGI_2), and endothelium-derived hyperpolarizing factor] or contractants (i.e., vasoconstrictors like endothelins) or by



▲ **FIGURE 163-1** Endothelium. In this postcapillary venule, endothelial cells are seen to line a channel. Nuclei are seen en face and in cross-section, and activated endothelial cells appear to have an edematous cytoplasm, which increases their visibility. This specimen is from an inflammatory lesion (Sweet syndrome; see Chap. 31) without signs of vessel damage.

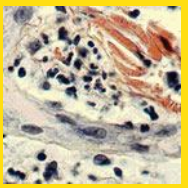
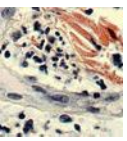
ENDOTHELIUM AT A GLANCE



- All blood vessel endothelial cells (ECs) perform three important constitutive functions:
  - Maintaining homeostasis of the blood
  - Forming a barrier that separates circulating blood from the tissue
  - Regulating the extent of local blood flow
- The cutaneous vasculature is divided into a superficial vascular plexus and a deep vascular plexus. The superficial vascular plexus is formed by parallel pairs of arterioles and venules that are connected via capillary loops that extend into the dermal papillae.
- ECs participate in innate and adaptive immune responses.
- Tumor necrosis factor-α and interleukin-1β are important modulators of EC function.
- Vascular ECs contribute to inflammation through distinctive patterns of adhesion molecule expression. In the skin, E-selectin, vascular adhesion molecule 1, and intercellular adhesion molecule 1 may be particularly important.
- Microvessels of the skin in situ basally express major histocompatibility complex (MHC) class I and II molecules at their luminal surfaces and may present antigen in an MHC-restricted manner to T cells.
- In the healthy adult, blood vessels are stable structures with very slow turnover of ECs. In chronic inflammation, tissue injury, wound healing, and tumor growth new vessels are formed (angiogenesis) and existing vessels undergo remodeling.
- Keratinocytes produce a wide range of angiogenic factors, including members of the fibroblast or transforming growth factor protein family, platelet-derived growth factor, and vascular endothelial growth factor, as well as chemokines like cutaneous T cell–attracting chemokine. Vascular remodeling is a prominent feature of psoriasis.



catalyzing the generation of vasoconstrictors from plasma protein–derived mediators (like angiotensin II). In the latter case, ECs express angiotensin-converting enzyme, which catalyzes the generation of angiotensin II from inactive angiotensin I and simultaneously degrades bradykinin, a plasma protein–derived agonist that acts on ECs to generate NO.

In addition to these constitutive functions, ECs may respond to mediators generated during inflammation or injury to acquire additional inducible functions. This activation of ECs is discussed later in the chapter.

STRUCTURE AND FUNCTION OF THE SKIN VASCULATURE

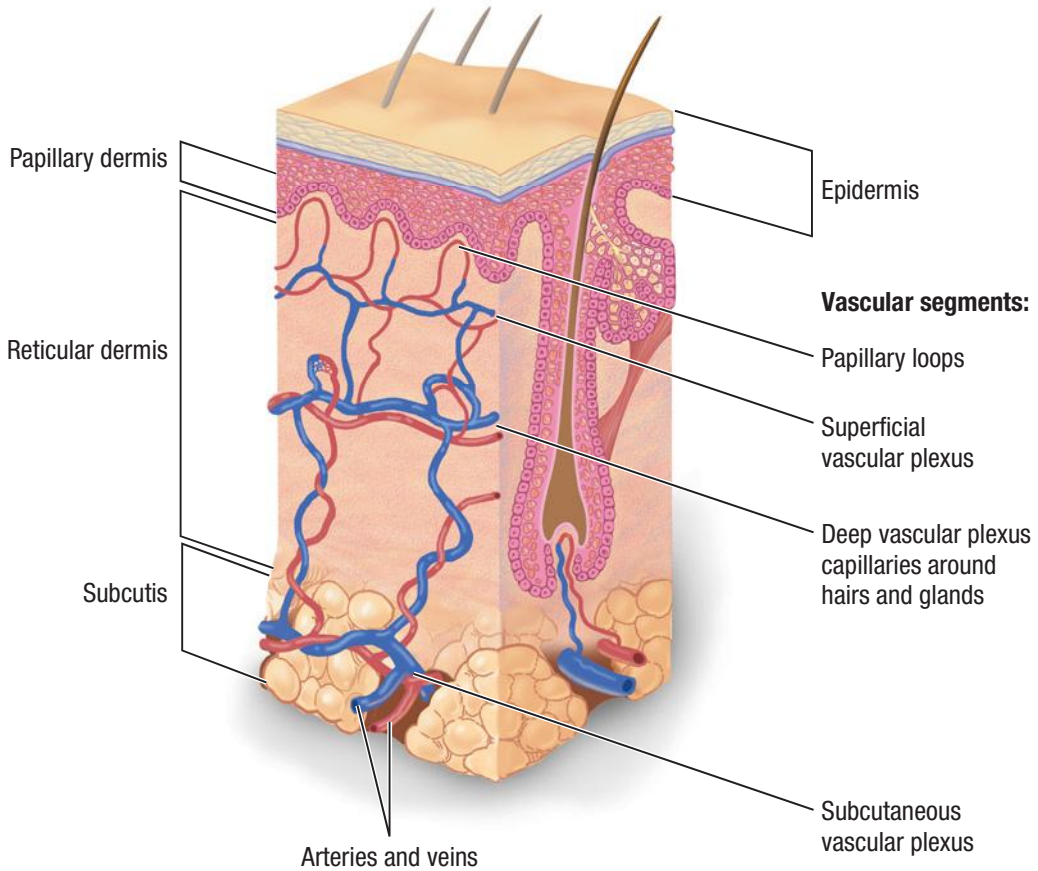
Approximately three decades ago Irwin Braverman described the organization of the vascular network of human skin, which he summarized in 1989.[1] Specifically, he noted that the human vascular system of the dermis consists of two interconnected systems—a superficial and a deep vascular plexus—with additional vascular networks surrounding sweat glands and hair follicles[2,3] (Fig. 163-2). The superficial vascular plexus (SVP) is comprised of paired arterioles and venules that form an interconnected network of vessels coursing on a plane parallel to and just beneath the epidermal surface.[3] Capillaries arise from the arterioles, extend upward within the papillary dermis at sites between the epidermal rete ridges, and then loop back down to the venules forming arcade-like structures. The basement membrane of the arterioles appears homogeneous by electron microscopy, whereas that of the venules is multi-layered. In normal skin, most of the capillary loop is invested with a basement membrane that resembles that of the arteriole. The capillaries acquire a venule-like investiture only at the level of the deepest rete just proximal to the anastomosis with the venule of the SVP.[2] There are no ultrastructural differences between capillary loops at different sites of the skin. Inflammatory leukocytes extravasate through the venule-like portions of the capillary and through the venule proper but only rarely infiltrate through the arteriole-like portions of the capillary or the arteriole itself.

The arterioles and venules of the SVP are connected by short, straight vessels to the arterioles and venules of a deeper planar network of anatomizing vessels called the *deep vascular plexus* (DVP) (see Fig. 163-2). The plane of the DVP is parallel to that of the SVP and courses above the boundary between the reticular dermis and the underlying subcutis (see Fig. 163-2). The DVP is fed through penetrating vessels from the subcutis. The DVP is drained by valve-containing veins into the subcutaneous fat. Valves are typically located where the small vessels join the larger ones, which implies a functional role in forward propulsion of blood. The vessel wall in the SVP consists of discontinuous layers of elastic fibers and smooth muscles. The DVP contains arterioles and venules of larger caliber consisting of three layers: an intima, a media, and an adventitia. Capillary networks connecting the arterioles and venules of the DVP provide nourishment for the adnexal structures within the reticular dermis. The venules of the DVP serve as portals of entry for leukocytes associated with inflammation of the adnexa or for inflammation within the reticular dermis itself, as occurs in erysipelas.

Dermal microvessels are surrounded by flat adventitial cells, ultrastructurally most closely resembling a fibroblast, called *veil cells*.[1] Veil cells are external to the wall, demarcating the vessel from the surrounding dermis. These cells test negative for lymphocyte markers and negative for HLA-DR and CD1a expression. They express glycoprotein Ib α, von Willebrand factor (vWF) receptor, and factor XIIIa, a coagulation transglutaminase, and are sometimes called *XIIIa-positive dendrocytes*. Interestingly, factor XIIIa–positive dendrocyte rarefaction is found in the classic type of Ehlers-Danlos syndrome, but the significance of this finding is not clear.

Dermal microvessels, especially capillaries, contain, in addition to ECs, a population of contractile mesenchymal cells called *pericytes*. Unlike veil cells, pericytes are an integral component of the vessel wall. They extend long cytoplasmic processes over the abluminal surface of the ECs and make interdigitating contacts. The coverage of ECs by pericytes varies considerably among different microvessel types, and the location of pericytes on the microvessel is not random but appears to be functionally determined. At points of contact, communicating gap junctions, tight junctions, and adhesion plaques are present. Specifically in the postcapillary venule, there is an intimate interdigitation between pericytes and ECs, with one pericyte making contact with two to four ECs.

Because pericytes are rich in contractile proteins and have complex interdigitations with ECs in postcapillary venules, it is assumed that they are responsible, at least in part, for gap forma-



▲ **FIGURE 163-2** Schematic diagram of the architecture of the skin vasculature.

tion in response to, for example, histamine or bradykinin (although cultured ECs are capable of contraction in the absence of pericytes). Moreover, interaction between pericytes and ECs is important for the maturation, remodeling, and maintenance of the vascular system via the secretion of growth factors or modulation of the extracellular matrix. There is also evidence that pericytes are involved in the transport across the blood-brain barrier and the regulation of vascular permeability.

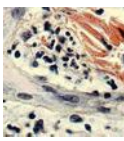
MORPHOLOGY AND MOLECULAR MARKERS

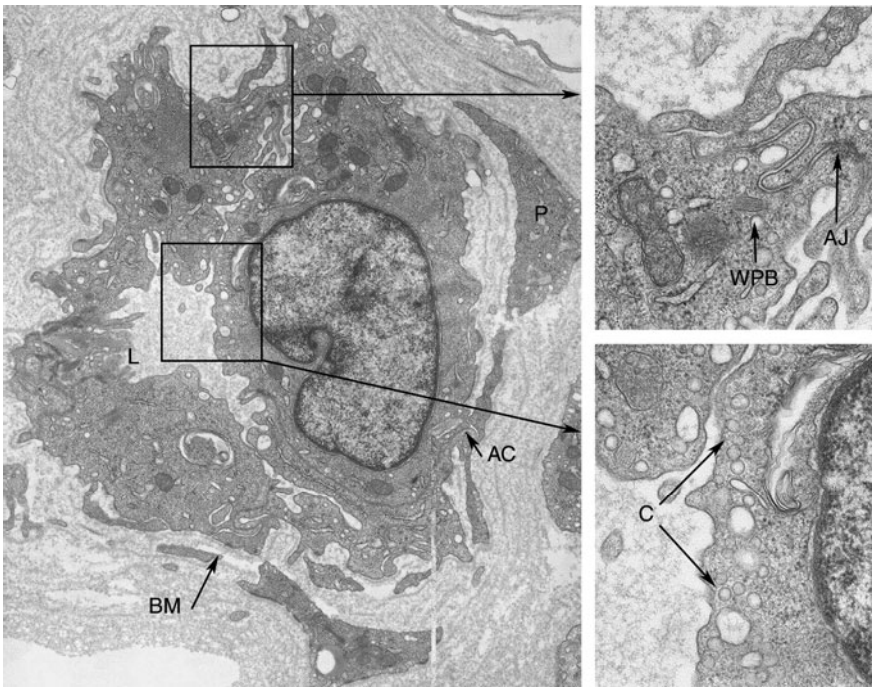
General Morphology

ECs usually appear as flattened epithelium-like cells, with a thickness typically less than 10 μm and a surface area covering up to 1000 μm^2 (see Fig. 163-1). In large vessels, ECs have an elongated shape, especially in regions of laminar flow, and have their long axis oriented in the direction of blood flow. ECs located in regions of disturbed flow (i.e., at branch points of the arterial tree) are often polygonal rather than elongated. Cultured ECs are typically polygonal but elongate when flowing medium is passed over them for periods of 24 hours or more.[4] These observations led to the conclusion that shear stress, the force imparted by viscous drag of flowing liquid, is responsible for inducing a cytoskeletal rearrangement and the change of shape from polygonal to elongated. Interestingly, the microtubular organizing center of ECs, located near the nucleus, is always oriented toward the heart (i.e., upstream of the nucleus in arteries and downstream of the nucleus in veins) regardless of the direction of blood flow.[5] The basis for this phenomenon is unknown. Moreover, ECs have an apical/luminal polarization, integrin receptors for matrix macromolecules are concentrated on the basal/abluminal surface, and adhesion molecules for leukocytes are almost exclusively displayed on their apical surface, which faces the lumen of the blood vessel.[6]

Specialized Organelles of Endothelial Cells

The ultrastructure of a postcapillary venule is shown in Fig. 163-3. ECs have a number of characteristic organelles. The best described are Weibel-Palade bodies (WPBs), fenestrae, and the caveolar system. WPBs are elongated, membrane-bound organelles that display longitudinal striations by electron microscopy. WPBs are distributed randomly throughout the cytoplasm in vascular ECs of most vertebrates. WPBs constitutively contain vWF (also called *factor VIII-related antigen*), P-selectin (CD62P),[7] lysosomal-membrane–associated glycoprotein 3 (or CD63),[8] 1,3-fucosyltransferase VI,[9] interleukin 8 (IL-8),[10] and angiopoietin 2.[11] The longitudinal striations within the WPBs are formed by highly polymerized forms of vWF, reaching sizes of up to 20,000 kd. On release, vWF polymers may attach to the basement membrane and stabilize platelet adhesion to the subendothelial matrix, particularly in high-velocity arterial flow. Although vWF is commonly used as an EC marker (see Molecular Markers of Endothelial Cells), it is also found in megakaryocytes, which appear to lack a physiologic mechanism of release, synthesizing vWF only for storage within the α granules of their platelet progeny. P-selectin is rapidly translocated to the cell surface as the WPB fuses with the plasma membrane, where it mediates leukocyte adhesion to ECs (see Leukocyte Adhesion). CD63 is a





▲ **FIGURE 163-3** Ultrastructure of a postcapillary venule. AC = area of contact between endothelial cell and pericyte; AJ = adherens junction; BM = basement membrane; C = caveolae; L = lumen; P = pericyte; WPB = Weibel-Palade body.

53-kd lysosomal membrane glycoprotein belonging to the tetraspanin superfamily; its function in the WPB is unknown.

Blood vascular ECs usually form a continuous monolayer, and most transendothelial transport takes place in the junctions between cells. One important exception is in the fenestrae of capillaries in lymph nodes, capillaries in the intestinal mucosa, renal glomerular ECs, and hepatic and bone marrow sinusoids. Fenestrae are 175 nm in diameter, are grouped into structures resembling sieve plates, and occupy 6 percent to 8 percent of the surface capillaries. They are specialized annular patches of attenuated cytoplasm and membrane characterized by an increased concentration of anionic lipids.[12] Fenestrated capillaries are much more permeable to water and small-molecular-size solutes than those of the continuous type. The anionic charge probably precludes the trans-fenestral passage of anionic plasma proteins. Fenestrae are unique to ECs. Various factors, such as pressure, alcohol, serotonin, nicotine, and infection, change the number and diameter of fenestrae. However, even ECs of the continuous type may become transiently fenestrated.

All ECs appear to contain numerous vesicles subjacent to the plasmalemma, both luminal and abluminal. Although such structures were originally interpreted as vesicles caught in the process of budding off or fusing to the membrane, on careful examination most of these vesicles turned out to have narrow tubular connections to the plasma membrane. These flask-shaped invaginations are called *caveolae*, literally "little caves," and are part of the surface membrane, either as a single caveola or as more complex racemose invaginations. In situ, they may account for 50 percent or more of the plasma membrane surface area of ECs. Caveolae are made in a late Golgi compartment and represent a stable membrane unit built up around caveolins, cholesterol, and glycosphingolipids. ECs are rich in caveolins 1 and 2, whereas cardiac myocytes and skeletal muscle fibers express caveolin 3. The lipid constituents of caveolae are the same as those of lipid rafts, but the latter lack caveolins and are flat. Caveolins bind to cholesterol and are required for caveolae formation; for example, the expression of caveolin 1 in cells normally lacking caveolae causes the formation of caveolae. Surprisingly, cultured ECs normally retain expression of caveolin 1 but lose their caveolae, with cholesterol and glycosphingolipids dispersing into submicroscopic lipid rafts on the now simplified plasma membrane.

Caveolae serve for vesicular transport and represent a platform for the assembly of signaling complexes at the surface of the cell. Caveolins interact with a variety of downstream signaling molecules, including Src-family of tyrosine kinases, p42/44 mitogen-activated protein kinase, and endothelial NO synthase (eNOS). They hold these signal transducers in the inactive conformation until activation by an appropriate stimulus. For example, the amount of caveolin is inversely related to NO production by eNOS.[13] Mice lacking caveolin 1 have impaired NO and calcium signaling in the cardiovascular system, which causes aberrations in EC-dependent relaxation, contractility, and maintenance of myogenic tone.[14]

Caveolin 1 is associated with a number of growth factor receptors. For these receptors, the invaginated structure of caveolae provides an optimal environment for receptor function, forming a more stable signaling complex and allowing for cross-talk with other receptors. The entire structure is stabilized by the caveolar coat, a function that results in reduced endocytosis and a more prolonged signal. The epithelial growth factor (EGF) receptor was one of the first receptors shown to be enriched in the caveolin-containing, low-density fraction of cells. Subsequently, it was shown that the high-affinity nerve growth factor receptor (TrkA), the insulin receptor, the platelet-derived growth factor (PDGF) receptor, and transforming growth factor (TGF) receptors I and II also associate with caveolae.[15] In addition, cytokine receptors like the tumor necrosis factor (TNF) receptor 1 (CD120a) also localize to caveolae.[16]

Endothelial Junctions

Neighboring ECs connect to each other by forming interdigitating protrusions connected by junctions. Junctions possess different degrees of complexity along the vascular tree, reflecting different permeability for proteins and cells. Intercellular tight (occluding) junctions constitute the anatomic basis for the tightly regulated interfaces of the blood-testis and blood-brain barriers.[17] They consist of a continuous belt-like meshwork of six anastomosing junctional strands, which prevent the transport of macromolecules into the tissue. The transmembrane protein occludin, linked to ZO-1 cytoplasmic proteins, appears to provide the molecular basis of this function. In addition, junctional adhesion molecules, called *JAMs*, members of the immunoglobulin superfamily, form homophilic adhesion sites in tight junctions and play a role in the generation of cell polarity, keeping luminal proteins from diffusing to the abluminal cell surface and vice versa.[18] Arterial

ECs also possess tight junctions; however, they consist of only one or two junctional strands. Tight junctions are virtually absent in postcapillary venules.

Adherens junctions are found in all vascular ECs (see Fig. 163-3). They are multimeric protein structures principally organized by CD144 [also called *cadherin 5* or *vascular endothelial cadherin (VE-cadherin)*]. Other junctional proteins may be recruited into this structure by association to VE-cadherin such as CD31 (also called *platelet/endothelial cell adhesion molecule 1* or *PECAM-1*)[19] or junctional adhesion molecule C (*JAM-C*). These adherens junction proteins appear to be involved in three different cell functions. First, they participate in capillary tube formation. Indirect evidence for the role of the transmembrane molecules PECAM-1 and VE-cadherin in vessel formation comes from investigations of malignant endothelial tumors with primitive or abortive vascular (luminal) differentiation, which have little to no VE-cadherin or PECAM-1 expression. Blocking VE-cadherin and PECAM-1 interactions with monoclonal antibodies inhibits vessel formation.[20] VE-cadherin–negative ECs derived by gene targeting fail to organize in vessel-like structures.[21] Whereas VE-cadherin appears critical for initial formation of blood vessels, for maintenance and remodeling of blood vessels a receptor-type phospho-tyrosine phosphatase called *VE-PTP* appears essential. VE-PTP binds to VE-cadherin via the extracellular domain and supports adhesive functions of VE-cadherin.[22] Second, PECAM-1 and VE-cadherin participate in the regulation of leukocyte transendothelial migration. Third, PECAM-1 and VE-cadherin may indirectly regulate cell growth by regulating the free cytoplasmic pool of β-catenin. ECs also express a neuronal cadherin, N-cadherin. However, this protein is localized outside the junction and appears to be nonfunctional.

The existence of a third type of junction in ECs has been demonstrated by transfer of microinjected small-molecular-weight tracers between adjacent ECs, which indicates the presence of gap junctional interendothelial communications. In EC, the gap junctional proteins are connexin-43, connexin-37, and connexin-40. Interestingly, ECs also may form hetero–gap junctions with pericytes or smooth muscle cells in the vessel wall and sometimes with adherent leukocytes.

A fourth kind of junction is particularly abundant in EC-related stellate cells that form the three-dimensional filter meshwork of the lymph node sinus. Stellate cells do not form a normal endothelial layer but are characterized by numerous thin filopodia-like processes forming a closely interwoven meshwork. They are connected by cell junctions with a unique molecular composition and are called *complexus adhaerens*. In lymph nodes they are integrated into a larger structural system termed *syndesmos*. They contain VE-cadherin, α- and β-catenin, protein $p120^{ctn}$, afadin, desmoplakin and plakoglobin, and tight junction proteins claudin-5 and ZO-1.

Endothelial Cell–Matrix Interactions

ECs rest on a basal lamina, which is formed by EC itself and by surrounding cells. It consists of laminin-1, collagens, fibronectin, nidogen (entactin), and heparan sulfate proteoglycans. Interaction with these matrix molecules is essential for maintaining normal endothelial function. For example, the laminin A chain peptide supports endothelial branching and formation of new capillaries.[23] Furthermore, a 20-kd C-terminal fragment of collagen XVIII specifically inhibits endothelial proliferation and angiogenesis,[24] which suggests that collagen XVIII is also a positive regulator of vessel growth. On the other hand, EC–collagen V interactions inhibit endothelial attachment and growth. ECs interact with these components of the basal lamina by numerous transmembrane adhesion molecules. The complexities of these interactions have only been partially characterized. Members of the integrin family are particularly important for this function. For example, $\alpha_6\beta_1$, $\alpha_2\beta_1$, $\alpha_5\beta_1$, and $\alpha_V\beta_3$ receptor complexes are important for endothelial attachment to, and migration on, laminin, collagen, and tenascin, and therefore serve important roles in angiogenesis. In addition, integrin binding to matrix proteins also has a multitude of intracellular effects on the organization of the endothelial actin skeleton and on signaling processes within the cell.[25] Endothelial cell growth factors have been shown to differentially upregulate the biosynthesis of α_2, α_5, β_1, and β_3 integrins, serving the different needs of endothelium during growth, spreading, and new vessel formation. Moreover, integrins show certain tissue- and vessel-restricted expression; for example, $\alpha_1\beta_1$ is found only in small blood vessels and capillaries but not in large-vessel ECs. Matrix proteins such as thrombospondins may also serve as inhibitors of angiogenesis.[26]

Molecular Markers of Endothelial Cells

ECs display a number of molecular markers that result in a characteristic profile detectable with antibodies, lectins, and other ligands (Table 163-1). In addition to containing molecules expressed on all endothelium, the skin vasculature shows several site-specific characteristics. Postcapillary venules of the SVP are $CD36^-$ and thus distinct from capillaries of the DVP and from capillaries of other tissues, which are $CD36^+$.[27] CD36 antigen is a cellular receptor for thrombospondin, collagen, low-density lipoproteins, long-chain fatty acids, and platelet-agglutinating protein p37.[28] Moreover, CD36 functions as one of the receptors that mediates the adhesion of *Plasmodium falciparum*–infected erythrocytes to microvascular EC. The functional consequences of the disparate CD36 expression on SVP and DVP endothelium are unknown. Microvessels are best characterized by expression of the PAL-E (pathologische anatomie Leiden-endothelium) antigen (which is identical with plasmalemmal vesicle 1 or fenestrated endothelial-linked structure protein),[29] N-cadherin, and CXCR4, and by their surrounding by smooth muscle actin–positive cells. This distinguishes them from lymphatic vessels, which express prospero-related homeobox 1, lymphatic vessel endothelial hyaluronan receptor 1, podoplanin, beta-chemokine receptor D6, and vascular endothelial growth factor receptor 3 (VEGFR-3).

Postcapillary venules of the skin express Toll-like receptor (TLR) family members and CD32 molecules (FcγRIIa).[30] CD32 binds complexed immunoglobulin G and is thought to function in the elicitation of type III (immune complex–mediated) hypersensitivity as well as in immune complex clearing. ECs of postcapillary venules express significantly higher levels of the histamine H_1 receptor than other ECs. Histamine produces increased albumin leakage and induces rolling of leukocytes, mediated in part by P-selectin expressed on the EC surface. Proteinase-activated receptor 2 expression at this site also plays a role in inflammatory reactions. Proteinase-activated receptor 2–activating peptides increase leukocyte rolling and adhesion to postcapillary venules. Finally, postcapillary vessels of the skin in situ constitutively express major histocompatibility complex (MHC) class I and II molecules at their luminal surfaces, which implies that ECs may directly participate in the

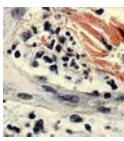


TABLE 163-1
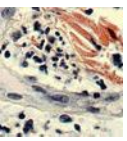
Molecular Markers of Endothelium

Marker	Location/Function	Expression Profile
vWF	WPB, biosynthetic organelles (Golgi, ER)	EC, megakaryocytes, platelets
CD31	Adhesion molecule, transmigration	EC, platelets, leukocytes
CD143 (angiotensin-converting enzyme)	Secreted then bound to cell surface	EC, macrophages
CD141	Anticoagulant thrombomodulin	EC, trophoblast of the placenta
Reactivity with the lectin UEA-1	Blood group H antigens	EC, erythrocytes, specialized epithelia
VEGFR-1 and VEGFR-2	Receptor tyrosine kinase	EC, macrophages, hematopoietic stem cells, motor neurons (R2)
Tie-1 and Tie-2	Receptor tyrosine kinase	EC, hematopoietic stem cells, peripheral nervous tissue (Tie-2)
ICAM-2	Adhesion molecule	EC
CD40, CD54, CD58, CD105	—	EC, broad expression pattern
CD9, CD13, CD31, C1q and C5a receptors, complement regulatory proteins	Common embryologic origin of the angioblast and the hematopoietic stem cell	EC, hematopoietic cells
CD26, CD40, CD44, CD47, CD54, CD58, CD146	—	EC, broadly expressed on other cell types
Class II MHC molecules	Antigen presentation	Constitutive on skin and kidney microvessels
Endoglin (CD105)	Surface receptor	EC, stromal cells
PAL-E antigen	Caveolae	Microvessels and veins
CD34	Proteoglycan, adhesion molecule	Microvessels, hematopoietic cells
CD36	Proteoglycan	Microvessels except brain and some skin ECs
CD32	Fc receptor	Liver and skin microvessels, leukocytes
P-selectin	Pre-stored in WPB	EC
VCAM-1 (CD106)	Inducible adhesion molecule	EC, macrophages, follicular-dendritic cells
E-selectin (CD62E)	Inducible adhesion protein	EC
MAdCAM-1	Adhesion molecule, sialomucin	Microvessels of intestine and breast
GlyCAM-1	Adhesion molecule, sialomucin	Lymph nodes, high endothelial venules
Peripheral node addressins (antibody MECA-79)	L-selectin ligands	EC of peripheral nodes and skin
ICAM-3	Adhesion molecule	Tumor vessels

EC = endothelial cell; ER = endoplasmic reticulum; GlyCAM = glycosylation-dependent cell adhesion molecule; ICAM = intercellular adhesion molecule; MAdCAM = mucosal addressin cell adhesion molecule; MHC = major histocompatibility complex; PAL-E = pathologische anatomie Leiden-endothelium; UEA = ulex europaeus agglutinin; VCAM = vascular adhesion molecule; VEGFR = vascular endothelial growth factor receptor; vWF = von Willebrand factor; WPB = Weibel-Palade body.

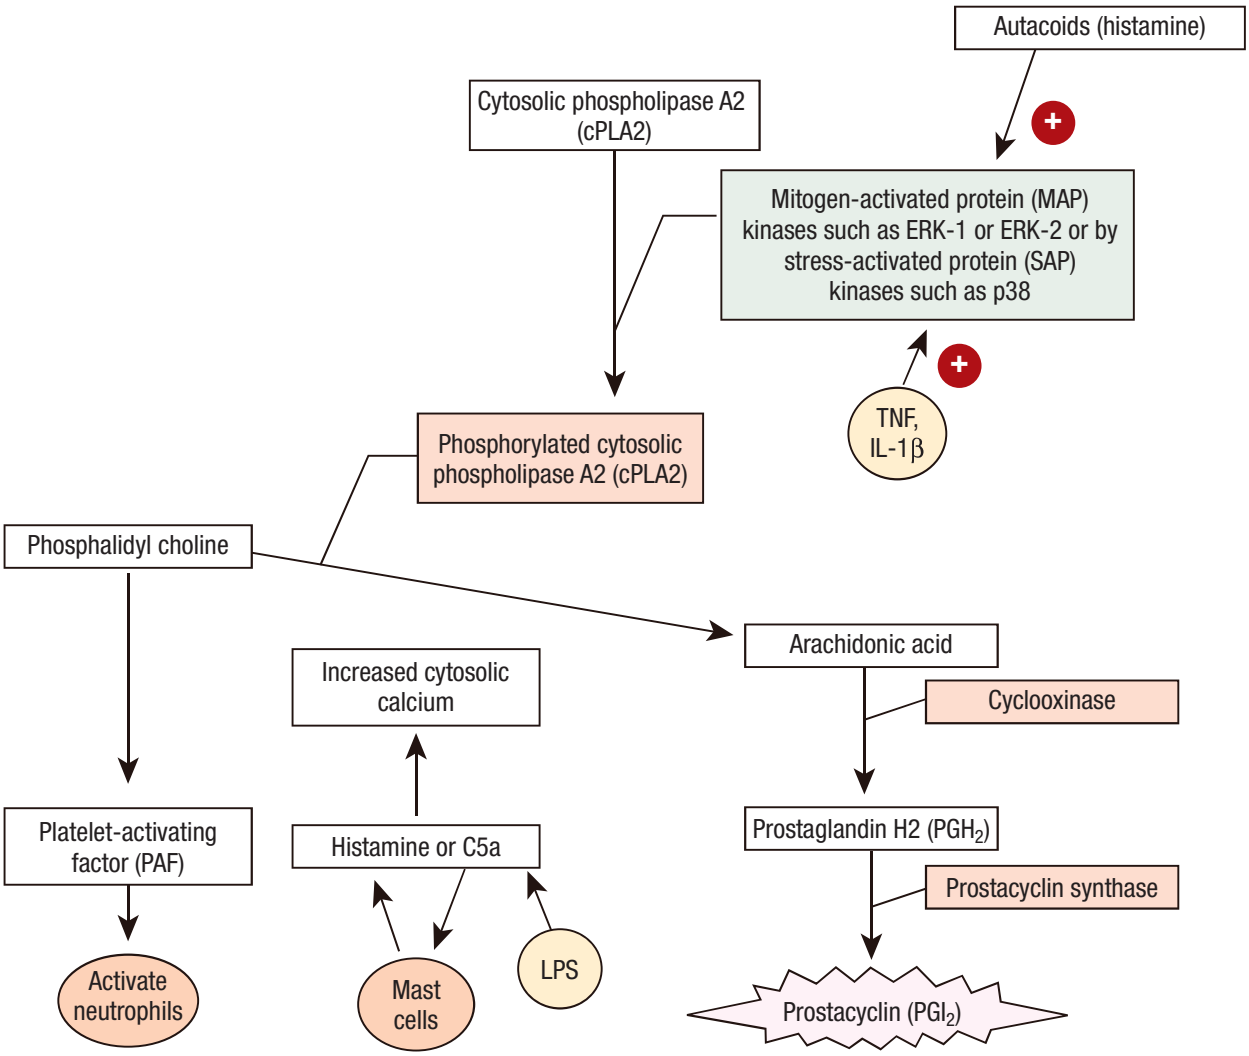


elicitation of antigen-driven immune responses. As discussed later (see Role of Endothelium in Adaptive Immunity), skin microvessels in cell culture appear able to process and present antigen in an MHC-restricted manner to T cells.[31]

ENDOTHELIUM IN INFLAMMATION

Innate Immunity

Innate immunity, also called *natural* or *native immunity*, comprises the host's defense systems against microbes that are independent of T and B lymphocytes and their receptors for specific antigens (see Chap. 10). The innate immune system is much older in evolutionary terms than the T- and B-cell–specific immune system (often called *adaptive immunity* to distinguish it from innate immunity), and elements of innate immunity have been found in invertebrates such as sponges and starfish. The humoral component primarily involves the complement system. The primary cellular effectors of innate immunity in humans are neutrophils, mononuclear phagocytes, and natural killer cells, but ECs also participate. For example, exposure to lipopolysaccharide, a major cell wall constituent of Gram-negative bacteria, results in endothelial activation through a receptor complex consisting of TLR-4, CD14, and MD2. Then, recruitment of the adaptor protein myeloid differentiation factor (MyD88) to the ligand-activated TLR-4 receptor initiates an MyD88-dependent pathway that culminates in the early activation of nuclear factor kappa B and the mitogen-activated protein kinases. In parallel, an MyD88-independent pathway results in a late-phase activation of nuclear factor kappaB.[32,33] ECs also express TLR-2, which serves as a signaling receptor for Gram-positive cell wall components, and intracellular TLRs that respond to various types of nucleic acids typically encountered during infections by viruses. Certain vascular beds express the macrophage mannose receptor (CD206), a receptor for oligosaccharides on the cell wall of bacteria, yeasts, and



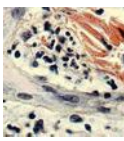
▲ **FIGURE 163-4** Prostaglandin I_2 (PGI_2) synthesis. ERK = extracellular signal–regulated kinase; IL = interleukin; LPS = lipopolysaccharide; TNF = tumor necrosis factor.

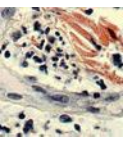
parasites. Other receptors of the innate immune system include a variety of lectin-type molecules, such as mannose-binding protein or galactins that recognize bacterial carbohydrates. Mannose-binding protein may stimulate the alternative pathway of complement activation.

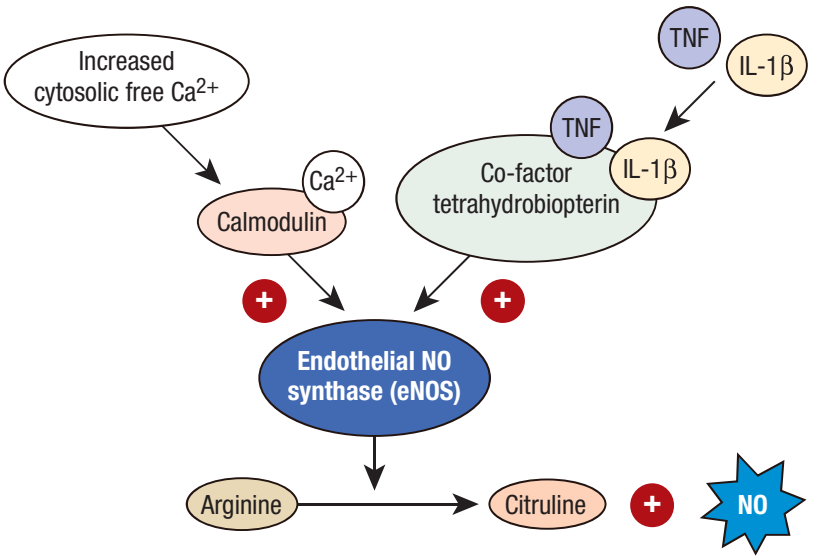
TNF and IL-1β are central effector cytokines of the innate immune response. In general, endothelial responses to TNF and IL-1 are similar and are considered together. At least five changes in the phenotype of ECs that promote inflammation, collectively called *endothelial activation*, have been described.

SYNTHESIS OF VASODILATORS TNF- or IL-1β–treated ECs increase production of vasodilators such as PGI_2 and NO. They relax smooth muscle cell tension, thereby producing vasodilation and increasing tissue perfusion. PGI_2, also called *prostacyclin*, is synthesized in ECs by a series of three sequential enzyme-catalyzed reactions.[34] ECs express one isoform of prostaglandin H synthase, PGHS-1, also called *cyclooxygenase 1*, that is constitutively active. Treatment of ECs with TNF or IL-1β dramatically increases PGHS activity by inducing de novo expression of a second isoform, PGHS-2, which is also called *cyclooxygenase 2*. This response markedly increases the capacity to make prostaglandin H_2 from arachidonic acid and subsequently PGI_2 (Fig. 163-4). Pharmacologic reduction in the generation of PGI_2 is thought to contribute to the anti-inflammatory actions of aspirin and nonsteroidal anti-inflammatory drugs that inhibit PGHS activity. NO is produced by conversion of arginine to citrulline through eNOS (Fig. 163-5). Although TNF may reduce eNOS expression by destabilizing its messenger RNA, it also increases eNOS activity by inducing phosphorylation by protein kinase B (also known as *Akt*) and by increasing synthesis of necessary co-factors, such as tetrahydrobiopterin.

LEUKOCYTE ADHESION (Tables 163-2 and 163-3) TNF- or IL-1β–treated ECs exhibit changes in the cell surface that favor the initial capture, rolling, and, ultimately, firm adhesion and spreading of leukocytes (Fig. 163-6). Adhesion is a prelude to extravasation of leukocytes into the tissues. Capture and rolling are typically mediated by selectins expressed on the leukocyte or on the EC.[35] There are three structurally related selectin proteins: L-selectin (CD62L), E-selectin (CD62E), and P-selectin (CD62P). In the presence of flowing blood, the leukocyte is propelled in the direction of blood flow, rapidly breaking and reforming selectin-mediated attachments. This results in rolling of the leukocyte along the EC surface (see Fig. 163-6). It should be noted that the ligands involved in selectin-mediated adhesion that participate in the initial capture may not be the same as those involved in rolling; for example, neutrophils may switch from L-selectin to E-selectin ligand-1 as the principal E-selectin ligand during







▲ **FIGURE 163-5** Nitric oxide (NO) synthesis. IL = interleukin; TNF = tumor necrosis factor.

these two phases of the interaction.[36,37] Studies using blocking monoclonal antibodies or adhesion molecule knockout mice have confirmed that selectins are required for neutrophil rolling and subsequent recruitment in vivo, although E- and P-selectin functions may be redundant (i.e., both molecules must be knocked out or inhibited for complete loss of rolling).

Firm adhesion of leukocytes to ECs is generally mediated by leukocyte integrins. Leukocytes use two different types of integrins to interact with ECs. The first of these are the CD18 or β_2 integrins, including lymphocyte function-associated antigen-1 ($\alpha_L\beta_2$ or CD11a/CD18) and Mac-1 ($\alpha_M\beta_2$ or CD11b/CD18). The adhesion mediated by LFA-1 or Mac-1 recognition of intercellular adhesion molecule 1 (ICAM-1) is much stronger than that mediated by selectins, so that once these molecules have engaged ICAM-1, leukocytes no longer roll. In the case of neutrophils, integrin engagement results in a gradual slowing of rolling velocity. In contrast, lymphocytes abruptly convert from rolling to firm adhesion. Once adherent, leukocytes spread out and then slowly crawl along the EC surface until they reach a cell junction, where they undergo diapedesis through the vessel wall into the tissues (see Fig. 163-6). It is likely that LFA-1–mediated attachment, disengagement, and reattachment to ICAM-1 play a role in the spreading, crawling, and diapedesis of leukocytes. Although ICAM-1 is initially (at 4 hours after treatment with TNF) upregulated diffusely on the luminal surface of the EC, it tends to preferentially localize to the intercellular junctions over the first few days.[6] Studies with blocking antibodies in knockout mice confirm that β_2 integrins and ICAM-1 play a major role in leukocyte adhesion to ECs and in subsequent recruitment.

The second group of integrins on leukocytes that mediate attachment to ECs are the α4 integrins (CD49d), which may pair with either β_1 (CD29) to form very late antigen-4 (VLA-4) ($\alpha_4\beta_1$) or with β_7 to form lymphocyte Peyer's patch adhesion molecule (integrin $\alpha_4\beta_7$). The principal EC ligand for VLA-4 is vascular adhesion molecule 1 (VCAM-1). This immunoglobulin superfamily mem-

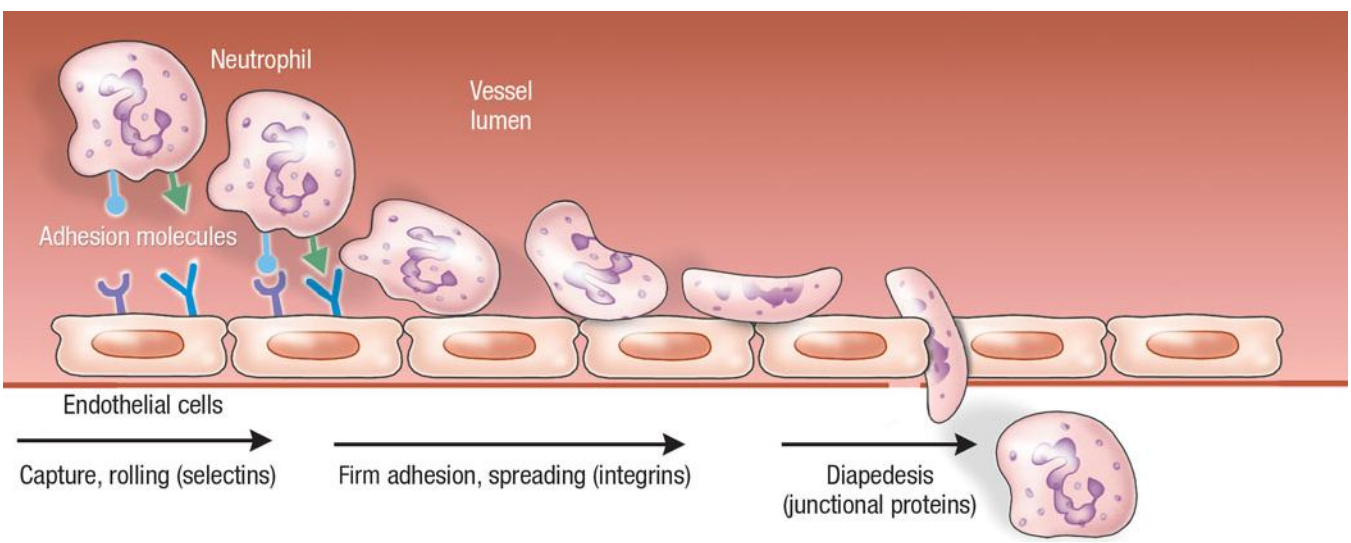
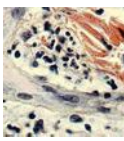
ber is not expressed on resting ECs under normal circumstances but is upregulated by TNF or IL-1β with a time course similar to that observed for ICAM-1. VCAM-1 may be selectively upregulated by IL-4, a cytokine associated typically with certain types of adaptive rather than innate immunity. Although VCAM-1 expression is not responsive to interferon-γ (IFN-γ) itself, IFN intensifies TNF-induced VCAM-1 expression.[38] Interestingly, VCAM-1 may support initial tethering and rolling of some leukocytes (e.g., of T cells but not of neutrophils), as well as firm adhesion, depending on whether the affinity/avidity of the leukocyte VLA-4 is increased by leukocyte activation. Both VLA-4 and VCAM-1 knockout mice are embryonically lethal mutations and shed no light on inflammatory processes; however, antibody-blocking experiments confirm a role for these molecules in leukocyte recruitment in vivo.[39]

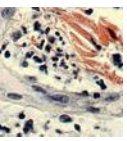
LEUKOCYTE ACTIVATION TNF- or IL-1β–treated ECs promote the activation of tethered or rolling leukocytes, triggering the transition from selectin-mediated low-affinity attachment to integrin-mediated firm adhesion and the transition from spherical, immotile leukocytes to spreading, migrating forms. In some experiments, engagement of selectins appears to be adequate by itself to trigger some of these changes, but most experiments indicate the requirement for a distinct signal. One candidate activator is the lipid mediator platelet-activating factor (PAF), which can be displayed in the EC plasma membrane. PAF synthesis is initiated by cytosolic phospholipase A2 activation, that is, the same reaction that provides arachidonic acid for PGI_2 synthesis. (In ECs, PAF contains acyl lipids rather than the alkyl lipids favored by leukocytes.) It has been reported that IL-1α (but not IL-1β) may promote PAF synthesis in ECs, but most studies emphasize the role of autacoids (e.g., histamine), rather than cytokines, as inducers of PAF synthesis.

The chemokines constitute an important group of TNF- or IL-1β–induced leukocyte activators that are defined by the presence and number of amino acids between two N-terminal cysteine residues (i.e., CC, CXC, etc.) (see Chap. 12). Chemokines induce migration and/or activation of various types of leukocytes through interaction with a group of seven transmembrane G protein–coupled receptors. The CXC chemokines (such as IL-8) are particularly important for neutrophil activation, and CC chemokines (such as MCP-1) are important for monocyte activation. IL-8 is stored in WPBs and released on stimulation with histamine or thrombin. Both IL-8 and MCP-1 are synthesized and secreted by TNF- or IL-1β–treated ECs. Furthermore, ECs can display their secreted chemokines in a complex with cell surface proteoglycans in a manner that renders them bioavailable to tethered or rolling leukocytes. The bound chemokines displayed by ECs could be made by ECs or could be captured and displayed once made by tissue cells or leukocytes. In addition, there is a transmembrane protein form of a chemokine called *fractalkine* that has its chemokine domain presented at the top of a mucin-like stalk. Fractalkine can be induced in vascular ECs and functions as an adhesion molecule. Accumulating evidence suggests that fractalkine mediates vascular injury in glomerulonephritis, allograft rejection, and atherosclerotic disease.[40–42] Chemokines may also play a role in activation and recruitment of specific lymphocyte subsets, as discussed later.



▲ **FIGURE 163-6** Leukocyte adhesion.





EXTRAVASATION OF LEUKOCYTES The interaction between TNF- and IL-β–treated ECs and leukocytes results in degradation of cellular and extracellular matrix barriers that normally separate leukocytes from the tissue space. The endothelial junctions contain proteins such as PECAM-1 (CD31) that appear to contribute to leukocyte transmigration, and as noted earlier, activated ECs also concentrate adhesive ligands, such as E-selectin, ICAM-1, and VCAM-1, at these same junctions. The details of interaction between leukocytes and ECs during diapedesis in vivo are incompletely defined. The principal pathway for extravasation appears to be through the intercellular junctions (see Table 163-2). Antibodies to PECAM-1 inhibit this process. However, in PECAM-1 knockout mice, effects on leukocyte transmigration appear to be mouse strain specific. The EC junctional protein CD99 plays a role in transmigration of monocytes and perhaps other types of leukocytes as well. VE-cadherin interacts with leukocytes through an interposed fragment of fibrin, which is formed through thrombin-induced fibrinogen activation followed by plasmin or urokinase digestion.[43] JAM proteins, also localized at endothelial junctions, interact with leukocytes by binding to integrins. The integrin LFA-1 mediates neutrophil and T-cell adhesion to JAM-1; the integrin $\alpha_4\beta_1$ mediates leukocyte adhesion to JAM-2. JAM-2–$\alpha_4\beta_1$ interactions appear to be dependent on interactions between JAM-2 and JAM-3. JAM-3 binds to CD11b/CD18 on neutrophils, and this interaction is thought to be important for neutrophil transepithelial migration.

In certain instances, leukocytes may extravasate through the EC body. The early stages of this process appear to involve phagocytosis of the leukocyte through membrane extensions enriched in ICAM-1 and VCAM-1. The factors that determine whether leukocytes use the intercellular or transcellular pathway are unknown. In addition, the rapid transmigration of T cells, but not other leukocyte subsets, appears to depend on the presence of venular levels of shear stress; the role that shear stress plays in this process is also unknown. TNF- or IL-1β–treated ECs secrete and activate matrix metalloproteinases (MMPs), which degrade the condensed region of connective tissue matrix, that is, the basement membrane that underlies the endothelial monolayer. ECs may also trigger leukocytes to synthesize or release MMPs, and the signals for this release may be cytokine-inducible molecules such as VCAM-1 or chemokines.[44]

VASCULAR LEAKAGE AND PROVISIONAL MATRIX Extravasation of plasma proteins into the tissue is a hallmark of inflammation. Autacoids such as histamine allow this to occur rapidly and transiently by causing ECs to contract their actin cytoskeleton, opening gaps between cells. VEGF may function similarly but also appears to have its primary effects on increasing fluid transit through vesiculo-vacuolar organelles. In contrast, TNF- or IL-1β–treated ECs permit the non-specific extravasation of fluid and plasma proteins, commonly called *vascular leak*, only after a delay of several hours in a process that depends on new protein synthesis. The loss of permselectivity (vascular leak) is a hallmark of inflammation. The principal purpose of this response is to allow plasma proteins, such as fibronectin and fibrinogen, to deposit in the tissues, where they form a provisional matrix that can be used by motile leukocytes. This is important because circulating leukocytes typically lack receptors that allow them to interact with the normal extracellular matrix, composed largely of interstitial collagens.

Collectively, these five TNF- or IL-1β–mediated responses of ECs promote the development of an inflammatory infiltrate initially comprised of neutrophils and later of mononuclear phagocytes. The infiltrating leukocytes serve to phagocytose the eliciting microbes and clean up damaged tissue. Infiltrating phagocytes also can cause tissue damage through the same mediators and enzymes they use to eradicate microbes (e.g., reactive oxygen intermediates, NO, and matrix-degrading enzymes such as elastase and MMPs). These mechanisms can and often do injure local ECs, which is manifested by EC retraction and/or denudation and often accompanied by intravascular thrombosis. Intravascular thrombi exacerbate tissue ischemia and injury. Fortunately, TNF- or IL-1β–treated ECs become more resistant to injury through expression of protective gene products such as detoxifying agents for reactive oxygen intermediates like manganese-superoxide dismutase and hemoxygenase; protease inhibitors like plasminogen activator inhibitor-1 and tissue inhibitors of metalloproteinases; and cytoprotective genes such as the zinc finger protein A20 and Bcl-related antiapoptotic genes such as A1. These protective responses allow ECs to survive many inflammatory reactions without triggering thrombosis and consequent tissue infarction.

The acquisition of cytoprotective features has been observed in the ECs of organ grafts that have evaded transplant rejection.[45] However, these protective responses are not always adequate. Moreover, some other TNF- or IL-1β–mediated endothelial responses, for example, induction of procoagulant proteins such as tissue factor coupled with loss of anticoagulant proteins such as thrombomodulin, may actually exacerbate tissue and vascular injury. This combination of neutrophil recruitment and activation with alterations in the endothelial coagulation system may underlie the tissue injury seen in the local Shwartzman reaction or in Gram-negative septicemia.

In summary, ECs, through their responses to cytokines, can contribute to host defense reactions mediated by the innate immune system. However, these same effector mechanisms may lead to endothelial injury and exacerbate tissue damage.

Role of Endothelium in Adaptive Immunity

As noted earlier in the chapter (see Molecular Markers of Endothelial Cells), ECs of microvessels constitutively express MHC molecules. To date, the only known function of class I and class II MHC molecules is to present peptides to T cells. Vascular ECs not only express MHC molecules but also express the proteins involved in generating peptides and loading these peptides into nascent class I and class II molecules.[46] The expression of class I genes (and the gene encoding the associated β2-microglobulin molecule), as well as the proteins involved in peptide generation and class I MHC molecule peptide loading, are all upregulated by cytokines, particularly by IFNs (IFN-α, IFN-β, and IFN-γ), and by TNF.[47] Under basal culture conditions human ECs do not express class II MHC molecules or the proteins responsible for peptide loading of class II molecules, but these proteins are induced by IFN-γ. In humans, class II molecules are basally expressed on microvascular cells in vivo.[47,48] It is unclear whether this "constitutive" expression depends on low levels of circulating IFN-γ or is truly constitutive.

The typical diameter of a capillary lumen is less than 10 μm; that is, nar-

rower than the diameter of a circulating lymphocyte. Consequently, circulating T cells are forced to encounter antigenic peptides complexed to both class I and class II MHC molecules displayed on the endothelial surface during the course of normal circulation. A key question is what effect this encounter has on the T cell. On recognition of peptide–MHC molecule complexes, T cells may become activated, may remain unchanged (a state called *immunologic ignorance*), or may become inactivated and unable to respond to future encounters (i.e., enter a state of anergy).

Studies of the consequences of T-cell recognition of antigen presented by ECs have largely used cell culture systems. In humans, such experiments often use the allogeneic response or polyclonal activators because the frequency of T cells specific for particular antigens is too low for most detection systems. In mice, investigators may use animals with transgenic expression of particular T-cell receptors so that every T cell can be stimulated by a single antigen or peptide. In vitro experiments using human cells suggest that naive T cells ignore antigens presented by ECs (or may become anergized), whereas resting memory T cells or recently activated T blasts respond by cytokine gene expression and a limited degree of proliferation. This limitation correlates with the observation that human ECs are deficient in expressing certain co-stimulatory molecules, for example, CD80 and CD86, and primarily co-stimulate T cells with LFA-3 (CD58).[49] Naive T cells poorly express CD2, the receptor for LFA-3. Another factor may be that naive T cells lack the expression of adhesion molecules necessary to attach firmly to ECs. In addition to constitutive expression of LFA-3, human ECs display inducible expression of ligands for inducible T-cell co-stimulator, CD137, and CD134 that are typically associated with the stimulation or reactivation of memory T cells.

Several non-exclusive roles have been proposed for presentation of antigen by ECs if it were to occur in vivo. The first is the maintenance of immunologic memory. Long-lived memory T cells may require periodic low-affinity signaling to survive, and the expression of MHC molecules bearing self-peptides by ECs may provide such low-affinity signals as these cells pass through the microcirculation. The second role might come into play when there is re-infection by a particular pathogen. In this case, ECs may present microbe-derived peptides in association with MHC molecules, providing an antigen-specific signal to circulating memory T cells that pathogen is present. This mechanism, if present, would serve to contribute to the efficiency of immune surveillance. This is a potentially important function, because T cells specific for any one antigen, even among memory T cells expanded by prior encounter with antigen, are rare (less than 1 in 10,000 to 100,000). Presentation of antigen by ECs could markedly increase the likelihood that antigen is recognized in a timely manner and that memory T cells are recruited to sites of danger. A third possibility involves the post-thymic induction and activation of $CD4^+25^+$forkhead box P3 regulatory T cells.[50] It has been shown that in mice alloantigen presentation by vascular ECs to $CD4^+$ T cells induces such regulatory T cells, which could be important for induction of tolerance. However, it must be noted that mouse ECs usually do not express class II MHC molecules in vivo and that cultured human T cells preferentially activate $CD4^+$ effector cells rather than regulatory T cells.

T cells may differentiate into specialized cytokine-producing subsets. For $CD4^+$ T cells, such responses may become polarized into T helper 1 (Th1) responses, dominated by T cells that produce IFN and lymphotoxin, or into T helper 2 (Th2) responses, dominated by T cells that produce IL-4 and IL-5. The Th1 subset favors recruitment and activation of mononuclear phagocytes and (in mice, at least) production of antibody isotypes that opsonize bacteria for phagocytosis. The Th2 subset favors recruitment and activation of eosinophils, favors production of antibody isotypes that target parasites for eosinophil-mediated killing, and triggers mast cells and basophils to release vasoactive mediators and cytokines. More recently, it has been appreciated that some effector $CD4^+$ T cells may selectively secrete IL-17, a pro-inflammatory cytokine, or IL-10 or TGF-β, inhibitory cytokines that downregulate T-cell responses. The biology of these T-cell subsets is less well understood.

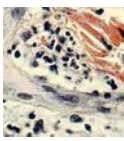
It is possible that cytokines released by Th1 or Th2 cells differentially shape EC activation patterns. For example, IFN-γ combined with lymphotoxin causes prolonged expression of E-selectin, an important ligand for Th1 T cells. Th1 cells, but not Th2 cells, are able to bind to P-selectin and E-selectin, and migration of Th1 cells into inflamed skin is blocked by antibodies against P- and E-selectin.[51] P-selectin glycoprotein ligand 1 appears to functions as P- and E-selectin ligands for Th1 cells, which correlates with increased expression of the α3-fucosyltransferases in Th1 cells.[51,52] In contrast, Th2-derived IL-4 increases VCAM-1 expression while suppressing E-selectin, a cell surface molecule that favors eosinophil and possibly also Th2-cell recruitment. In other words, T cell–derived cytokines may modify the innate EC responses in a way that biases leukocyte recruitment toward recruitment of specific effector cells. Finally, differential expression of chemokine receptors may also account for selective recruitment of T-cell subsets. For example, CCR5 and, to a lesser degree, CXCR3 are preferentially found on Th1 cells, whereas CCR4, CCR8, and, more controversially, CCR3 and CXCR4 are preferentially found on Th2 cells.

SKIN MICROVESSELS IN INFLAMMATION AND REPAIR

Skin Microvessels in Cutaneous Inflammation

It is clear that vascular ECs are important participants in the development of inflammatory responses. It has now been elucidated that tissue-specific differences in ECs may partly determine the unique patterns of inflammation observed in different organs. One mechanism by which vascular ECs may contribute to tissue-specific inflammatory patterns is through distinctive patterns of adhesion molecule expression, which results in selective recruitment and diapedesis of circulating leukocytes bearing the proper ligands. In the skin, E-selectin, VCAM-1, and ICAM-1 may be particularly important in this process, and they have been extensively evaluated in normal and disease states[27,53–55] (see Table 163-3).

The induction of E-selectin appears to be particularly important in cutaneous inflammatory reactions. In addition to being readily inducible by cytokines and uniformly associated with leukocytic infiltration, E-selectin may play a role in the selective recruitment of lymphocytes to cutaneous sites of inflammation through binding to the cutaneous lymphocyte antigen (CLA).[56,57] CLA is a carbohydrate moiety on the surface of T cells closely related to sialylated Lewis X, which has homology to the core structure of P-selectin glycoprotein-1.[58] By using the identifying monoclonal an-



tibody HECA-452, CLA has been found on 80 percent to 90 percent of skin infiltrating lymphocytes compared with 5 percent to 10 percent at other peripheral sites. CLA is also present on circulating precursor Langerhans cells and presumably plays a role in their eventual localization to the skin. The expression of E-selectin in cultured dermal microvascular ECs is relatively persistent compared to endothelium derived from other sources. This persistent expression of E-selectin in vivo has been proposed to be responsible for the preferential homing of CLA-positive lymphocytes to the skin. Work in a chimeric human mouse model of inflammation suggests that CLA-positive lymphocytes specifically migrate through the superficial, as opposed to the deep, vascular plexus.[59] It is unlikely that E-selectin–CLA interactions alone are sufficient for the homing of lymphocytes to the skin. The transmigration of CLA-positive lymphocytes across activated ECs is dependent on interactions with VCAM-1 and ICAM-1, in addition to E-selectin.

The induction of E-selectin on cutaneous microvessels also appears to play a role in immediate hypersensitivity reactions in atopic individuals. These reactions are characterized by an immunoglobulin E–dependent biphasic response. Within minutes after exposure, the relevant antigen cross-links immunoglobulin E, which is bound to the high-affinity FcRε receptors on the surface of mast cells, and results in histamine release. Histamine-dependent stimulation of ECs leads to vasodilation and increased vascular permeability, which produces the classic wheal-and-flare response that typically resolves within 30 to 90 minutes. This reaction, known as the *early-phase response*, is not accompanied by endothelial E-selectin upregulation or inflammatory cell recruitment. The late-phase reaction begins 3 to 4 hours after antigen challenge and is characterized by the infiltration of eosinophils, neutrophils, and mononuclear cells into the inflamed area. Granulocytes are most prominent at 6 to 8 hours, and by 24 to 48 hours the cellular infiltrate consists largely of mononuclear cells. The expression of E-selectin, which indicates endothelial activation, is detectable at the onset of infiltration. Although this E-selectin induction may simply be due to cytokine release from infiltrating inflammatory cells, there is evidence that the necessary mediators are first released from skin-resident cells. In skin organ culture, the addition of antigen either before or during the culture period results in significant E-selectin expression without inflammatory infiltrate.[60]

VCAM-1 may play a role in the specific homing of leukocytes to the skin through binding to the integrin $\alpha_4\beta_7$ on the surface of lymphocytes. This integrin is associated with the specific localization of lymphocytes to the gut through binding to mucosal addressin cell adhesion molecule 1 (Madcam)-1 on ECs of intestinal microvessels.[55] Another ligand for $\alpha_4\beta_7$ includes fibronectin. $\alpha_4\beta_7$ has been found to be expressed on a high percentage of intraepidermal lymphocytes, particularly in cutaneous T-cell lymphoma (CTCL) and, to a lesser degree, in spongiotic dermatitis.[55] Interestingly, in CTCL, the expression of $\alpha_4\beta_7$ strongly correlated with the expression of integrin $\alpha_E\beta_7$. $\alpha_E\beta_7$ is also found on a high percentage of gut (intraepithelial) and intraepidermal lymphocytes.

In chronic inflammatory conditions such as psoriasis and CTCL, the cutaneous microvascular endothelium develops a "high endothelial venule" morphology similar to that seen in peripheral lymph nodes. This is accompanied by the expression of peripheral lymph node addressin identified by the antibody MECA-79, which serves as an L-selectin ligand. This has led to the speculation that peripheral node addressins in chronic T cell–mediated skin diseases are responsible for sustained lymphocyte recruitment. Interestingly, there is MECA-79 reactivity in the perifollicular vessels in noninflamed skin.[61] This constitutive expression in normal skin may serve a function in continuous lymphocyte recirculation.[62]

Chemokines also play a role in the selective homing of T cells to the skin. CCR4 is expressed at high levels by CLA-positive memory T cells. The CCR4 receptor TARC is constitutively expressed on ECs in cutaneous postcapillary venules. In vitro TARC triggers CLA-positive T cells that are rolling on E-selectin to firmly adhere ICAM-1. Another skin-associated chemokine, CCL27 (cutaneous T cell–attracting chemokine), is produced by keratinocytes and also preferentially attracts CLA-positive memory T cells.[63]

New Vessel Formation in the Skin

DEFINITION OF ANGIOGENESIS AND VASCULOGENESIS In the healthy adult, blood vessels are stable structures with very slow turnover of ECs. In settings of chronic inflammation, tissue injury, or tumor growth, new vessels may be formed and existing vessels may undergo remodeling. Much of the process of vessel formation has been learned by the study of the formation of the vascular system during embryogenesis. In the embryo, ECs arise from angioblasts,[64,65] which migrate from their site of origin (initially blood islands, later liver, and ultimately bone marrow) to peripheral tissues, where they form primitive blood vessels (vasculogenesis). Subsequently, new blood vessels arise from pre-existing ones (angiogenesis). Mesenchymal cells are then recruited into the vessel wall, where they subsequently differentiate into smooth muscle cells and pericytes, as part of a process called *vascular remodeling*. New vessels can be formed in the adult as part of chronic inflammation or as part of the repair of injured tissues. In the adult, most new vessels develop through angiogenesis, but this may be supplemented by hematogenic "seeding" of endothelial progenitor cells, mesoangioblasts, and multipotent adult progenitor cells derived from the adult bone marrow (vasculogenesis).[66,67] Transgenic and genetic knockout animal models have revealed that vasculogenesis and angiogenesis are largely regulated by growth factors and their specific receptor tyrosine kinases.[68]

REGULATION OF ANGIOGENESIS AND VASCULOGENESIS (Table 163-4) Molecules of the VEGF family, VEGF A through E, and their receptors, VEGFR-1 (Flt-1), VEGFR-2 (KDR or Flk-1), and VEGFR-3 (Flt-4), are required to initiate the formation of primitive vessels. Mice with a targeted disruption of VEGF or VEGFR-2 genes fail to develop a vasculature. VEGFR-1 knockout mice have immature leaky vessels. Disruption of VEGFR-3 results in the disorganization of large vessels and lymphatic hypoplasia. A missense mutation in VEGFR-3 occurs in primary human lymphedema.[68–70] Fibroblast growth factors 1 and 2 (FGF-1 and FGF-2, also called *acidic* and *basic FGF*, respectively) mainly signal through FGF receptor I.[71] Knockout mice die before vasculogenesis starts; thus specific evaluation of FGF function in vascular development is not possible in these animals. Both FGF-1 and FGF-2 are potent EC mitogens but also act on smooth muscle cells and fibroblasts. FGFs "synergize" with VEGF in stimulation of cultured EC mitogenesis and in bioassays of angiogenesis. In the adult, FGF-1 and FGF-2 are stored in the cytoplasm of a variety of cells, which is consistent with the fact that these proteins lack the signal sequences required for efficient secretion. Stored FGFs are released when cells are injured, acting as "wound hormones" to

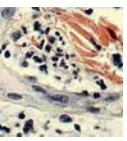


TABLE 163-4
Molecules Important in Vasculogenesis and Angiogenesis

MOLECULE	FUNCTION	RECEPTOR
VEGF family • Five splice variants (VEGF A–E) • Homolog PlGF	Specific mitogen for ECs	Family of closely related receptor tyrosine kinases • VEGFR-1 (Flt-1) binds VEGF A and B, PlGF • VEGFR-2 (KDR or Flk-1), main mediator of VEGF-induced vascular development and angiogenesis, binds all isoforms of VEGF • VEGFR-3 (Flt-4) binds VEGF C and D
FGF-1 and FGF-2	Involved in vasculogenesis and angiogenesis in embryonic development	FGFR-I
Angiopoietins • Ang-1 • Ang-2 • Murine Ang-3 • Human Ang-4	Ang-1 positively affects vascular stability Ang-2 is a competitive inhibitor of Ang-1	Tie-1 and Tie-2 receptor tyrosine kinases • Tie-2 mediates dialog between primitive mesenchymal cells and EC of immature vessels • Tie-1 ligands not known
PDGF	Secreted by ECs, acts on mesenchymal cells to promote migration, matrix biosynthesis, and differentiation	Receptor tyrosine kinase
TGF-β	Secreted by ECs, acts on mesenchymal cells to promote migration, matrix biosynthesis, and differentiation	Protein serine/threonine kinase Endoglin (CD105) important for vascular development
TSP-1	Anti-angiogenic, inhibits MMP-9, activates TGF-β	Integrin $\alpha_V\beta_3$ CD36

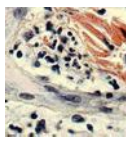
Ang = angiopoietin; EC = endothelial cell; FGF = fibroblast growth factor; FGFR = fibroblast growth factor receptor; KDR = kinase insert domain protein receptor; MMP = matrix metalloproteinase; PDGF = platelet derived growth factor; PlGF = placental growth factor; TGF = transforming growth factor; TSP = thrombospondin; VEGF = vascular endothelial growth factor; VEGFR = vascular endothelial growth factor receptor.

stimulate local angiogenesis and connective tissue growth.[71] Other polypeptide factors have also been found to act on ECs in vivo and in vitro, including epidermal growth factor,[72] heparin-binding EGF–like growth factor,[73] and hepatocyte growth factor (HGF)/scatter factor (SF).[74]

For vascular remodeling and stabilization, tyrosine kinase receptors 1 (Tie-1) and 2 (Tie-2; Tek) are required. Tie-2 mediates the dialogue between mesenchymal cells and the endothelium of the immature blood vessel through binding to angiopoietins (Ang-1, Ang-2, murine Ang-3, and its human ortholog Ang-4). In humans, Tie-2 mutations cause venous malformations typified by enlarged vascular channels lacking smooth muscle cells. Ang-2 appears to be a competitive inhibitor of Ang-1, and Ang-2 overexpression results in a phenotype resembling an Ang-1 knockout animal.[75] Ligands for Tie-1 are not known, but knockout of this receptor results in defective vascular maturation later in embryonic development.[68,76] The eph family of receptor tyrosine kinases (ephA1 to ephA8 and ephB1 to ephB6) and their corresponding ephrin ligands (ephrin-A1 to ephrin-A5 and ephrin-B1 to ephrin-B3) are membrane bound and appear to mediate bidirectional cell-to-cell signaling. Mice lacking ephrin-B2 and its ephB4 receptor have lethal defects in early angiogenic remodeling.[77] During vascular development ephrin-B2 marks the ECs of early arterial vessels and ephB4 marks the ECs of early veins.[78]

PDGF and TGF-β are secreted by ECs and promote migration of mesenchymal cells, matrix biosynthesis, and differentiation.[79] PDGF acts through a receptor protein tyrosine kinase; TGF-β signals through a protein serine/threonine kinase. TGF-β also uses nonsignaling receptors that present TGF-β to the signaling receptor, for example, endoglin (CD105). A truncation mutation in the endoglin gene in humans causes a hereditary form of vascular malformations (hereditary hemorrhagic telangiectasia type I)[80] and endoglin knockout mice die of defective vascular development.

Matrix glycoproteins such as fibronectin and laminin and receptors for matrix glycoproteins such as β_1 and β_3 integrins are also believed to play a role in vasculogenesis and angiogenesis.[81] This seems intuitive, because neither ECs nor mesenchymal cells can survive unless they interact with matrix proteins via integrin receptors. Knockout of most of these molecules causes early embryonic death, which prevents a direct test of their role in vascular embryology. An exception is the β_3 integrin knockout mouse, which shows normal development but enhanced tumor angiogenesis. Coagulation factors, like tissue factor or coagulation factor V, are implicated in vasculogenesis by observations of defective vascular development in knockout mice.[82] It is thought that these defects are an indirect result of defective thrombin production, because knockout of the thrombin receptor PAR-1 produces similar phenotypes.



CUTANEOUS ANGIOGENESIS AND VASCULOGENESIS Cutaneous angiogenesis and vasculogenesis occur in wound healing, inflammation, and tumorigenesis. New vessel formation in the skin differs in several ways from that in other organs. Skin harbors hair follicles, which, besides having a role in forming hair shafts, appear to play a role in new vessel formation. The follicle contains a distinct population of presumptive follicular stem cells that express nestin, also a marker for neural stem cells. These nestin-expressing follicle cells are located in the follicular bulge region. During the follicular growth cycle, they differentiate into the various cell types of the hair follicle and, in addition, can form a variety of epidermal cells. It has been shown that these nestin-positive cells can also develop into cutaneous blood vessels that originate from hair follicles and form a follicle-linked vascular network. The quantitative contribution of hair follicle–derived angiogenesis compared with conventional angiogenesis through local sprouting and/or hematogenic seeding of endothelial progenitors is still unknown.

Skin endothelium is also unique by virtue of its close proximity to keratinocytes, which form the overlying epidermis coating. Keratinocytes have been shown to express a wide range of angiogenic factors, including members of the fibroblast or TGF protein family, platelet PDGF, or VEGF.[83,84] Under conditions of injury, hypoxia, or inflammation, keratinocytes produce and release these growth factors. Concomitantly, VEGFR-2 is upregulated on ECs, which augments endothelial responses to VEGF.[85] Ang-1 and Ang-2 are also upregulated during in-

jury, which is consistent with the role they are thought to play in the destabilization, followed by stabilization, of the vasculature. This allows a window for VEGF-mediated sprouting and elongation, followed by Ang-1–mediated remodeling.[68] FGF-2 is released in cutaneous wounds and is derived from ECs and from infiltrating macrophages. Antibodies against FGF-2 inhibit wound angiogenesis nearly completely.[86]

Adhesion molecules are necessary for physiologic angiogenesis in the skin. The expression of integrin $\alpha_V\beta_3$ on the tips of growing capillaries appears to facilitate endothelial migration and to be required for wound healing. In an in vivo model in which human skin placed on immunodeficient mice was wounded, blocking antibodies directed to CD31 and VE-cadherin reduced wound vascularization and healing.[20] In a similar model, blocking antibodies directed against $\alpha_V\beta_3$ inhibited angiogenesis and wound healing.[87] Administering $\alpha_V\beta_3$ inhibitors reduces granulation tissue formation and wound-induced angiogenesis, which suggests that $\alpha_V\beta_3$ is required for proper wound healing. In contrast, mice lacking β_3 integrins show enhanced wound healing with complete re-epithelialization several days earlier than do wild-type mice,[88] apparently due to an increase in TGF-β1 and enhanced dermal fibroblast infiltration into wounds of β_3-null mice. This suggests that the role of β_3 integrins is complex and that these molecules may influence both angiogenic and anti-angiogenic effects.

Angiogenesis is also necessary in skin tumorigenesis to maintain adequate nutritive supply. Skin tumors are known to produce angiogenic factors such as VEGF, FGF-2, EGF, and HGF/SF.[89] Some of these growth factors play a role in the pathogenesis of both benign and malignant skin tumors. There is a significant vascular contribution to the growth and metastasis of cutaneous melanoma and increased number of vessels in primary melanomas compared with severely atypical nevi. This vascular proliferative response appears to be in part mediated by FGF-2, which is produced by melanoma cells. Antisense oligonucleotides directed against FGF-2 inhibit the proliferation of both primary and metastatic melanoma.[90] HGF/SF and VEGF are also produced by melanoma cells and also contribute to vascularization. Peptide growth factors also appear to play a role in the pathogenesis of vascular tumors. The spindle cells of Kaposi sarcoma also produce large amounts of VEGF (see Chap. 128). When human ECs are cultured in the presence of HGF/SF, they acquire a Kaposi sarcoma cell–like morphology. In hemangiomas high levels of FGF-2 and VEGF characterize the proliferative phase. However, there is also abundant FGF-2 expression in the involuting phase.

VASCULAR REMODELING IN THE SKIN Vascular remodeling plays a role in the pathogenesis of some inflammatory skin diseases, notably psoriasis (see Chap. 18). Psoriatic vessels become tortuous and elongated, and the normally well-defined boundary between capillary ECs resting on an arteriole-like homogenous basement membrane and ECs on a venule-like laminated basement membrane becomes unclear. The intrapapillary portions of capillaries acquire a venular phenotype.[91] It is unknown whether this is due to metaplasia from arteriolar to a venular endothelium or to an elongation of the postcapillary venule. Light-microscopic investigations on eruptive guttate psoriatic lesions demonstrated that vascular alterations are the first ultrastructurally detectable alterations within the dermal compartment. These alterations consist of gap formation within postcapillary venules, EC hypertrophy with a cuboidal shape similar to that seen in high endothelial venules, and compression of the vascular lumen, all of which precedes the invasion of inflammatory cells into the tissue.[91] This morphologic alteration is accompanied by altered endothelial function. For example, there is increased blood flow in perilesional psoriatic skin even in the absence of any microscopically detectable changes.[92] The role angiogenic factors play in vascular remodeling in psoriasis has been partly characterized. It has been suggested that these vascular alterations may, in part, be mediated by increased production of VEGF by keratinocytes. There is also increased expression of VEGFR-1 and VEGFR-2 on the papillary dermal microvascular ECs.[93] VEGF appears to directly upregulate expression of ICAM-1, VCAM-1, and E-selectin. The VEGF-mediated vascular leak and adhesion molecule upregulation can be inhibited by concurrent overexpression of Ang-1. The role of angiogenesis in inflammatory processes has been further exemplified by the anti-inflammatory effects of angiogenesis inhibitors.[94]

CONCLUSION

The skin vascular system is unique in several respects. It is organized into functionally distinct vascular segments: the loops within the tips of the papillae, the SVP and the DVP, and the subcutaneous vascular plexus. These segments may individually or conjointly respond to exogenous or endogenous stimuli, thereby influencing skin disease expression. Due to their proximity to the epidermis, ECs of the SVP may directly respond to keratinocyte-derived factors like cutaneous T cell–attracting chemokine or VEGF, which results in an altered vascular architecture, phenotype, and function. Moreover, skin EC may be directly exposed to environmental antigens. In this context, the constitutive expression of HLA class II molecules by postcapillary venules implies that ECs play a role in antigen presentation, which may increase the likelihood that antigen is recognized in a timely manner to efficiently recruit memory T cells to sites of danger.

CHAPTER 164

Cutaneous Necrotizing Venulitis

Nicholas A. Soter
Jose L. Diaz-Perez

Necrotizing angiitis or vasculitis comprises a diverse group of disorders that combine segmental inflammation with necrosis of the blood vessels. The vascular damage may result from immunologic and/or other inflammatory mechanisms. Clinical syndromes are based on criteria that include the gross appearance and the histologic alterations of the vascular lesions, the caliber of the affected blood vessels, the frequency of involvement of specific organs, and laboratory abnormalities. Necrotizing vasculitis may be a primary disease, may develop as a feature of a systemic disorder, or may be idiopathic.

Necrotizing vasculitis in the skin involves predominantly venules and is known as *cutaneous necrotizing venulitis* (CNV) and *leukocytoclastic vasculitis.* The occurrence of CNV in association with systemic involvement of the small blood vessels has been termed *hypersensitivity angiitis* or *vasculitis, systemic polyangiitis,* and *microscopic polyangiitis* (see Chap. 165). CNV may occur in association with an underlying chronic disease, may be precipitated by infections or drugs, or may develop for unknown reasons (Table 164-1). Although immunoglobulin A (IgA)–mediated small-vessel necrotizing vasculitis has been proposed as a nosologic entity, at the present time an immunopathobiologic classification of CNV is not possible. Systemic forms of necrotizing vasculitis that affect larger blood vessels are considered in Chap. 165.

TABLE 164-1
Cutaneous Necrotizing Venulitis

- Associated chronic disorders
  - Rheumatoid arthritis
  - Sjögren syndrome
  - Systemic lupus erythematosus
  - Hypergammaglobulinemic purpura
  - Paraneoplastic vasculitis
  - Cryoglobulinemia
  - Ulcerative colitis
  - Cystic fibrosis
  - Antineutrophil cytoplasmic or antiphospholipid antibody syndromes
- Precipitating events
  - Bacterial, viral, and mycobacterial infections
  - Therapeutic and diagnostic agents
- Idiopathic disorders
  - Henoch-Schönlein syndrome
  - Acute hemorrhagic edema of childhood
  - Urticarial vasculitis and variants
  - Erythema elevatum diutinum
  - Nodular vasculitis
  - Livedoid vasculitis
  - Genetic complement deficiencies
  - Eosinophilic vasculitis
  - Idiopathic

EPIDEMIOLOGY

The age of patients has a limited influence on CNV. The associated chronic disorder usually determines the age of the affected individual. In children, CNV is most commonly described as the Henoch-Schönlein syndrome or acute hemorrhagic edema of childhood. Antineutrophil cytoplasmic antibody (ANCA)–associated vasculitides are most common in patients older than 50 years of age.

ETIOLOGY AND PATHOGENESIS

Experimental studies in animal models and observations in humans implicate immune complexes as a major pathobiologic mechanism in the production of CNV. Data obtained in animal models suggest that the localization in venules is related to vasoactive amines and subsequent vasopermeability alterations. Additional factors that are operative in the localization of immune complexes include endothelial–cell surface receptors and the defective clearance of immune complexes by the reticuloendothelial system.

The most frequently postulated mechanisms in the production of CNV are the local deposition of circulating immune complexes formed during antigen excess or the formation of immune complexes in situ in the skin. Immune complexes may activate the complement system and lead to the generation of C5a anaphylatoxin, which attracts neutrophils. In turn, the neutrophils release lysosomal enzymes that damage tissue. The neutrophil superoxide-generating system may produce reactive oxygen products, which also cause tissue injury. The generation of the chemoattractant leukotriene (LT) B_4 from infiltrating neutrophils enhances the influx of neutrophils. An infiltrate composed predominantly of neutrophils in the lesional skin of patients with CNV is consistent with tissue damage induced by immune complexes that activate the complement system. In the Henoch-Schönlein syndrome, the fragmentation of neutrophils was attributed to apoptosis on the basis of the detection of in-

CUTANEOUS NECROTIZING VASCULITIS AT A GLANCE

- Signature lesions are erythematous papules that do not blanch when the skin is pressed and are known as *palpable purpura.*
- Palpable purpura persists for 1 to 4 weeks and resolves at times with transient hyperpigmentation and/or atrophic scars.
- Macules, papules, urticaria/angioedema, pustules, vesicles, ulcers, necrosis, and livedo reticularis may also be present.
- May even be characterized by episodes of recurrent and chronic urticaria and angioedema.
- Lesions may occur anywhere on the skin but are most common on the lower extremities or over dependent areas, such as the back and gluteal regions.
- May be associated with connective-tissue diseases, notably rheumatoid arthritis, Sjögren syndrome, systemic lupus erythematous, and hypergammaglobulinemic purpura.
- There may be many precipitating causes but infections and drugs are most common.
- The most widely recognized subgroup of idiopathic cutaneous necrotizing vasculitis is the Henoch-Schönlein syndrome, otherwise known as *anaphylactoid purpura.*
- Histologic criteria include necrosis of the blood vessels with the deposition of fibrinoid material and dermal cellular infiltrates that consist of neutrophils with nuclear debris, mononuclear cells, and extravasated erythrocytes.

ducible nitric oxide synthase and nitrotyrosine in the infiltrates and the detection of interleukin 8 on vascular endothelial cells.[1]

In patients with CNV, circulating immune complexes have been demonstrated in serum as mixed-type cryoglobulins and indirectly by assays that detect C1q precipitins, materials that bind to complement receptors on human lymphocytoid (Raji) cells, materials that bind to monoclonal rheumatoid factor, and substances that function in the antibody-dependent cellular cytotoxicity inhibition assay. The presence of immune complexes is inferred from the occurrence of serum hypocomplementemia with activation of the classic activating pathway and by the detection of increased plasma levels of C4a and C3a anaphylatoxins.

Immune complexes have been detected in lesional tissues by ultrastructural observation as electron-dense subendothelial deposits; and the membrane-attack complex, C5b-9, of the complement system has been detected on the surface of endothelial cells and infiltrating neutrophils. Decay-accelerating factor, a regulatory complement protein that prevents the assembly of the membrane-attack complex, is not present on the surface of endothelial cells of the upper dermal microvasculature. Tissue immune complexes also have been detected by direct immunofluorescence techniques as deposited immunoglobulins and complement proteins. In time-course studies of the evolution of cutaneous vascular lesions, immune reactants have been identified in lesions less than 24 hours old. Antigens have been identified in only a few instances as bacterial, viral, mycobacterial, or rickettsial proteins by direct immunofluorescence techniques or by the polymerase chain reaction.

A role for lymphocytes, mononuclear cells, and Langerhans cells in the production of CNV is suggested by a perivenular infiltrate in skin lesions that is rich in lymphocytes with large and hyperchromatic nuclei, and by a prominence of mononuclear cells in the vascular skin lesions of patients with CNV and Sjögren syndrome. The lymphocytes express CD3, CD4, CD1a, CD36, intercellular adhesion molecule-1, and lymphocyte function–associated antigen-1. Lymphocytes may be activated by immune complexes, by cellular immune mechanisms, or by primary activation in autoimmune disease to produce lymphokines. Endothelial cells also can present antigens to and activate T lymphocytes. Activated macrophages secrete chemokines and lysosomal enzymes. γ/δ T cells have been detected in CNV with a neutrophil-rich pattern and with a documented infectious etiology.[2] In these specimens, a 72-kd heat shock protein was expressed by endothelial cells and antigen-presenting cells.

The participation of mast cells in CNV is suggested by hypogranulated mast cells with shed extracellular granules, by a decreased number of mast cells in biopsy specimens of skin lesions, and by the development of vascular lesions after the intracutaneous injection of histamine in patients with active episodes of CNV. Mast cells can be activated directly by immune complexes through FcγRIII or by complement fragments acting through their specific receptors. Through the production of histamine, prostaglandin D_2, and cysteinyl LTs, the mast cell could alter venular permeability; interendothelial cell gaps have been noted in venules in patients with CNV. Eosinophils and neutrophils could be recruited by mast cell–derived chemotactic factors. The neutral proteases and acid hydrolases of mast cells may facilitate tissue damage, and the release of tumor necrosis factor (TNF)-α may increase expression of E-selectin on endothelial cells, thereby facilitating neutrophil recruitment.

Evidence for the role of the mast cell is provided by time-course analyses of the sequential histopathologic changes in individuals with physical urticaria. In a patient with circulating immune complexes and hypocomplementemia, in whom cold and trauma elicited CNV, initial mast cell degranulation was followed by the infiltration by neutrophils with an influx of eosinophils and basophils, the deposition of fibrin, and venular endothelial-cell necrosis. A postulated sequence of events would be the activation of the mast cell by physical stimuli, the release of vasoactive mediators, the deposition of circulating immune complexes with activation of the complement system, the influx of neutrophils, and the development of CNV. Another example of the time course of necrotizing venulitis in human skin has been provided in an individual with exercise-induced vasculitis.[3] At 3 hours, the number of mast cells decreased and the eosinophil was the next cell to appear around the venules with the deposition of eosinophil peroxidase. TNF-α levels were elevated, and E-selectin was expressed on endothelial cells. Subsequently, an influx of neutrophils appeared with the deposition of neutrophil elastase and the development of CNV.

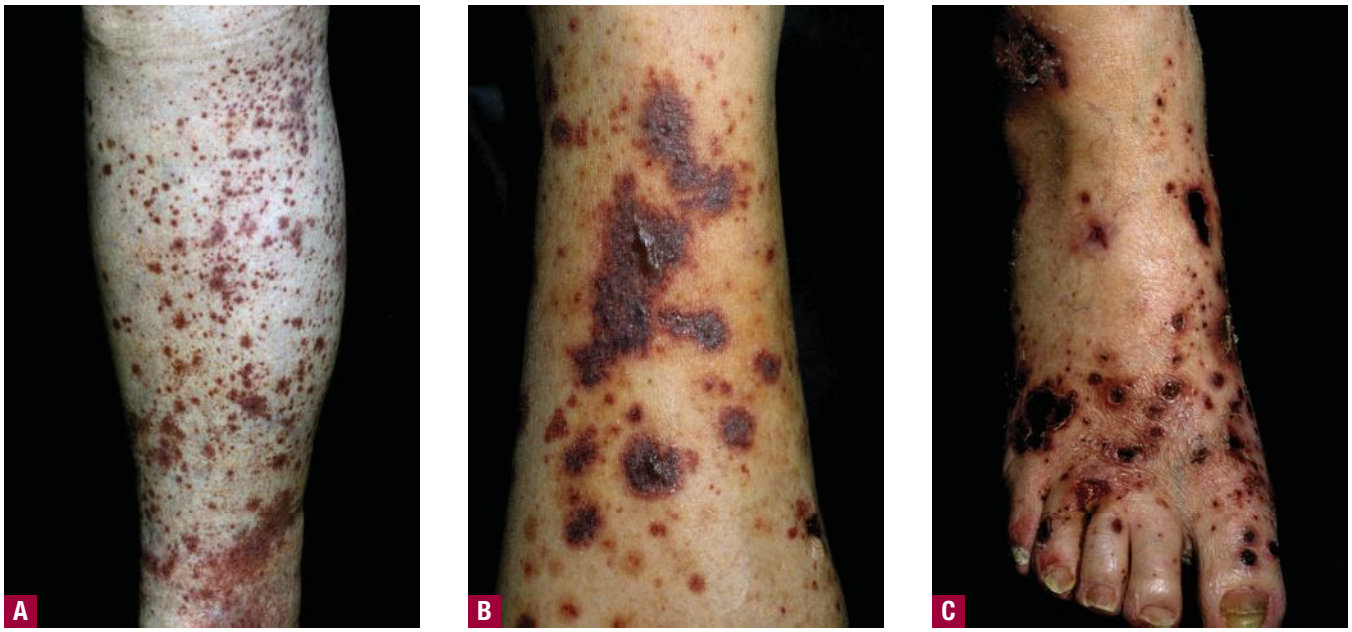
Early in the course of necrotizing venulitis, endothelial cells show increased expression of intercellular adhesion molecule-1 and E-selectin without the expression of vascular cell adhesion molecule (VCAM)-1 in response to TNF-α (see Chap. 163). Because E-selectin is an adhesion molecule for neutrophils and for skin-homing, memory T lymphocytes, the increase in E-selectin is consistent with the appearance of an infiltrate of neutrophils that express CD11b within the first 24 hours.[4]

In skin biopsy specimens from patients with idiopathic cutaneous vasculitis, hypersensitivity vasculitis, urticarial vasculitis, and Henoch-Schönlein syndrome, E-selectin was detected on endothelial cells of lesions less than 48 hours old and was associated with an infiltrate of neutrophils expressing CD11b. The endothelial cells expressed HLA-DR and very-late activating antigen-1 but not P-selectin, and the perivascular cells demonstrated VCAM-1 and HLA-DR. Diminished cutaneous fibrinolytic activity with reduced release of plasminogen activator from venular endothelial cells occurs in patients with CNV; the subsequent reduction in fibrinolytic activity leads to fibrin deposition. Increased levels of plasma thrombomodulin, tissue-type plasminogen activator, and plasminogen activator inhibitor-1 were detected in patients with Henoch-Schönlein syndrome.[5,6]

Cutaneous nerve fibers can release neuropeptides, such as substance P, neurokinin A, and calcitonin gene-related peptide, that cause vasodilation (see Chap. 101). Substance P activates mast cells and macrophages and increases fibrinolytic activity mediated by plasminogen activator. Calcitonin gene-related peptide induces expression of E-selectin on endothelial cells and is chemotactic for T lymphocytes.

Eosinophils are minor infiltrating cells in CNV except in eosinophilic vasculitis. Eosinophils could produce LTC_4 and platelet-activating factor, which increase vascular permeability. Eosinophil granule proteins are toxic to endothelial cells and cause the release of chemical mediators from mast cells.

Associations have been recognized between small-vessel necrotizing vasculitis and ANCAs, which have specificity for proteins of the cytoplasmic granules of neutrophils and the lysosomes of monocytes. Two forms are recognized: cytoplasmic (c-ANCAs) and perinuclear



▲ **FIGURE 164-1** **A.** Palpable purpura on the lower leg in a patient with Henoch-Schönlein syndrome. **B.** Palpable purpura with more severe tissue damage leading to hemorrhagic vesicles and bullae. **C.** With even more tissue damage, multiple necrosis and subsequent ulcers develop.

(p-ANCAs). In patients with necrotizing vasculitis, most c-ANCAs are specific for proteinase 3 and most p-ANCAs are specific for myeloperoxidase. Antiendothelial cell antibodies have been detected in the sera of patients with systemic vasculitis, rheumatoid arthritis with vasculitis, microscopic polyangiitis, and Sneddon syndrome.

An increased prevalence of the HLA haplotype HLA-A11, Bw35 in patients with CNV and associated connective tissue disorders suggests that genetic factors may be operative.

CLINICAL FINDINGS

The skin lesions of CNV are polymorphous; however, erythematous papules that do not blanch when the skin is pressed, which are known as *palpable purpura,* are the signature lesions (Fig. 164-1A). Macules, papules, urticaria/angioedema, pustules, vesicles, hemorrhagic blisters (see Fig. 164-1B), necrosis and ulcers (see Fig. 164-1C), and livedo reticularis may be present. Occasionally, there is subcutaneous edema below the area of the dermal lesions.

The eruption most often appears on the lower extremities or over dependent areas such as the back and gluteal regions. The lesions may occur anywhere on the skin but are uncommon on the face, palms, soles, and mucous membranes. The clinical lesions are episodic and may recur over weeks to years. Palpable purpura persists for 1 to 4 weeks and resolves at times with transient hyperpigmentation and/or atrophic scars. Lesional symptoms include pruritus or burning and, less commonly, pain.

An episode of cutaneous vascular lesions may be attended by fever, malaise, arthralgias, or myalgias irrespective of a defined underlying or associated disease. Systemic involvement of the small blood vessels most commonly occurs in the synovia, gastrointestinal tract, voluntary muscles, peripheral nerves, and kidneys.

Associated Chronic Disorders

CNV is associated with connective-tissue diseases, notably rheumatoid arthritis, Sjögren syndrome, systemic lupus erythematosus (SLE), and hypergammaglobulinemic purpura. It rarely occurs in mixed connective-tissue disease, relapsing polychondritis, and scleroderma. In patients with rheumatoid arthritis and CNV, the development of vascular lesions is related to the severity of the disease, which is generally but not always seropositive. Subcutaneous nodules, as well as cutaneous ulcers, may be present. Patients with rheumatoid arthritis often have involvement of larger vessels with associated peripheral neuropathy, nail fold infarcts, and digital gangrene.

In patients with SLE, the vasculitis is associated with exacerbations of the underlying disease. Vasculitis, however, is rare in patients with subacute cutaneous lupus erythematosus. Approximately 5 percent of women with necrotizing vasculitis without connective-tissue disease have anti-Ro antibodies, and their infants may be born with neonatal lupus erythematosus.

In patients with Sjögren syndrome, the vascular lesions are located predominantly on the lower extremities and appear after exercise. Both hyperpigmentation and cutaneous ulcers are common features. Hypergammaglobulinemic purpura occurs in older women and may be associated with Sjögren syndrome, SLE, or a lymphoproliferative disorder. Dermatomyositis in children, but not in adults, may be associated with vasculitis of the gastrointestinal tract.

Paraneoplastic vasculitis is used to describe CNV with associated malignant conditions, including Hodgkin disease, lymphosarcoma, adult T-cell leukemia, mycosis fungoides, myelofibrosis, acute and chronic myelogenous forms of leukemia, IgA myeloma, diffuse large-cell leukemia, hairy-cell leukemia, squamous-cell bronchiogenic carcinoma, prostatic carcinoma, renal carcinoma, and colon carcinoma. However, the association between CNV and neoplasia is rare. It is not necessary to evaluate all patients with CNV for associated malignant conditions.

Cryoglobulins (see Chap. 170), especially mixed types II and III, may be found in patients with idiopathic CNV and in patients with CNV associated with connective-tissue diseases, lymphoproliferative disorders, and hepatitis A, B, and C virus infections, although hepatitis C virus is the most common infection, especially when also associated with cryoglobulinemia.[7,8] CNV oc-

curs in patients with cystic fibrosis, inflammatory bowel diseases of the colon, and Behçet disease.[9]

Both ANCAs and anti-phospholipid antibodies are associated with various forms of necrotizing vasculitis. ANCAs are present in patients with microscopic polyangiitis and cutaneous vasculitis with hepatitis C virus infection (see Chap. 165). The most common cutaneous feature in patients with ANCAs is palpable purpura. Microscopic polyangiitis is associated with small-vessel systemic vasculitis that involves the cutaneous venules and arterioles, kidneys with necrotizing and crescentic glomerulonephritis, and p-ANCAs. A male patient has experienced microscopic polyangiitis restricted to the skin and ANCAs for 20 years without progression to systemic vascular disease.[10]

Anti-phospholipid antibodies, either anticardiolipin antibodies and/or lupus anticoagulant, occur in patients with autoimmune and connective-tissue diseases and as an idiopathic disorder. Livedo reticularis is the most frequently recognized cutaneous finding.[11] Anti-phospholipid antibodies of the IgA class were detected in 6 of 10 patients with idiopathic CNV, and anti-phospholipid antibodies have been detected in some individuals with livedoid vasculitis.[12] A female patient with anti-phospholipid antibodies and cutaneous nodules that demonstrated vasculitis and thrombosis on biopsy has been reported.

Precipitating Infections and Drugs

Infections and drugs precipitate episodes of CNV. The most commonly recognized infectious agents are group A hemolytic streptococci, *Staphylococcus aureus, Mycobacterium leprae,* and hepatitis B and C viruses. Transient episodes of urticaria may occur early in the course of hepatitis B virus infection and represent immune complex–induced vasculitis; episodes of palpable purpura may occur in patients with chronic active hepatitis. Cutaneous vasculitis was identified in patients with hepatitis A and C infections.[13] Cutaneous vasculitis has been recognized in a limited number of individuals with human immunodeficiency virus infection; the skin lesions consisted of palpable purpura, at times with a follicular localization, and cutaneous ulcers.

Erythema nodosum leprosum (see Chap. 186), which appears as cutaneous nodular lesions in lepromatous leprosy, is a form of necrotizing vasculitis involving capillaries, venules, arterioles, small- to medium-sized arteries, and veins. The vascular lesions occur spontaneously or are precipitated by the administration of chemotherapeutic agents. They may be accompanied by fever, malaise, arthralgias, lymphadenopathy, and polyneuritis.

Necrotizing vasculitis caused by the direct invasion of the blood vessel wall occurs in *Neisseria meningitidis* bacteremia, in Rocky Mountain spotted fever, and in infections localized at the site of a catheter.

Palpable purpura is one of the less common forms of drug reactions (see Chap. 40). The most commonly incriminated therapeutic agents are penicillin, sulfonamides, thiazides, allopurinol, hydantoins, and nonsteroidal anti-inflammatory agents. Propylthiouracil[14] and hydralazine may cause vasculitis in association with ANCAs. Cutaneous vasculitis has occurred after the administration of streptokinase, radiocontrast media, monoclonal antibodies, granulocyte colony-stimulating factor, staphylococcal protein A column immunoadsorption therapy, drug additives, and etanercept.[15]

Idiopathic Disorders

HENOCH-SCHÖNLEIN SYNDROME The most widely recognized subgroup of idiopathic CNV is the Henoch-Schönlein syndrome, formerly known as *anaphylactoid purpura*. It occurs predominantly in children, with a peak incidence at 5 to 6 years of age, but it may occur in adults.[16,17] A history of a recent upper respiratory tract infection, especially streptococcal, is obtained in up to 75 percent of individuals; however, Henoch-Schönlein syndrome has been associated with other infections. Sites of involvement include the skin, synovia, gastrointestinal tract, and kidneys. Symptoms may be colicky abdominal pain, melena, arthralgia, and hematuria. Long-term morbidity from progressive renal disease occurs in 5 percent of patients. The spread of purpura to the upper parts of the trunk is a predictive factor for renal involvement.[16]

ACUTE HEMORRHAGIC EDEMA OF CHILDHOOD This uncommon disorder, which often goes unrecognized or has been confused with Henoch-Schönlein syndrome, affects infants and children younger than 2 years of age, but it has been reported in one adult. The lesions appear as painful, edematous petechiae and ecchymoses that affect the head and distal portions of the extremities. Facial edema may be the initial sign. The skin lesions may be associated with a target-like appearance and may develop bullae and necrosis. Infection, drugs, or immunization may be triggering factors. Acute hemorrhagic edema of childhood is distinguished from Henoch-Schönlein syndrome by its occurrence in children aged 4 months to 2 years, lack of systemic features, and resolution within 1 to 3 weeks without sequelae.

URTICARIAL VASCULITIS Episodes of recurrent and chronic urticaria and angioedema may be a clinical manifestation of CNV.[18,19] Known as *urticarial vasculitis,* this edematous form of necrotizing venulitis occurs in patients with serum sickness, connective-tissue disorders, an IgM_K M component, infections, and physical urticarias; after the administration of potassium iodide and nonsteroidal anti-inflammatory agents; and as an idiopathic disorder. Single case reports exist of patients with urticarial vasculitis and colon carcinoma, IgA myeloma, polycythemia vera, Muckle-Wells syndrome, and Cogan syndrome. Infections include hepatitis B and C viruses and infectious mononucleosis. The term *hypocomplementemic urticarial vasculitis syndrome* has been used to describe patients with more severe systemic manifestations and an autoantibody to Clq.

The skin lesions appear as erythematous, occasionally indurated, wheals that may contain foci of purpura (Fig. 164-2; see Fig. 165-2 and Chap. 165). Other skin manifestations include angioedema, macular erythema, livedo reticularis, nodules, and bullae. Although the individual urticarial lesions may last for fewer than 24 hours, they often persist for up to 3 to 5 days. The lesions are

▲ **FIGURE 164-2** Urticarial vasculitis. Some of the wheals have been marked 24 hours previously to show persistent character of the urticarial lesions.

TABLE 164-2
Extracutaneous Manifestations of Urticarial Vasculitis

- General features
  - Fever
  - Malaise
  - Myalgia
- Specific organ involvement
  - Lymphadenopathy
  - Hepatosplenomegaly
  - Synovia (arthralgia, arthritis)
  - Kidneys (glomerulitis, glomerulonephritis)
  - Gastrointestinal tract (nausea, vomiting, pain, diarrhea)
  - Respiratory tract (laryngeal edema, shortness of breath, chronic obstructive pulmonary disease, and, less commonly, interstitial pulmonary disease)
  - Eyes (conjunctivitis, episcleritis, iridocyclitis, uveitis)
  - Central nervous system (headache, benign intracranial hypertension)

pruritic or possess a burning or painful quality; they usually resolve without residua, although some individuals may develop contusions or hyperpigmentation as a result of hemosiderin deposition in the tissue. The episodes of urticaria are chronic, range in duration from months to years, and vary in frequency. Approximately 70 percent of affected individuals are women. The prevalence of this disorder remains unknown. General features include fever, malaise, and myalgia; the lymph nodes, liver, and spleen may be enlarged (Table 164-2).

Episodic arthralgias are a major clinical manifestation and affect the elbows, wrists, fingers, knees, ankles, and toes. Arthritis with necrotizing venulitis apparent in biopsy specimens of the synovial tissue occasionally develops. Urticarial vasculitis is associated with Jaccoud syndrome.[20] Renal involvement occurs as a diffuse glomerulitis or glomerulonephritis; however, progression to severe impairment of renal function is rare. Gastrointestinal tract manifestations include nausea, vomiting, diarrhea, and pain. Laryngeal edema may occur. Chronic obstructive pulmonary manifestations and, less frequently, interstitial lung disease may develop. Conjunctivitis, episcleritis, iridocyclitis, and uveitis develop in some individuals. Rarely, cardiac valvular involvement may occur.[21] There is one report of an individual becoming blind. Headaches and pseudotumor cerebri (benign intracranial hypertension) reflect central nervous system involvement.

The natural history of urticarial vasculitis is unknown, although individuals have been described with historic episodes of cutaneous lesions for up to 25 years. In one series of patients followed for 1 year, 40 percent experienced complete resolution of skin lesions; in another series of individuals followed for as long as 14 years, resolution occurred in only one patient. Sjögren syndrome and SLE have developed. Deaths have been reported from pulmonary disease, sepsis, and myocardial infarction.

The prevalence of urticarial vasculitis in individuals with chronic idiopathic urticaria is unknown, although series have reported rates ranging from 1 percent to 50 percent. Most of these data have been reported from tertiary referral centers, and the prevalence is most likely less than 1 percent.

Necrotizing vasculitis of cutaneous venules has been described in isolated instances of dermographism, cold urticaria, delayed pressure urticaria, solar urticaria, and exercise-induced urticaria.[3] However, the prevalence of necrotizing vasculitis in patients with physical urticaria is unknown, and the importance of this histologic finding for prognosis and therapy remains to be elucidated. Individuals with these physical urticarias have provided experimental models for time-course studies of the evolution of necrotizing vasculitis in human skin.

Schnitzler syndrome consists of episodes of urticarial vasculitis that occur in association with a monoclonal IgM_K M component. Associated features include fever, lymphadenopathy, hepatosplenomegaly, bone pain with osteosclerosis, and a sensorimotor neuropathy. Evolution into a lymphoplasmacytic malignant condition has been reported in 15 percent of patients.[22]

ERYTHEMA ELEVATUM DIUTINUM Erythema elevatum diutinum occurs as symmetric, persistent, red-purple or red-brown plaques that are predominantly disposed over the joints of extensor surfaces and over the gluteal area (see Chap. 166).

NODULAR VASCULITIS Nodular vasculitis (see Chap. 68) appears as tender, red, subcutaneous nodules over the lower extremities, especially the calves, without systemic manifestations (Fig. 164-3; see Fig. 68-5 and Chap. 68). At times, lesions develop on the thighs, buttocks, trunk, and arms, and ulcerated nodules are present. Recurrent episodes are common. It is more common in women and has a peak incidence in individuals between 30 and 40 years of age. Erythema induratum is a form of nodular vasculitis, that has been associated with *M. tuberculosis* infection, as demonstrated by polymerase chain reaction amplification for *M. tuberculosis* DNA in skin biopsy specimens.[23] Various sizes of blood vessels, including venules, are affected.[24]

▲ **FIGURE 164-3** Nodular vasculitis with ulceration on lower legs (see Fig. 68-5).

LIVEDOID VASCULITIS Livedoid vasculitis (Fig. 164-4), known also as *livedoid vasculopathy*, *livedo vasculitis*, *segmental hyalinizing vasculitis*, and *atrophie blanche*, occurs as recurrent, painful ulcers of the lower extremities in association with a persistent livedo reticularis (*livedo racemosa*) that often is deep purple in color (see Fig. 165-6 and Chap. 165). Healing results in sclerotic pale areas surrounded by telangiectases that are designated atrophie blanche (Fig. 164-5). Many patients have arteriosclerosis or stasis of the lower extremities, and mononeuritis multiplex has been identified in a single patient.[25] Livedoid vasculitis is more common in women, may occur in patients with SLE who develop central nervous system features, and has been reported in two patients with protein C deficiency.[26] Atrophie blanche, however, probably represents the end stage of a variety of forms of vascular damage in the skin (see Chap. 175). Elevation of fibrinopeptide A levels may occur in blood. Pathogenesis has focused on a hypercoagulable state with fibrin thrombi in the lumina of the superficial blood vessels. Some consider this condition a thrombogenic vasculopathy rather than a small-vessel vasculitis. Anti-phospholipid antibodies have been detected in a few individuals.[12]

Sneddon syndrome[27,28] is a condition in which livedo reticularis and livedoid vasculitis are associated with ischemic cerebrovascular lesions, hypotension,

▲ **FIGURE 164-4** Livedoid vasculitis with recurrent extremely painful irregular ulcers and a background of livedo reticularis.

and extracerebral arterial and venous thromboses (see Fig. 174-9 in Chap. 174). Anti-endothelial cell antibodies were detected in the serum in 35 percent of individuals; anti-phospholipid antibodies, anti-β_2-glycoprotein antibodies, and anti-prothrombin antibodies[29] were detected in some patients.

GENETIC COMPLEMENT DEFICIENCIES Genetic C2 deficiency has been recognized in association with CNV in three children, and a C4 deficiency was present in one child with CNV. Deficiencies of C4A and C4B isotypes were found in some children and adults with Henoch-Schönlein syndrome. A partial C4B deficiency with C4 A1, A3, B1, and a null allele B*QO was reported in a 51-year-old woman with CNV.[30]

▲ **FIGURE 164-5** Atrophie blanche over the medial malleolus with bizarre, porcelain white atrophy, telangiectasia, and punctate ulcers.

EOSINOPHILIC VASCULITIS Eosinophilic vasculitis has been described as an idiopathic syndrome in individuals with recurrent, pruritic, and purpuric papular skin lesions, urticarial plaques, and angioedema. Skin biopsy specimens showed an infiltrate composed of eosinophils expressing CD40[31] and VCAM-1 on endothelial cells of involved vessels. Eosinophilic vasculitis also has been described in some individuals with a hypereosinophilic syndrome[31] (see Chap. 35) and in others with connective-tissue disorders.[32,33]

IDIOPATHIC Individuals with CNV who do not meet the criteria for recognized syndromes are classified as idiopathic.

LABORATORY FINDINGS

The laboratory evaluation of patients with CNV depends on information obtained from the history and physical examination (Table 164-3). An elevated erythrocyte sedimentation rate is the most consistent abnormal laboratory finding. The platelet count is usually normal. Other abnormalities reflect either a co-existent chronic disorder or the involvement of additional organ systems. Occasionally, leukocytosis, anemia, thrombocytosis, an abnormal urine sediment, circulating immune complexes, rheumatoid factor, and antinuclear antibodies have been reported in idiopathic disease.

TABLE 164-3
Laboratory Evaluation of Cutaneous Necrotizing Venulitis

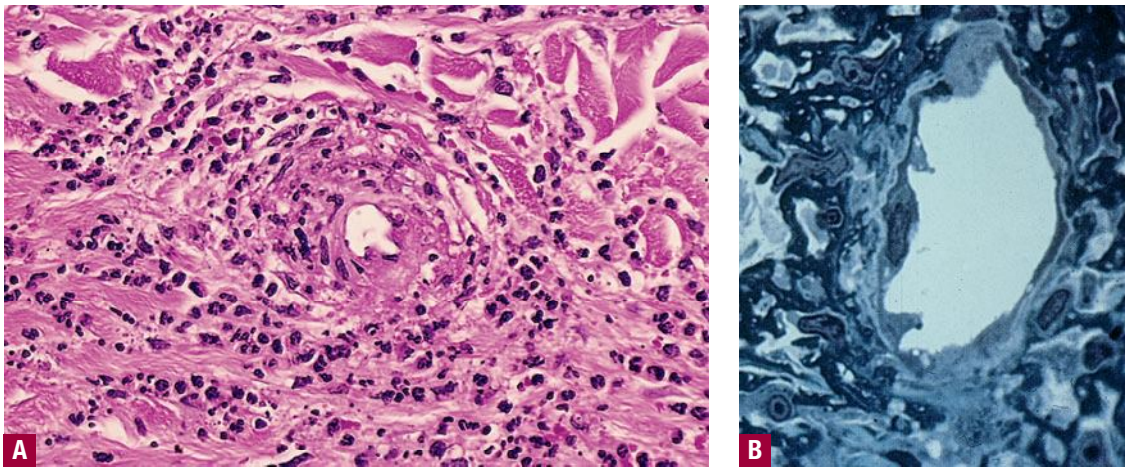
- Cryoglobulins
- CH50
- Anti-nuclear antibody
- Rheumatoid factor
- Antineutrophil cytoplasmic antibodies
- Anti-phospholipid antibodies
- Circulating immune complexes
- Skin biopsy

Serum complement levels are usually normal. Hypocomplementemia may develop in patients with concomitant connective tissue diseases or cryoglobulinemia and reflects the associated disease or the composition of the cryoglobulin. Hypocomplementemia also occurs in some individuals with idiopathic CNV and in 40 percent of individuals with urticarial vasculitis.

In some patients with the hypocomplementemic urticarial vasculitis syndrome, a low-molecular-weight 7s C1q precipitin, identified as an IgG autoantibody against the collagen-like region of C1q, was detected. The antigen-antibody interaction involves the $F(ab')_2$ fragment of IgG. Autoantibodies to vascular endothelial cells were detected in patients with the hypocomplementic urticarial vasculitis syndrome, in patients with SLE and urticarial vasculitis, and in patients with urticarial vasculitis alone.[34] In a single patient with Schnitzler syndrome, autoantibodies against dermal microvascular endothelial cells, mast cells, and the FcεRIα receptor were detected.[35] In Henoch-Schönlein syndrome, serum IgA1 levels are elevated. In patients with CNV, various types of circulating immune complexes and IgA ANCAs[36] have been described. IgG autoantibodies against IgE also have been identified in four of eight patients with urticarial vasculitis.

HISTOPATHOLOGY

In skin biopsy specimens of palpable purpura and urticarial vasculitis stained



▲ **FIGURE 164-6** **A.** Perivenular infiltrate of neutrophils with fibrin deposition. (Hematoxylin and eosin stain, ×50 in original magnification.) **B.** Endothelial cell necrosis of venule with perivenular fibrin and neutrophils. (1-μm section, Giemsa stain, ×1000 in the original magnification.)

with hematoxylin and eosin (Fig. 164-6A), the histologic criteria requisite for the diagnosis of CNV include necrosis of the blood vessels with the deposition of fibrinoid material and dermal cellular infiltrates that consist of neutrophils with nuclear debris, mononuclear cells, and extravasated erythrocytes. The dermal inflammatory infiltrates vary in intensity and are usually perivenular in location but at times are dispersed widely. The fibrinoid material consists of fibrin, necrotic endothelial cells, and deposited immunoreactants.

Studies with 1-μm–thick sections (see Fig. 164-6B) show two distinct cellular patterns in CNV: one rich in neutrophils and the other in lymphocytes. Neither pattern appears to be the result of evolution of the tissue changes associated with the dynamic nature of the cellular infiltrate. Although the infiltrate of neutrophils regresses with the persistence of an infiltrate of mononuclear cells, repeat biopsy specimens in some patients consistently demonstrated an infiltrate of mononuclear cells. In a time-course study over 6 days of the evolution of experimentally induced CNV in a patient with physical urticarias, the number of infiltrating neutrophils decreased without a concomitant increase in lymphocytes, although the number of monocyte-macrophages was increased at 48 hours and 72 hours. Other features in both cell patterns of CNV include hypogranulated mast cells, macrophages containing debris, and the perivenular and interstitial deposition of fibrin. Venular alterations in both cell patterns consist of endothelial cell swelling, activation of nuclei, wrinkling of nuclear membranes, necrosis (see Fig. 164-6B), and basement membrane reduplication and thickening. The arterioles are not affected. Some patients with connective-tissue disorders and cutaneous vasculitis have an infiltrate of inflammatory cells composed of eosinophils with deposited major basic protein and decreased numbers of mast cells.[32]

By direct immunofluorescence techniques, fibrin deposition in venules is routinely identified in biopsy specimens, whereas the deposition of immunoglobulins and complement proteins varies widely. IgG is the most commonly deposited immunoglobulin, although IgM and IgA also have been detected. IgA is deposited about blood vessels in the skin, intestines, and kidneys in the Henoch-Schönlein syndrome and has become an immunopathologic marker of this condition. In the skin in Henoch-Schönlein syndrome, IgA1 is the dominant subclass deposited.[37] C3 is the only complement protein that has been sought with frequency.

DIFFERENTIAL DIAGNOSIS

Thrombocytopenia may result in purpura; however, these lesions are flat. Other causes of non-palpable cutaneous purpura include local trauma to the skin of aged individuals with vascular fragility, chronic sun exposure, and endogenous or iatrogenic hypercorticism. Erythema elevatum diutinum may resemble Kaposi sarcoma (see Chap. 128) or multicentric reticulohistiocytosis (see Chap. 149). Scurvy may appear as hemorrhagic, follicular papules over the lower extremities. Various infectious agents may be associated with hemorrhagic skin lesions that arise from disseminated intravascular coagulation or septic emboli. The cutaneous manifestations of disseminated intravascular coagulation, known as *purpura fulminans,* appear as extensive areas of purpura with a slate-gray color (see Chap. 145). These lesions occur in patients with acute meningococcemia but also with gram-positive coccal sepsis; skin biopsy specimens show thrombosis but not necrotizing venulitis. Septic emboli occur as finite numbers of hemorrhagic pustules, papules, and vesicles distributed over acral areas. Rarely, echo and coxsackievirus infections may cause purpuric papules. Rocky Mountain spotted fever typically begins as purpuric papules over the ankles and wrists that spread to include the trunk. Cholesterol embolization includes purpura, livedo reticularis, ulcers, and nodules.

The progressive pigmentary purpuric dermatoses (purpura simplex) (see Chap. 169), which include a number of disorders, appear as macular, petechial, pigmented, or lichenoid lesions.

The differential diagnosis of cutaneous nodules includes erythema nodosum, panniculitis, superficial forms of thrombophlebitis, fat necrosis associated with pancreatic disease, and systemic vasculitides, such as polyarteritis nodosa, Wegener granulomatosis, and Churg-Strauss syndrome.

TREATMENT

Therapeutic approaches may be divided into removal of the antigen, treatment of an underlying disease, and treatment of CNV. Treatment of necrotizing vasculitis consists of prevention of the deposition of immune complexes, suppression of the inflammatory response, modulation of underlying immunopathologic mechanisms, and local therapy. When the eruption is associated with a precipitating event, withdrawal of the medication or treatment of the in-

TABLE 164-4
Algorithm for Treatment of Cutaneous Necrotizing Venulitis

- Phase one

  - Dapsone
- Phase two
  - Systemic glucocorticoids
  - Azathioprine
  - Cyclophosphamide
  - Intravenous gammaglobulin
  - Cyclosporine
  - Plasmapheresis

fection results in resolution of the cutaneous lesions. If a co-existent chronic disease is present, treatment of the underlying disease may be associated with improvement in the cutaneous vascular lesions. In many cases, CNV is a self-limited condition, and double-blind, placebo-controlled, prospective trials of therapeutic agents are usually lacking.

The treatment of CNV can be divided into two phases (Table 164-4), each of which depends on an analysis of the cutaneous disability as well as the toxicity and side effects of the therapeutic agents. H_1 antihistamines are used in patients with palpable purpura to alleviate lesional symptoms and perhaps to reduce tissue deposition of circulating immune complexes. Nonsteroidal anti-inflammatory agents are combined with the H_1 antihistamine. Depending on the therapeutic response, colchicine or hydroxychloroquine sulfate can be added to or substituted for these agents. However, colchicine was shown to have no significant therapeutic effect in a prospective, randomized, controlled trial. If there is no benefit, dapsone can be used. If there still is no therapeutic response, a major decision must be made because the medications to be considered in the second phase (systemic glucocorticoids, azathioprine, methotrexate, cyclophosphamide, plasmapheresis, cyclosporine,[38] and intravenous immunoglobulin[39]) are associated with more serious side effects. Although all of these agents have been reported to benefit some patients, controlled clinical trials are not available. The administration of interferon-α is associated with clearing of cutaneous vasculitis in patients with hepatitis C virus infection.

The treatment of urticarial vasculitis is similar to that of palpable purpura. Additional case reports exist on the treatment of patients with intramuscular gold therapy, cyclophosphamide-dexamethasone pulse therapy,[40] mycophenolate mofetil,[41] and psoralen plus ultraviolet A photochemotherapy.[42]

In patients with erythema elevatum diutinum, dapsone is the drug of choice. Plasma exchange plus chlorambucil was a successful treatment for one individual with erythema elevatum diutinum and a monoclonal IgA paraprotein.[43] The treatment of nodular vasculitis consists of empiric trials of a variety of therapeutic agents that include a saturated solution of potassium iodide, nonsteroidal anti-inflammatory drugs, colchicine, and systemic glucocorticoids. Thalidomide is the treatment of choice for erythema nodosum leprosum.

In the treatment of livedoid vasculitis, support stockings are useful. Empiric trials of aspirin and dipyridamole, colchicine, dapsone, danazol,[44] low-dose heparin, systemic glucocorticoids, nicotinic acid, low-molecular-weight dextran, phenformin and ethylestrenol, nifedipine, and pentoxifylline are used. Infusions of prostacyclin, prostaglandin E_1, and intravenous immunoglobulin[45] have been used successfully in one patient each.

CHAPTER 165

Systemic Necrotizing Vasculitis

Carmen E. Gota
Brian F. Mandell

EPIDEMIOLOGY

Vasculitic syndromes are uncommon. The overall annual incidence is estimated to be between 10 and 42 cases per million per year. Takayasu arteritis (TA) occurs preponderantly in young females. Kawasaki disease and Henoch-Schönlein purpura are the most common types of childhood vasculitis, and temporal arteritis [giant cell arteritis (GCA)] occurs in patients generally older than 55 years of age. Small vessel vasculitis, predominantly cutaneous, occurs at all ages; but the underlying etiology differs between children and older adults.

ETIOLOGY AND PATHOGENESIS

Blood vessels may be affected by a number of diverse processes, including the hypercoagulability syndromes, Raynaud vasospasm, myointimal proliferation with occlusion (e.g., scleroderma), embolic occlusion, congenital or acquired dysplasias (e.g., Marfan syndrome, fibromuscular dysplasia), atherosclerosis, and inflammation. Vascular damage and remodeling results from contributions of both the attacking immune cells and the responding blood vessel wall, which is not just an innocent bystander. Rather, the vessel wall response to the injury can be both regenerative and maladaptive.

Blood vessels targeted by an inflammatory insult have limited ways of responding to injury: increased permeability may lead to edema and purpura, attenuation of the vessel wall may lead

SYSTEMIC VASCULITIS AT A GLANCE

- Heterogenous group of rare inflammatory conditions in which blood vessel walls are primarily targeted by an inflammatory reaction.
- Etiology unknown; geographic, environmental, and genetic factors are important.
- Incidence up to 42 cases per million per year.
- Diagnosis established in patients with multiple but variable organ involvement; supported by laboratory or radiologic studies and histologic evidence of inflammatory reaction in blood vessels.
- Cutaneous involvement can occur in any of the primary systemic vasculitic syndromes.
- Cutaneous features are often not sufficient to provide complete diagnosis and staging.
- Classification:
  - Primary process (no cause or association)
  - Secondary
    - Drug ingestion
    - Infection
    - Systemic, non-vasculitic disease
    - Malignancy
    - Local factors (e.g., trauma)
- Primary vasculitis is a diagnosis of exclusion after causes of secondary vascular inflammation have been ruled out.
- Determinants of prognosis and treatment include the specific vasculitic syndrome, whether critical organs are involved, the severity of involvement, and the rate of disease progression.
- Treatment often requires steroids and the use of other immunosuppressive drugs.

to aneurysm formation or hemorrhage, and intimal proliferation or thrombosis may cause stenosis or occlusion with tissue ischemia or infarction.

Several pathogenetic mechanisms have been implicated in generating a vasculitic process. Immune complex deposition has been found to be associated with many vasculitic syndromes, especially those involving small vessels. The antigens implicated in the process include medications, foods, infections (e.g., hepatitis B and C, bacterial endocarditis), and endogenous or tumor antigens. The immune complexes trigger an inflammatory response with the participation of complement activation products, neutrophils, and lymphocytes.

Antineutrophil cytoplasmic antibodies (ANCAs) are found in small vessel vasculitides such as Wegener granulomatosis (WG), Churg-Strauss syndrome (CSS), and microscopic polyangiitis (MPA). Whether ANCAs directly participate in the pathogenesis of these vasculitides remains debatable.

CLINICAL FINDINGS

History and Physical Examination

The first step in the diagnosis of a vasculitic syndrome is to perform a detailed patient history and physical examination to evaluate and document specific organ involvement (Fig. 165-1). Special attention should be paid to finding evidence of inflammation in the eyes, ears, nose, paranasal sinuses, mouth, trachea, joints, intestine, kidneys, or peripheral nerves. The presence of adenopathy, periungual capillary abnormalities, cardiac abnormalities, asymmetric peripheral pulses, or abdominal and subclavian bruits provide other diagnostic clues. The principal clinical clue to the diagnosis of a specific vasculitic disorder is the pattern of organ involvement.

Cutaneous Involvement in Systemic Vascultis

Systemic and localized vasculitis often affects the skin and subcutis, likely due in part to their large vascular bed, structure of the postcapillary venules, hemodynamic factors (e.g., stasis in lower extremities), and environmental influences (e.g., cold exposure; see Chap. 164).[1] Physical signs of vasculitis include urticaria (Fig. 165-2), palpable purpura (Fig. 165-3; see Chap. 164), infiltrative erythema, ulcers (Fig. 165-4), digital ischemia (Fig. 165-5), livedo reticularis (Fig. 165-6), and nodules. In the presence of cutaneous vasculitis, a thorough evaluation for systemic involvement is mandatory. In addition to a detailed history and physical examination, urinalysis looking for the presence of blood, protein, and cellular casts; blood testing to evaluate for anemia, elevated creatinine, and/or transaminases; and a chest x-ray looking for lung infiltrates are simple methods to screen for clinical emergencies such as rapidly progressing glomerulonephritis and alveolar hemorrhage.

LABORATORY, RADIOLOGIC, AND HISTOPATHOLOGY TESTING

The inflammatory process per se is often associated with laboratory and clinical abnormalities, but these, however prominent, tend to be non-specific (e.g., elevated erythrocyte sedimentation rate, anemia, fatigue, fevers) and do not substantially aid in distinguishing vasculitis from other inflammatory or proliferative diseases. Although it is reasonable to include a few "basic" laboratory tests in the initial evaluation, more specialized studies should be obtained only after a focused differential diagnosis is generated. Initial studies should include a complete blood count with differential, serum creatinine, transaminases, and a dipstick and microscopic urinalysis. The urinalysis should ideally be a fresh morning sample. It should be immediately examined by a physician; urine that has been allowed to sit for several hours before analysis does permit identification of cellular casts that may rapidly degenerate ex vivo. Red blood cell casts are highly supportive of the presence of glomerulonephritis. A clinical axiom is that the primary vasculitides are almost never associated with leukopenia or thrombocytopenia. The presence of these laboratory findings should suggest alternative diagnoses such as systemic lupus erythematosus (SLE), vasculitis associated with malignancy, disseminated intravascular coagulation, infection, or drug-induced cytopenias. Some disorders that may mimic or are associated with a vasculitis are shown in eTable 165-0.1 in on-line edition.

The value of indiscriminate testing for anti-nuclear antibodies, rheumatoid factor, and angiotensin-converting enzyme to look for the presence of possible "immune" disease is arguable, at best. These studies should be primarily used as aids in supporting a tenable clinical diagnosis. Angiographic and selected serologic studies may provide support for certain diagnoses, but are not by themselves pathognomonic for any specific form of vasculitis.

Histopathologic diagnosis is desirable and often required. The term *vasculitis* reflects conditions in which inflammatory cells significantly damage

Detailed history and physical

Systemic
- fever, night sweats
- weight loss
- arthralgias/arthritis
- myalgias

EAR, NOSE, AND THROAT
- chronic sinusitis
- otitis media and/or interna
- saddle nose
- nasal septal perforation
- nasal crusting
- epistaxis
- subglottic stenosis

Ophthalmologic
- conjunctivitis
- anterior and/or posterior uveitis
- retinal vasculitis
- anterior optic nerve ischemia
- proptosis

Cardiovascular
- pericarditis
- myocarditis
- myocardial ischemia
- carotidynia
- bruits
- strokes
- asymmetric blood pressure
- absent pulses

Gastrointestinal
- ischemic bowel
- acalculous cholecystitis

Cutaneous
- palpable purpura
- periungual capillary lesions
- digital infarcts
- skin ulcers
- nodules
- panniculitis
- oral ulcers
- gums hypertropy (WG)
- desquamation of hands and feet (Kawasaki)
- fissuring of lips (Kawasaki)

Pulmonary
- infiltrates
- nodules
- cavitary lesions
- alveolar hemorrhage

Renal
- glomerulonephritis
- hypertension
- rise in creatinine

Neurologic
- mononeuritis multiplex
- sensory motor neuropathy
- seizures
- cranial nerve palsy
- confusion, dementia

Laboratory data

Initial studies
- Westergren sedimentation rate
- C-reactive protein
- complete blood count with differential
- creatinine
- transaminases
- urinalysis for protein, blood, cellular casts

Useful serologic studies
- hepatitis B, C, HIV
- complement levels
- cyroglobulins
- ANCA

Laboratories to exclude other etiologies
- drug screen
- blood cultures
- lupus serologies
- antiphospholipid antibodies
- lupus anticoagulant

Radiologic imaging
- X-rays
- CT scans
- MRIs
- angiograms

Histopathologic diagnosis

Rule in vasculitis

Rule out vasculitis mimics

▲ **FIGURE 165-1** Algorithm for diagnosis of vasculitides. ANCA = antineutrophil cytoplasmic antibody; CT = computed tomography; HIV = human immunodeficiency virus; MRI = magnetic resonance imaging; WG = Wegener granulomatous.

vessels and not merely traverse through them to enter the surrounding tissue.

The type of lesion chosen for skin biopsy has a great impact on the diagnostic yield of the biopsy. The optimal time for skin biopsy is 24 to 48 hours after the appearance of a vasculitic lesion. In the first 24 hours, the affected vessels show fibrin deposits and neutrophilic infiltration of the vessel wall, surrounding hemorrhage, and nuclear debris. After 24 hours, neutrophils are replaced by lymphocytes and macrophages. Biopsies of lesions more than 48 hours old may show perivascular lymphocyte-rich infiltrates. The choice of a shave biopsy, punch biopsy, or excisional biopsy affects which vessels are examined, as the type of vessel is dependent on location within the skin and subcutis (the deeper the skin, the larger the vessel).[2]

The diagnosis of vasculitis can be unequivocally made if there are inflammatory infiltrates in the walls of vessels accompanied by fibrin deposition within and around the vessel wall, a finding called *fibrinoid necrosis*. These changes co-exist with signs of endothelial damage in the form of endothelial swelling

▲ **FIGURE 165-2** Urticarial vasculitis (see Chap. 164). Urticarial lesions change their morphology only slowly, are persistent (24 to 72 hours), may be associated with purpura, and resolve with pigmentation.

or sloughing (see Chap. 164).[2] Identification of qualitative pathologic changes in affected organs (pattern of necrosis, presence of granulomas, eosinophilic infiltration) further delineates the differential diagnosis.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of the systemic vasculitides often includes distinct or co-existent coagulopathy, occult malignancy, or infection, particularly deep-seated abscess, viral hepatitis, or bacterial endocarditis. Thus, an approach directed towards ruling in a specific form of vasculitis should be pursued, in addition to ruling out specific alternatives.

▲ **FIGURE 165-4** Leg ulcer in a patient with polyarteritis nodosa.

CLASSIFICATION OF VASCULITIDES

There is no universally accepted classification system for vasculitis, although several different schemes have been proposed based on clinical and histopathologic features. The most widely used diagnostic classification systems are based on the caliber of affected blood vessels (Table 165-1),[3] pattern of organ involvement, and the presence or absence of granulomas and/or eosinophilic infiltration. Such schemes are useful in providing a diagnostic framework to distinguish clinical disorders with distinct differences in prognosis and response to treatment. Classification systems provide useful constructs for communication and the design of research protocols. The American College of Rheumatology classification criteria (1990)[4] and definitions based on a consensus conference at Chapel Hill (1993)[5] are the most commonly used sets of agreed-on classification criteria and definitions for vasculitis in current practice. These schemes emphasize distinction between fully expressed vasculitic syndromes; they are less useful in diagnosing early and evolving systemic vasculitic disorders.

Some authors have proposed a prime diagnostic role for the presence or absence of specific serum ANCAs, particularly antibodies to proteinase 3 (PR3-ANCA) and myeloperoxidase (MPO-ANCA). We believe that the role of these tests at the present time is to support a rationally developed clinical diagnosis, not to define one. In patients who do not neatly fit into a well-defined diagnostic category, these serologic tests should not supplant an attempt to obtain a tissue diagnosis if the latter is feasible.

TABLE 165-1
Classification of Primary Systemic Vasculitides According to the Size of the Blood Vessels

- Predominantly large vessels
  - Takayasu arteritis
  - Giant cell arteritis
  - Cogan syndrome
  - Behçet disease
- Predominantly medium-sized vessels
  - Polyarteritis nodosa
  - Buerger disease
  - Kawasaki disease
- Predominantly small vessels
  - Antineutrophil cytoplasmic antibody–associated vasculitides
    - Wegener granulomatosis
    - Churg-Strauss syndrome
    - Microscopic polyangiitis
  - Cryoglobulinemic vasculitis
  - Cutaneous leukocytoclastic angiitis
  - Hypocomplementemic urticarial vasculitis
  - Henoch-Schönlein purpura
  - Erythema elevatum diutinum
  - Goodpasture syndrome
  - Renal limited vasculitis

SPECIFIC VASCULITIC SYNDROMES

Small Vessel Vasculitis

Small vessel vasculitis involves arterioles, capillaries, and venules.[6] There may be co-existent medium-vessel disease, but the small vessel component is usually the predominant manifestation. The vasculitic process may be limited to the skin or may affect the skin along with visceral involvement such as pulmonary hemorrhage, intestinal ischemia or hemorrhage, or glomerulonephritis. Therefore, a primary cutaneous small vessel vasculitis should be a diagnosis of exclusion after systemic involvement has been ruled out (see Chap. 164).

Small vessel vasculitis can occur as an isolated primary cutaneous disorder or be secondary to another process (Table 165-2).

Palpable purpura tends to occur in crops of lesions of similar age (see Figs. 164-1A and 165-3). Small vessel vasculitis/purpura is generally more pronounced in gravitydependent areas. One exception is vasculitis due to cryoglobulinemia, especially in association with lymphoma.

Cutaneous vasculitis of the legs may be associated with such striking edema as to suggest nephrotic syndrome. Findings such as livedo reticularis (see Fig. 165-6) may be seen in patients with peripheral vascular disease of various etiologies. Both systemic and localized forms of small vessel vasculitis occur, and in addition to histopathology, immunohistology and autoimmune serology are important for full definition of the disorders in this group.

TABLE 165-2
Classification of Small Vessel Vasculitis

- Primary
- Secondary
  - Drug allergy
  - Infections
    - Bacterial endocarditis
    - Viral infections; (e.g., hepatitis B or C, parvovirus B19, cytomegalovirus, Epstein-Barr virus)
    - Disseminated *Neisseria*, *Rickettsiae* infections
  - Defined systemic autoimmune disorders (e.g., Sjögren syndrome, systemic lupus erythematosus, dermatomyositis, rheumatoid arthritis)
  - Malignancies
    - Hematologic
    - Lymphoid
    - Solid organ malignancies
  - Systemic vasculitic syndromes

There are mainly three immunopathologic types of small vessel vasculitis: antibody mediated (e.g., Goodpasture syndrome), immune complex mediated (e.g., Henoch-Schönlein purpura (Table 165-3), essential cryoglobulinemic vasculitis, urticarial vasculitis (Table 165-4), and ANCA-associated, pauci-immune vasculitides (WG, CSS, MPA).

Therapy of isolated cutaneous vasculitis is directed at the underlying process if one can be identified. Infections should be treated. Suspected offending agents, such as drugs, should be withdrawn. If no inciting agent is found, the choice of therapy depends on the severity of organ involvement (Table 165-5).

The primary systemic vasculitides include WG, CSS, and MPA. These conditions are also referred to by some investigators as *ANCA-associated vasculitides*. This term emphasizes similarities between these conditions, including the predominant involvement of small- and medium-sized vessels, the similar renal histology (focal segmental glomerulonephritis without immune complexes), and the association with ANCA.

Wegener Granulomatosis

WG is a relatively uncommon, potentially lethal disease that is characterized by necrotizing granulomatous inflammation and vasculitis of small- and medium-sized vessels. Diagnosis mandates systemic therapy, usually with two drugs. Multiple organs are often involved, with a predilection for the upper and lower respiratory tracts, eye, and the kidney.[7] Males and females of all ages can be affected. Upper airway disease tends to be particularly striking, but is often initially attributed for months or even years to "routine" sinus disease until other manifestations of WG are recognized.

TABLE 165-3
Henoch-Schönlein Purpura

- More common in children than in adults, often after a respiratory tract infection
- Annual incidence, 20/100,000 children/yr
- Clinical manifestations in children
  - Cutaneous (leukocytoclastic vasculitis)
    - Purpura
    - Urticarial rash with local edema
  - Gastrointestinal (intestinal vasculitis, intussusception)
    - Colicky abdominal pain
    - Gastrointestinal bleeding
  - Renal disease (glomerulonephritis)
    - Hematuria and proteinuria
    - Nephritic syndrome
    - Acute renal failure
- Clinical manifestations in adults
  - Joint symptoms more common
  - Renal disease, more severe
- Confirmation of diagnosis of Henoch-Schönlein purpura
  - Evidence of tissue deposition in the skin or kidney of immunoglobulin A by immunofluorescence microscopy
- Overall outcome (generally good)
  - Complete recovery
  - Recurrent episodes of purpura and nephritis
  - Persistent disease
- Treatment
  - No specific therapy (most patients)
  - Corticosteroids (arthritis, abdominal pain)
  - Immunosuppressive drugs (nephritis with crescents)
  - Plasmapheresis (severe disease)

The clinical manifestations in WG are summarized in Table 165-6.

The clinical presentation of dermatologic lesions in WG is highly variable, including palpable purpura (Fig. 165-7A), tender subcutaneous nodules, papules, pustules, livedo reticularis, infarction of the fingertips, pyoderma gangrenosum, gingival hyperplasia, and necrotic ulcers in the nasal and oral mucosa (see Fig. 165-7B). Necrotic papules of the limbs, though not a frequent or a specific manifestation, are suggestive of WG. The skin biopsy may reveal necrotizing vasculitis, granulomatous vasculitis, or ex-

TABLE 165-4
Urticarial Vasculitis

- Episodes of urticaria are accompanied by histopathologic features of leukocytoclastic vasculitis
- Prevalence of 5% in patients with urticaria
- Histopathology
  - Leukocytoclastic vasculitis
  - Immunofluorescence: Deposits of immunoglobulins, complement, or fibrin within vessel walls
- Clinical presentation
  - Cutaneous (see Fig. 165-2)
    - Burning, tender, painful, or pruritic lesions
      Wheals or serpentine papules
      Angioedema
    - Persistence 24–72 h
    - Residual effects
      Purpura
      Hyperpigmentation
  - Systemic
    - Arthralgias/arthritis
    - Abdominal pain
- Etiology
  - Idiopathic
  - Underlying autoimmune disorder (systemic lupus erythematosus or Sjögren syndrome)
  - Immunoglobulin M paraproteinemia (Schnitzler syndrome)
  - Viral infections (hepatitis, acute Ebstein-Barr viral infection)
  - Henoch-Schönlein purpura
- Hypocomplementemic urticarial vasculitis syndrome
  - Urticaria > 6 mo
  - Hypocomplementemia
  - Dermal venulitis by biopsy
  - Arthralgia or arthritis
  - Uveitis, episcleritis
  - Glomerulonephritis
  - Recurrent abdominal pain
  - Angioedema
  - Obstructive lung disease
- Treatment
  - Moderate doses of daily corticosteroids
  - Colchicine
  - Dapsone
  - Nonsteroidals
  - Antimalarials
  - Immunosuppressive drugs

travascular granulomas, and, occasionally, palisading granulomas.

Return of cutaneous manifestations with drug tapering almost always portends a systemic flare.

The diagnosis of WG should be considered in patients with otherwise unexplained inflammation of the upper or lower respiratory tract, eye, or glomerulonephritis. Suspicion of WG should be increased when multiple organ involvement is demonstrated, the upper airway disease is destructive, or pulmonary nodules (especially with cavities) are demonstrated by radiography. Any combination of organ involvement is conceivably possible, but most patients exhibit upper airway involvement at the time of diagnosis. If the entire clinical picture is compatible with WG, and alternative diagnoses have been appropriately ruled out, the finding of cytoplasmic ANCA with anti-PR3 specificity in the patient's serum is sufficient to make the diagnosis and initiate therapy. However, if there are any atypical features or special concerns regarding the initiation of immunosuppressive therapy or if the patient does not respond appropriately to therapy, tissue documentation of the diagnosis is mandatory (see eFig. 165-7.1 in on-line edition). Because WG generally requires glucocorticoid plus cytotoxic drug therapy, it should be distinguished from other inflammatory disorders, including other vasculitic syndromes, which may be effectively treated with a less toxic approach.

TABLE 165-5
Principles of Treatment in Primary Small Vessel Vasculitis

- Cutaneous involvement only
  - Nonsteroidal anti-inflammatory drugs
  - Colchicine
  - Pentoxifylline
  - Dapsone
  - Thalidomide
  - Short-term, low-dose corticosteroids
- Visceral involvement
  - Higher dose corticosteroids
  - Immunosuppressive therapy (e.g., methotrexate, azathioprine, cyclophosphamide)

The most recent therapeutic approaches in WG have separated treatment into two phases: induction, where active disease is placed in remission, and maintenance. In most cases, initial remission occurs within 3 to 6 months (Table 165-7). For severe, life-, or organ-threatening disease, cyclophosphamide should be used as an induction therapy along with corticosteroids.

Corticosteroids may induce symptomatic improvement in the upper airway, lungs, skin, and musculoskeletal system, but only rarely produce remission. Corticosteroids alone essentially never control aggressive renal disease. Even if improvement follows single drug treatment with corticosteroids, tapering usually results in a flare in the disease. Despite immunosuppression, the relapse rate in WG is approximately 50 percent. We do not routinely use sequential cytoplasmic ANCA measurements to dictate changes in immunosuppressive therapy. Local nasal and sinus care and otolaryngoscopic evaluations are a routine part of the therapy of patients with WG and upper airway disease.

Churg-Strauss Syndrome (Allergic Angiitis and Granulomatosis)

CSS, like WG, affects small- to medium-sized arteries and veins.[8] There are clinical similarities to WG in terms of the pattern of organ involvement and pathology. This is especially true in regard to upper and lower airway disease and glomerulonephritis. CSS differs most strikingly from WG in that the former usually occurs in patients with a history of atopy, asthma, or allergic rhinitis, which is often ongoing. In the prevasculitic atopy phase, as well as during the systemic phase of the illness, eosinophilia is characteristic and often of striking degree (1000 eosinophils/mm^3 or more). When eosinophilia is present in WG, it is usually more modest (500/mm^3 or less).

Systemic features of CSS include some combination of pulmonary infiltrates, cardiomyopathy, coronary arteritis, pericarditis, polyneuropathy (symmetric or mononeuritis multiplex), ischemic bowel disease, eosinophilic gastroenteritis, ocular inflammation, nasal perforations, glomerulonephritis, and cutaneous nodules and/or purpura (Table 165-8).

The skin is involved in about half of patients with CSS. Strauss, Churg, and Zak divided the clinical findings in allergic granulomatosis into three categories: erythematous maculopapules resembling erythema multiforme, hemorrhagic lesions ranging from petechiae to extensive ecchymosis, often associated with wheals, and cutaneous and subcutaneous nodules. It has been suggested that the initial small vessel vasculitis evolves into a pattern of inflammation with granulomas that coalesce into the palpable nodules. The histopathologic features of the first two types were non-specific; however, the pathologic changes in the third type, cutaneous and subcutaneous nodules consisting of necrotic collagen in the center surrounded by a palisading granuloma, were thought to be suggestive for allergic granulomatosis. Similar nodules can be found in WG, SLE, or rheumatoid arthritis. Additional clinical findings in

TABLE 165-6
Clinical Manifestations in Wegener Granulomatosis

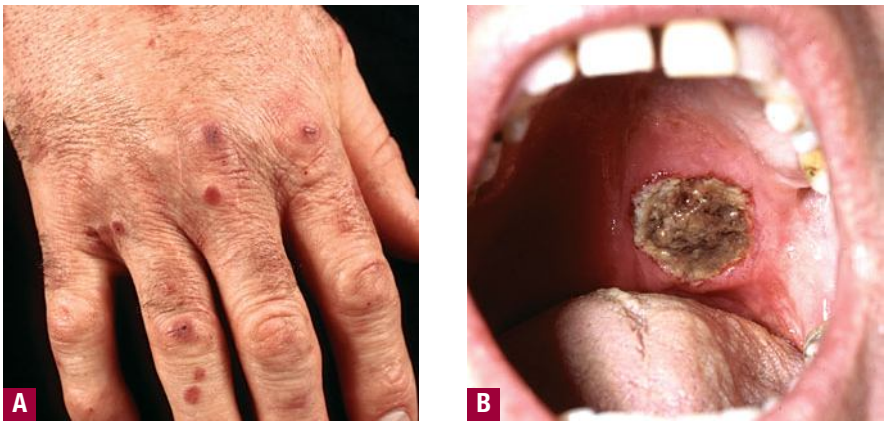
Organ Involvement	Symptoms and Signs	Histopathology	Useful Tests
Upper airway disease	Pansinusitis, often destructive Nasal crusting Epistaxis Septal perforation Saddle nose deformity Otitis media Ear chondritis Neurosensorial hearing loss Subglottic stenosis	Nasal tissue biopsy Low yield for specific diagnosis	CT of the sinuses
Lower airway and lungs	Diffuse alveolar hemorrhage Lung infiltrates Lung nodules Cavitary lesions	Open lung biopsy Highest yield for diagnosis but not specific Areas of necrosis in "geographic pattern," giant cell granulomas, vasculitis (see eFig. 165-7.1A,B in on-line edition) Diffuse alveolar hemorrhage with capillaritis and hemosiderin-laden macrophages	CT scan of the chest Bronchoscopy with bronchoalveolar lavage cultures to exclude infections Transbronchial biopsy (very low yield for specific diagnosis)
Renal involvement	Glomerulonephritis Acute renal failure	Renal biopsy Focal segmental glomerulonephritis with variable proliferative changes Rapidly progressive crescentic glomerulonephritis No immune complex deposition (pauci-immune) helps distinguish from systemic lupus erythematosus, Goodpasture syndrome, viral etiologies	Urinalysis; serum creatinine, 24-h protein collection
Ocular	Orbital pseudotumor Nasolacrimal duct stenosis Conjunctivitis Scleritis Uveitis Retinal vasculitis		CT or magnetic resonance imaging of the orbit
Musculoskeletal	Arthralgias Migratory or fixed polyarthritis		Rheumatoid factor frequently positive; x-rays: no erosions
Neurologic	Peripheral neuropathy Oculomotor involvement by retro-orbital mass impingement Central nervous system involvement uncommon		Electromyogram
Cutaneous involvement	Acute indolent deep inflammatory masses Palpable purpura Pyoderma-like ulcerations Gingival hyperplasia Papules Ulcers Panniculitis and subcutaneous nodules	Skin biopsy No pathognomonic histopathology Leukocytoclastic vasculitis Granulomatous vasculitis	
Gastrointestinal	Ulcerations Ischemic bowel		
Cardiovascular	Cardiac ischemia Conduction abnormalities Pericarditis		

CT = computed tomography.

CSS include ulcers, livedo reticularis, facial edema, and deep pannicular vasculitis.

Histologically, cutaneous lesions can be divided into three categories: extravascular granulomas, leukocytoclastic vasculitis with or without prominent eosinophilic infiltration, and cutaneous polyarteritis nodosa (PAN).

Histopathology of involved skin, nerve, lung, heart, and gastrointestinal tract typically exhibits a vascular or extravascular granulomatous inflammation, with a prominent eosinophilic infiltrate and vasculitis. Vasculitis in a given tissue section may be granuloma-



▲ **FIGURE 165-7** Wegener granulomatosis. **A.** Palpable purpura, which has a more pronounced papular component than in the more common types of leukocytoclastic vasculitis. **B.** Deep ulcer on the soft palate.

tous or nongranulomatous. Granulomas can be found in tissue at areas separate from the demonstrable vasculitis. Eosinophilic infiltrates are more striking than in WG. Neither abundant eosinophils, granulomas, nor giant cells are found in classic PAN. However, the pathology of these nodules is not by itself sufficient to make a diagnosis of CSS because similar pathology can be seen in lymphoma and sarcoidosis.

CSS is generally a corticosteroid-responsive disease. Some patients are able to be withdrawn from steroids. However, bronchial asthma and sinus disease may require ongoing therapy, even if the vasculitic component of the disease has remitted. It seems appropriate to extend the principles for treatment of WG to all ANCA-associated vasculitides. Cyclophosphamide should be added to glucocorticoids for remission induction in all patients who present with disease manifestations that threaten the patient's life or the function of a vital organ. For patients with less severe disease, methotrexate, azathioprine, or mycophenolate mofetil can be used as glucocorticoid-sparing therapies.

Polyarteritis Nodosa and Microscopic Polyangiitis

Attempts to neatly separate these two forms of necrotizing medium/small-sized vessel arteritis have not been universally accepted, and older literature frequently combined these disorders. A recent international consensus conference proposed that the diagnosis of these disorders be based on the absence of granulomatous inflammation in both, and the lack of involvement of arterioles, capillaries, venules, and glomerular capillaries in classic PAN. MPA involves vessels ranging in size from capillaries and venules to medium-sized arteries. Glomerulonephritis, particularly rapidly progressive glomerulonephritis, and alveolar hemorrhage are particularly common in MPA, and by definition absent in PAN. Antibody to myeloperoxidase, a type of perinuclear ANCA, is detected in 60 percent of sera from patients with MPA. It may well be that some cases of classic PAN do involve the smaller vessels, and until it can be demonstrated that the two syndromes have distinct pathophysiologies, attempts to clearly distinguish MPA from PAN remain imperfect. Hepatitis B and C infections have been associated with a classic PAN-like syndrome as well as MPA-like disease.

Given the diagnostic nuances and disagreements, it is not surprising that a clear-cut distinction cannot be provided in terms of prognosis or response to therapy between the two syndromes. Most important, because the distinction between these two syndromes is still being defined, it is difficult to interpret the clinical descriptions of the older studies on PAN, which included patients with both classic PAN and MPA. This accounts for some of the wide variation in the reported frequency of cutaneous, pulmonary, or glomerular involvement in PAN.

Constitutional symptoms, such as fever, asthenia, and myalgias, are common in both PAN and MPA. Elevated acute phase reactants, thrombocytosis, leukocytosis, and the anemia of inflammatory disease are also common. MPA is typically manifest by purpura; crescentic necrotizing, segmental glomerulonephritis; and/or alveolar hemorrhage in conjunction with small- and medium-sized vessel vasculitis in other organ systems.

It is important to note that alveolar hemorrhage in MPA and other entities may manifest as dyspnea, pulmonary infiltrates, and anemia in the absence of hemoptysis. Peripheral neuropathy with symmetric mixed motor and sensory

TABLE 165-7
Treatment of Wegener Granulomatosis (WG)

Drug	Indication	Dose	Side Effects	Comments
Cyclophosphamide (Cytoxan)	Remission induction: severe disease; life-threatening or major organ-threatening disease (e.g., alveolar hemorrhage, acute glomerulonephritis, mononeuritis multiplex)	2 mg/kg/day PO	Infections, cytopenias, bladder cancer, leukemia	Dramatically increased survival in WG patients compared to steroids alone
Methotrexate	Remission induction: systemic disease; not life-threatening or major organ-threatening; remission maintenance	0.3 mg/kg/wk PO, SC, IV	Pneumonitis, elevation in transaminases, cytopenias	Should be avoided in patients with renal insufficiency
Azathioprine (Imuran)	Remission maintenance	2 mg/kg/day PO	Cytopenias, pneumonitis, hypersensitivity	
Mycophenolate mofetil (CellCept)	Remission maintenance	2 g/day PO	Cytopenias, infections	
Leflunomide (Arava)	Remission maintenance	20–40 mg/day PO	Diarrhea, hepatotoxicity

- Gastrointestinal involvement
  - Eosinophilic gastroenteritis
  - Mesenteric vasculitis

components or mononeuritis multiplex pattern is common. Upper airway and ocular inflammation may occur, which occasionally makes distinction from WG difficult. Purpura and/or splinter hemorrhages are commonly found in MPA.

Classic PAN may present with hypertension and/or renal insufficiency with a bland urine sediment on microscopic analysis. Renal ischemia may result from inflammation, stenosis, or occlusion of pre-glomerular muscular arteries. Peripheral neuropathy, testicular pain/epididymitis, and ischemic myalgias occur fairly frequently. Both PAN and MPA may cause ischemia in the heart and gastrointestinal tract. PAN is associated with the development of 1- to 5-mm microaneurysms in the mesenteric, hepatic, or renal arteries in perhaps 40 percent of cases. Microaneurysms can also occur in MPA, WG, CSS, Behçet, SLE, and other disorders affecting medium-size vessels.

Skin manifestations occur in 15 percent of cases. Subcutaneous inflammatory, bright red to bluish nodules (0.5 to 2.0 cm) are violaceous, become confluent to form painful subcutaneous plaques, and are accompanied by livedo reticularis (see Fig. 165-6); "starburst" livedo is pathognomonic and marks a cluster of nodular lesions (Fig. 165-8). Ulcers follow ischemia nodules (see Fig. 165-4) and are usually found bilaterally on lower legs and thighs. Other areas: arms, trunk, head, neck, buttocks. Livedo reticularis may extend to trunk. The duration is from days to months and resolves with residual violaceous or postinflammatory hyperpigmentation. Skin lesions in systemic and cutaneous PAN are identical.

When the clinical picture of PAN or MPA is recognized, it is imperative to be certain that it is not secondary to, or associated with, infection with hepatitis B or C. The presence of hepatitis B or C infection does not seem to dramatically alter the presentation of the PAN or MPA syndrome, although membranous glomerulonephritis, liver failure, and thrombocytopenia are more likely to occur with viral hepatitis infection. Infection with parvovirus B19 and human immunodeficiency virus should also be excluded.

The diagnosis of these disorders should ideally be based on histopathology and clinical pattern of disease. In the patient with a urine sediment analysis suggestive of glomerulonephritis or neuropathy, a renal biopsy or biopsy of a clinically involved nerve may support the diagnosis of MPA. The presence of serum perinuclear ANCA with anti-myeloperoxidase specificity further supports the clinical diagnosis, but is not specific for this disease. The renal biopsy tissue in MPA, as in WG, is negative for immune complexes by immunofluorescent staining and electron microscopy—so called *pauciimmune glomerulonephritis*. Lung biopsy in the setting of pulmonary infiltrates or hemorrhage may demonstrate "capillaritis," but yields less specific pathology than in WG. Biopsy is most useful to rule out alternative pulmonary diagnoses. The diagnosis of classic PAN is often more difficult in the setting of dominant but non-specific constitutional symptoms and the absence of easily accessible disease-affected tissue such as nerve. Biopsy of skin lesions can be diagnostic when segmental necrotizing arteritis is found (Fig. 165-8B). Biopsy of clinically uninvolved tissue (i.e., asymptomatic muscle) is not usually fruitful. Several diagnostic algorithms have been proposed. If biopsy is not indicated due to the absence of accessible involved tissue, complete abdominal angiography should be considered to evaluate the medium-size vessels. The sensitivity and specificity of this procedure is not well defined, especially in the absence of abdominal complaints. Angiography is generally avoided, whenever possible,

▲ **FIGURE 165-9** **A.** Temporal arteritis. Necrosis of the scalp first manifests with a black eschar, which is adherent, but later shed, leaving a deep ulcer that may extend to the bone and, later, granulates under corticosteroid therapy as shown here. **B.** Histopathology of the temporal artery shows necrosis of the media, inflammatory infiltrates consisting of lymphocytes, and giant cells. There is also subintimal proliferation of fibroblasts and fibrosis. **C.** Elastic tissue stain reveals destruction of the lamina interna and externa.

in the setting of progressive or significant renal insufficiency.

Treatment of both PAN and MPA is still somewhat empiric. Corticosteroids in high doses remain the initial mainstay of therapy for both PAN and MPA. Corticosteroids alone may be sufficient therapy in patients who do not have critical organ involvement, defined as renal insufficiency, gastrointestinal ischemia, cardiomyopathy, dense peripheral neuropathy, and central nervous system involvement. Such patients have increased risk of morbidity or mortality and are usually treated with glucocorticoids and an additional immunosuppressive agent such as cyclophosphamide. Although this is common practice, the use of initial combination therapy in this setting has not been formally studied. Patients with MPA may be more likely to suffer relapses after a course of treatment than those with PAN.

When active hepatitis B or C infection is present, a relatively short course of steroids should be considered, based on disease severity, in conjunction with antiviral therapy, and, perhaps, apheresis. Controlled studies have not been conducted to objectively assess the value of adding apheresis to the combination of antiviral and corticosteroid therapy. The possibility of drug-induced MPA or PAN syndromes should always be considered. Common drugs include propylthiouracil, hydralazine, leukotriene inhibitors, sulfasalazine, minocycline, D-penicillamine, ciprofloxacin, phenytoin, and allopurinol.

Large Vessel Arteritis (Takayasu Arteritis and Temporal Arteritis)

TA and GCA are the most common inflammatory diseases of the aorta and its major branches. Similar vascular targeting may occur in Behçet disease (see Chap. 167), Cogan syndrome, and sarcoidosis (see Chap. 153). These diseases are readily distinguished by their associated extravascular features. GCA and TA have similar histology but differ in the age of onset. GCA generally affects individuals older than 55 years of age. TA preferentially affects women in their first through third decades of life. GCA and TA can be associated in some patients with the syndrome of polymyalgia rheumatica. Polymyalgia rheumatica is characterized by proximal muscle pain and stiffness with nocturnal and early morning worsening. There may be a subjective sense of weakness, without true weakness on examination; serum muscle enzyme levels are normal. The clinical findings in GCA are presented in Table 165-9. Skin lesions in GCA are scalp tenderness, cyanosis of extremities, and scalp necrosis, which may be extensive (see Fig. 165-9A).

Diagnosis of GCA is generally made by biopsy of the superficial temporal artery. Pathology of GCA usually reveals chronic mononuclear cell infiltrates, giant cells, and necrosis of the media (see Fig. 165-9B and C). There are isolated reports of GCA overlap syndromes also involving medium-sized vessels of the viscera, but generally this disease is not associated with small (capillary, venule) blood vessel inflammation.

TA (pulseless disease) is also a chronic inflammatory disease affecting the aorta and its major branches. Although it is usually recognized in younger, predominantly female patients of reproductive age, it can also occur in young children and older patients of either sex. TA is

TABLE 165-9
Clinical Manifestations in Giant Cell Arteritis

General	Fever, night sweats, weight loss

Cutaneous manifestations	Extremity cyanosis, pallor; scalp necrosis

more commonly associated with aortic and aortic branch vessel stenoses and aneurysms than GCA. It is uncertain whether TA and GCA are distinct or the same disorder with modified expression in different age groups. The characteristic features of the disease reflect the ischemia produced by the inflammatory stenoses of the aorta and its major branches.

Diagnosis is usually made by arteriographic demonstration of stenotic and obstructive lesions; aneurysms are less commonly observed. The entire arch as well as abdominal aorta and renal vessels should be evaluated; central arterial pressure should be obtained at the time of angiography and compared with simultaneously obtained arm and leg pressures. The role for vascular magnetic resonance imaging in the evaluation and follow up of these patients is currently under investigation. Pathologic documentation is more difficult to obtain in TA, but the histopathology is similar to that described in GCA.

Initial therapy of both TA and GCA is with corticosteroids. GCA is generally quite steroid responsive, although the choice of the most appropriate initial dose remains controversial. Different authors have advocated an initial daily dose of between 20 mg and 1 mg/kg, with tapering of the corticosteroids over 8 to 12 months. Measurement of acute phase reactants provides an imperfect marker of disease activity and an imperfect guide to steroid tapering. If significant steroid side effects occur, or if patients relapse on tapering, a "second line" agent such as methotrexate is often (empirically) added to the corticosteroids. TA is less consistently responsive to initial corticosteroid therapy than GCA, but this has not been carefully studied. Some authors have advocated earlier use of methotrexate therapy in TA to reduce the long-term toxicity risks of corticosteroids. Other drugs, such as cyclophosphamide, azathioprine, and the newer anti-tumor necrosis factor drugs, etanercept and infliximab, have been used with variable but generally less than hoped for success. Vascular reconstructive surgery or angioplasty are adjunctive therapeutic options in some patients.

SOME CAVEATS AND GENERAL COMMENTS CONCERNING THE TREATMENT OF PATIENTS

The systemic vasculitides are potentially life threatening and often require potent anti-inflammatory and immunosuppressive therapy. After the initiation of therapy, there is a prolonged window of increased susceptibility to opportunistic infection. The greatest risks occur in patients with marked neutropenia or lymphopenia. One must be particularly wary about attributing new problems to "flares" in the underlying disease without considering the possibility of a new or recrudescent infection. Varicella zoster may present with fever and pain before the appearance of the tell-tale vesicles. Pneumocystis carinii, cytomegalovirus, systemic fungal infections, or reactivation of mycobacterial disease are observed more frequently than in the normal host. Significant immunosuppression from steroids and other medications frequently is associated with mucosal candidiasis, less commonly molluscum contagiosum, and, rarely, Kaposi sarcoma. Methotrexate may cause a flu-like illness after each dose. Methotrexate, azathioprine, or cyclophosphamide may cause leukopenia and, less often, other cytopenias. Steroids can cause a significant amount of facial and truncal acne, which, especially in younger patients, must be addressed to encourage compliance with therapy. Cutaneous complications, including allergic purpura, can also result from adjunctive medications for hypertension, epilepsy, or arthritis. Reactions to thrombolysis or angiographic studies may include urticaria as well as the cholesterol embolization syndrome in patients with atherosclerosis (see Chap. 174). Drug-induced pneumonitis has been reported with the use of immunosuppressive agents, especially with methotrexate and cyclophosphamide.

CHAPTER 166

Erythema Elevatum Diutinum

Nneka I. Comfere
Lawrence E. Gibson

Erythema elevatum diutinum (EED) is a chronic leukocytoclastic vasculitis (LCV) that was initially described by Hutchinson in 1888 and subsequently by Bury in 1889. The name *EED* was first used by Radcliff-Crocker and Williams who separated it into two groups.[1–3] The Bury type tended to occur more commonly in younger women with a history of underlying rheumatologic disease, and the Hutchinson type tended to occur in elderly males.

EPIDEMIOLOGY

The incidence of EED is unknown; however, it appears to be a rare disease. There is no significant mortality associated with EED. It presents predominantly in males, in the fourth to sixth decade of life.

PATHOGENESIS

The pathogenesis of EED is not entirely clear; however, the prevailing and traditional theories are based on immune complex deposition within vessel walls, complement fixation, inflammation, and subsequent vascular destruction.[1] The various disease associations seen in EED (see Co-Occurring Diseases) have provided further understanding of the underlying pathomechanism of EED.

ERYTHEMA ELEVATUM DIUTINUM

AT A GLANCE

- Rare disease; unknown incidence.
- A chronic leukocytoclastic vasculitis typified by a distinctive clinical pattern.
- Symmetric, erythematous, violaceous, or yellow-brown papules/nodules/plaques.
- Most common sites of involvement are the extensor surfaces of the hands, fingers, elbows, knees, legs, and Achilles tendon. Trunk is usually spared.
- Co-occurring diseases include monoclonal paraproteinemias, lymphoproliferative disorders, chronic infection, autoimmune conditions, and connective tissue diseases.
- Pathology consists of leukocytoclastic vasculitis in early stage lesions and a granulation-tissue–like response with fibrosis in later stages.

▲ **FIGURE 166-1** Erythema elevatum diutinum. Nodular lesions on dorsal hand present for several years.

Antineutrophil cytoplasmic antibodies (ANCA) of the immunoglobulin G (IgG) type have proven useful for the diagnosis and monitoring of disease activity in various systemic vasculitides, including Wegener granulomatosis (WG), microscopic polyangiitis (MPO), polyarteritis nodosa, and Churg-Strauss syndrome.[4]

There are reports in the literature documenting the occurrence of IgA ANCAs in patients with neutrophil-driven dermatoses such as Henoch-Schönlein purpura, inflammatory bowel disease, and various cutaneous vasculitides, including EED.[6,7] It seems likely that abnormal functioning or activation of the neutrophil, which is the primary inflammatory cell in EED, may represent the central event. Most importantly, some of the neutrophilic dermatoses, including EED, have been associated with underlying paraproteinemias (monoclonal and polyclonal IgA gammopathies)[8] and hematologic malignancies. The severity of EED does not, however, appear to be dependent on the total paraprotein levels. Nevertheless, immunoelectrophoresis screening for monoclonal gammopathies as a marker of EED has been recommended.[9] Hence, IgA ANCAs against yet unidentified neutrophilic antigenic targets may prove to be useful clinical markers in EED.[10]

In a recent analysis of the clinical, histopathologic, and immunohistochemical features in six patients with EED by Wahl et al.,[9] the vascular endothelium of EED was immunoreactive for CD31, CD34, vascular endothelial growth factor, and factor VIIIa but nonimmunoreactive for factor XIIIa, transforming growth factor-β, and latency-associated nuclear antigen of human herpesvirus 8. The staining properties of the endothelium in EED were compared to endothelial staining in similar lesions, including LCV, urticarial vasculitis, dermatofibromas, and capillary hemangiomas. No significant differences in the immunohistochemical staining properties were observed. The authors concluded that the chronic and recurrent nature of EED is the primary means of distinguishing it from other entities that are similar clinically and histologically.[9]

CLINICAL FEATURES

EED typically presents as multiple, persistent, symmetric, and erythematous to violaceous papules/nodules/plaques on the extensor surfaces of the hands (Fig. 166-1), elbows (Fig. 166-2), wrists, knees (Fig. 166-3), ankles, Achilles tendons, fingers (Fig. 166-4) and toes, buttocks (see eFig. 166-4.1 in on-line edition), face, ears, legs, forearms, and genitals.[1] The trunk, however, is usually spared, but may be involved rarely.[11] Other atypical sites of involvement include the retroauricular and palmoplantar regions.[1,11,2] Overlying epidermal changes, such as vesiculation or ulceration, may be present. Lesions may be exacerbated by cold exposure and may become more raised, erythematous, and firm in the evening.[12–14]

With time, the lesions may become firmer and develop a yellowish-brown coloration, resembling xanthomata (see Fig. 166-2). These eventually heal with dyspigmentation. The onset of new lesions may be associated with symptoms of pruritus, burning, stinging sensations, paresthesias, or may be completely asymptomatic. Constitutional symptoms,

▲ **FIGURE 166-2** Multiple erythematous scaly papules coalescing into plaques on extensor elbow.

▲ **FIGURE 166-3** Crusted brown and violaceous papules over knee and anterior thigh.

including fever and arthralgias, are seen commonly.[1,15]

The clinical presentation of EED in human immunodeficiency virus (HIV)–infected individuals is somewhat different and can mimic lesions of Kaposi sarcoma and bacillary angiomatosis usually seen in immunosuppressive states.[16] Nodular lesions have been reported in HIV-infected patients.

LABORATORY FINDINGS

Histopathology

Histopathologic findings are predominantly those of a chronic LCV, with thickening of blood vessel walls, mural and luminal neutrophilia, vascular occlusion, fibrinoid necrosis of vessel walls, endothelial cell swelling, leukocytoclasia, and dermal neutrophilia with lymphocytes (Fig. 166-5). Epidermal changes of hyperkeratosis, acanthosis, ulceration, subepidermal edema, and bulla formation may also be observed.[1,3,17]

The histopathologic features characteristic for EED are not usually all present within the same lesion. There is an evolution of the pathologic features that can be seen with progression from the early stages into the later stages of disease.

Early stage lesions are characterized by leukocytoclastic vasculitis with a moderately dense perivascular inflammatory infiltrate consisting of neutrophils, leukocytoclastic debris, macrophages, and histiocytes (see eFig. 166-5.1 in on-line edition). Fibrin deposition is also evident within the vascular walls. At this stage, the histologic differential diagnosis is broad and includes all the potential causes of LCV. However, the histologic features of EED at this early stage may mimic those of dermatitis herpetiformis. The distinguishing feature for dermatitis herpetiformis includes a limitation of the neutrophilic infiltrate to the papillary dermis, whereas in EED the infiltrate tends to be more diffuse. Other entities to consider in the differential diagnosis include the neutrophilic dermatoses, such as Sweet syndrome, bowel bypass syndrome, and rheumatoid neutrophilic dermatitis, none of which has LCV as a predominant feature.[18] Clinicopathologic correlation is necessary to establish the diagnosis in the early stages of disease.

With progression of disease, a granulation tissue–like response with fibroplasia and capillary proliferation becomes the predominant feature[1,3] (see eFigs. 166-5.1 and 166-5.2 in on-line edition). The infiltrate is increasingly composed mostly of histiocytes, some with phagocytosed nuclear debris. At this stage, the histopathologic features (see eFig. 166-5.3 in on-line edition) may be indistinguishable from other fibrosing lesions, such as a solitary sclerotic fibroma, fibrous histiocytomas, and dermatofibrosarcoma protuberans, or vascular lesions such as pyogenic granuloma, Kaposi sarcoma, and bacillary angiomatosis.[1,18,19] In the later stages of disease, xanthomatization is occasionally observed. This is characterized by the presence of both intra- and extracellular cholesterol deposits within infiltrating histiocytes and the dermis as demonstrated by ultrastructural studies.[1,20]

Direct immunofluorescence findings of lesional skin are generally non-diagnostic and range from few to many blood vessels within the superficial to mid-dermis, with variable staining with various conjugates, including IgG, IgM, C3, and fibrinogen.[15,21]

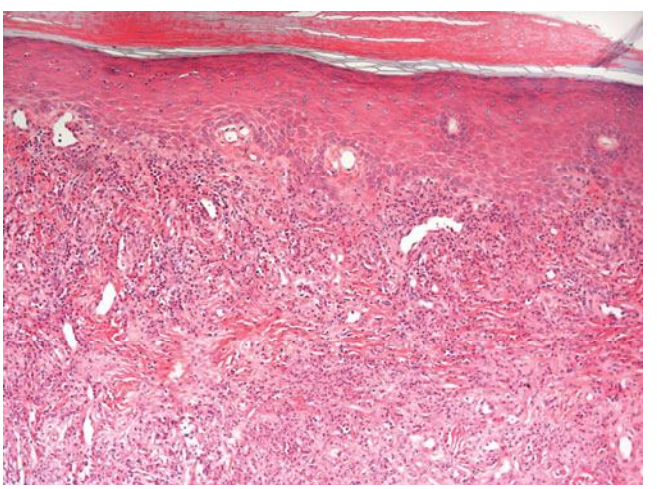
Other Laboratory Findings

(See Co-Occurring Diseases and Table 166-1)

CO-OCCURRING DISEASES

EED has been reported in association with a wide range of disease processes (see Table 166-1). Notable associations include chronic bacterial infections, especially streptococcal infections; HIV infection; underlying monoclonal and polyclonal gammopathies; and connective tissue diseases. Some of these dis-

▲ **FIGURE 166-4** Smooth, flesh-colored to slightly erythematous papules on extensor fingers over proximal interphalangeal joints.



▲ **FIGURE 166-5** Early stage lesion of erythema elevatum diutinum: Focal leukocytoclastic vasculitis with a fairly dense perivascular and interstitial infiltrate composed of neutrophils, lymphocytes, histiocytes, and leukocytoclastic debris. Mild capillary proliferation is also evident.

TABLE 166-1
Co-Occurring Entities

Infectious Diseases	Inflammatory Diseases	Connective Tissues Diseases/Autoimmune Conditions	Malignancy	Medications	Miscellaneous
Chronic bacterial infections	Crohn disease	Cutaneous lupus erythematosus	Polycythemia vera	Rifampin	Pulmonary infiltrates
HIV, HIV-2	Mixed cryoglobulinemia	Relapsing polychondritis	Myelodysplasia	Pyrazinamide	Pleural effusions
Human herpesvirus 6	Pyoderma gangrenosum	Rheumatoid arthritis	IgA/IgG paraproteinemia (monoclonal gammopathy/ MGUS/myeloma)	Isoniazid	Mosquito bites

ease associations have provided further insight into the pathogenesis of EED.

The most frequent disease association with EED is IgA paraproteinemia. Lesions of EED have been noted to flare with increased IgA levels. Hence, IgA paraprotein levels have been proposed to be a useful clinical marker in EED.[22] Other notable associations have included chronic bacterial, viral, and parasitic infections. Bacterial infections, especially streptococcal infections, have been associated with EED, and typical skin lesions have been reproduced or exacerbated by the intradermal injection of streptococcal antigens.[1,3,22] Juxta-articular nodules of EED have been observed in patients with HIV infection. The histopathology of these nodules usually reveals a predominance of fibrosis rather than a neutrophilic infiltrate, probably secondary to the advanced/chronic stage of such lesions.[16,23,24] The role of infectious agents in the etiopathogenesis of EED is still unclear, but evidence suggests that perhaps these agents serve as antigenic triggers of a hypersensitivity response that manifests as EED.

Connective tissue diseases and autoimmune diseases have also been seen in association with EED.

TREATMENT

As is the case with cutaneous vasculitis, treatment is aimed at alleviating discomfort associated with the lesions, diminishing damage to the skin, and eradication/minimization of underlying/associated conditions. Reports in the literature on treatment options are primarily anecdotal or based on experience in small case series. Management of EED remains challenging due to the chronic and recurrent nature of the disease. In general, treatment of the underlying cause or infectious process may result in resolution of lesions.[1] Dapsone- and sulfone-based therapies are considered first-line treatment choices for EED.[1,3,15,25] Dramatic and rapid response is usually seen within 48 hours of initiation of therapy, with near complete resolution of lesions within weeks to months.[25] However, lesions may recur with discontinuation of therapy.[1,22] The responsiveness of EED and other neutrophil-driven dermatoses to dapsone and sulfonamides is not completely known but is thought to be secondary to its inhibitory effects on neutrophil chemotaxis and function.[14] In patients with HIV infection, treatment with a combination of antiretroviral agents and dapsone or sulfonamides may be beneficial.[1] Other reported treatments with variable success in EED include niacinamide and tetracycline,[26] colchicine,[27] intralesional, potent topical or oral corticosteroids,[3] phenformin,[28,29] clofazimine,[13] and cyclophosphamide.[5]

CONCLUSION

EED is a distinctive form of cutaneous vasculitis. It is the clinical pattern combined with the chronicity of this process that is unique to EED. Repeated antigenic stimulation or infection appears to play a key role in the pathogenesis. Although microscopic features of early lesions are shared with other cutaneous vasculitides, in the chronic phase of the disease, the microscopic pattern may resemble various other entities characterized by granulation response and healing skin. It is important to search for an underlying disease and to evaluate patients carefully for infection. Otherwise, treatment recommendations are anecdotal and similar to those used for other cutaneous vasculitides.

CHAPTER 167

Adamantiades-Behçet Disease

Christos C. Zouboulis

Adamantiades-Behçet disease is a multisystem inflammatory disease of unknown etiology, classified as systemic vasculitis involving all types and sizes of blood vessels and characterized clinically by recurrent oral aphthous and genital ulcers, skin lesions, and iridocyclitis/posterior uveitis, occasionally accompanied by arthritis and vascular, gastrointestinal, neurologic, or other manifestations[1,2] (Fig. 167-1).

HISTORICAL ASPECTS

EPIDEMIOLOGY

Adamantiades-Behçet disease presents a worldwide occurrence with varying prevalence, being endemic in the eastern and central Asian and the eastern Mediterranean countries (along the so-called Silk Road) and rare in northern European countries, central and southern Africa, the Americas, and Australia.[4] A prevalence of 80 to 420 patients per 100,000 inhabitants has been reported in Turkey;[5] 7 to 30 patients per 100,000 inhabitants in the rest of the Asian continent (Japan, 14 to 31:100,000; Korea, 7.3:100,000; northern China, 14:100,000; Saudi Arabia, 20:100,000; Iran, 17:100,000) and 1.5 to 7.5:100,000 in southern Europe. In northern Europe (0.27 to 1.18:100,000) and the United States (0.12 to 0.33:100,000), the disease is rare.[4] In countries with several ethnic populations, including Turkmen and Mongol descents, the latter are mainly affected. The increasing prevalence of the disease is due to its chronic character. Its annual incidence is low; 0.75 to 1.0 new cases per 100,000 inhabitants were assessed in Japan (1990) and Germany (2005).[6] Adamantiades-Behçet disease most often affects patients in their 20s and 30s; however, early and late onsets (first year of life to 72 years) have been reported. Juvenile disease rates are 2 percent to 21 percent in different ethnic groups; its prevalence was estimated to be 0.17:100,000 in France. In contrast to old Japanese and Turkish reports of male predominance, the male to female ratio drastically decreased in the last 20 years. Currently, both genders are equally affected; a male predominance is still observed in Arab populations, whereas female predominance is evident in Korea, China, some northern European countries, and the United States.

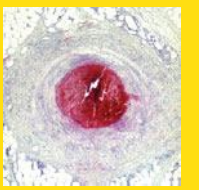
ETIOLOGY AND PATHOGENESIS

The etiology of the disease remains unknown, although genetic factors, infectious agents, environmental pollution, immunologic mechanisms, and endothelial and clotting factors have been implicated and studied intensively.[7,8] The endemic occurrence along the historical Silk Road, the major involvement of certain ethnic groups (mostly of Turkmen and Mongol descent), and associated immunogenetic data support the hypothesis that the disease followed the migration of these old nomadic tribes. On the other hand, the wide variation of the disease prevalence in the same ethnic group in association with different geographic areas of residence indicates an additional environmental triggering factor. Therefore, transfer of genetic material and/or of an unknown exogenous agent may have been responsible for the expansion of the disease.

Genetics and Immunogenetics

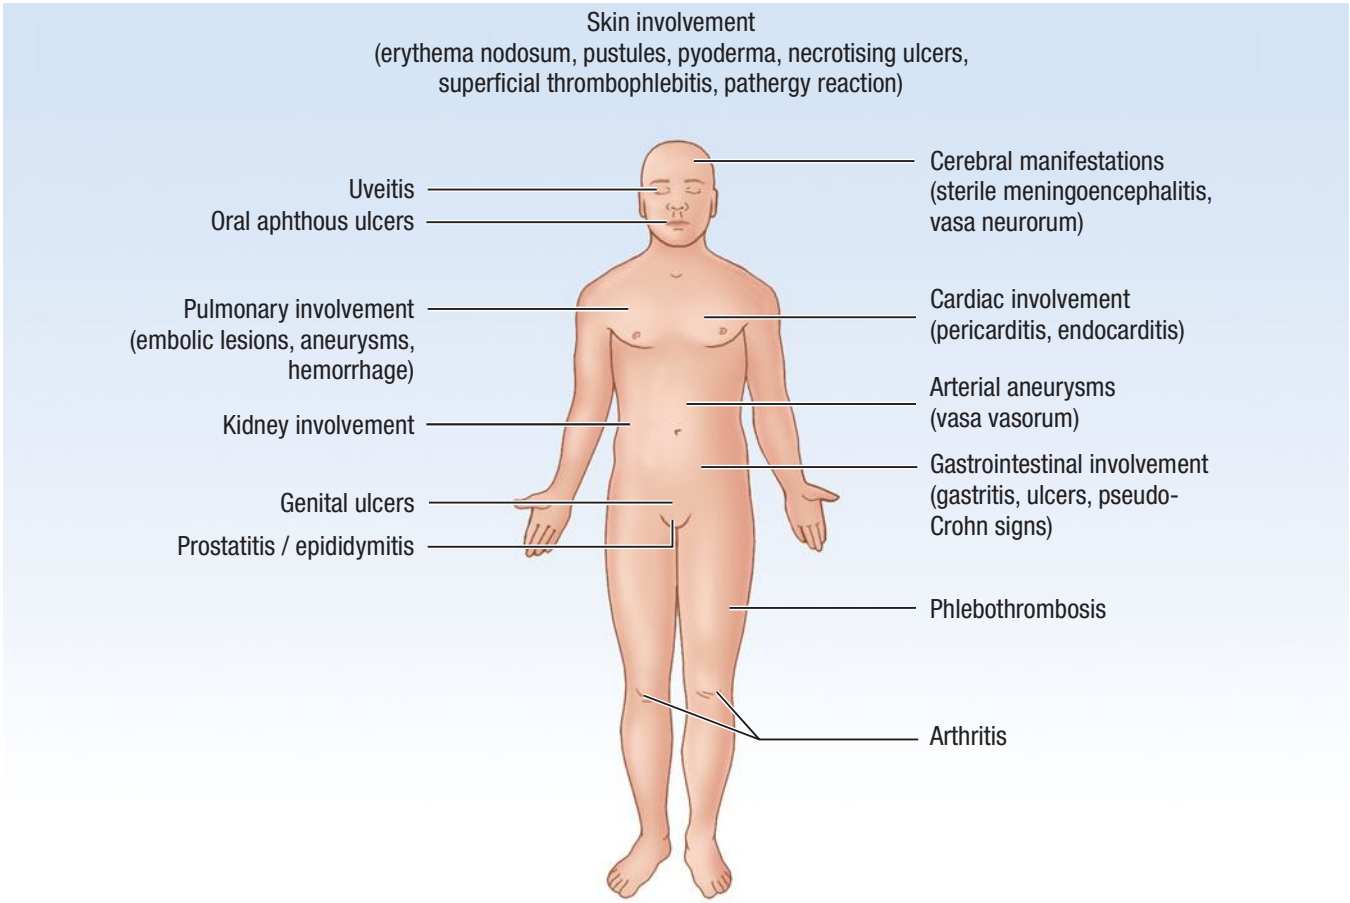
There is no specific mode of Mendelian transmission in Adamantiades-Behçet disease.[7,8] Familial occurrence with regional differences has been reported, being more frequent in Korea (15 percent) than in Japan or China (2 percent to 3 percent) and in Arab countries, Israel, and Turkey (2 percent to 18 percent) than in Europe (0 percent to 5 percent). An earlier disease onset in children compared with their parents and a higher frequency of familial cases in juveniles than in adults has been observed.

ADAMANTIADES-BEHÇET DISEASE AT A GLANCE



- Rare disease with worldwide distribution but strongly varying prevalence; certain ethnic groups are mainly affected.
- A genetically determined disorder with a probable environmental triggering factor.
- Multisystem occurrence, with oral aphthous ulcers, genital ulcers, papulopustules, erythema nodosum–like lesions, uveitis, and arthropathy as most common signs.
- Inflammatory disease representing a neutrophilic vascular reaction or vasculitis.
- Chronic relapsing progressive course and potentially poor prognosis (especially in males with systemic presenting signs; mortality, 0 percent to 6 percent).

A significant association exists between the disease and human leukocyte antigen (HLA)-B51 in Japan, the Middle East, and the Mediterranean countries; however, this relationship is not as strong in Western countries. The allele also seems to be associated with a more severe prognosis.[9] Its exact role in the disease mechanism is still unknown; however, it may be involved in the disease development through specific antigen presentation, molecular mimicry with microbial antigens, or participation in linkage disequilibrium with a presently unknown susceptibility gene.[10]



▲ **FIGURE 167-1** Adamantiades-Behçet disease: A multisystem disorder.

Infectious Precipitants

Adamantiades-Behçet disease is not considered contagious, as no horizontal transmission has ever been reported. However, viral and bacterial infections have been implicated in initiating immunopathologic pathways, leading to the onset of the disease.[7,8]

VIRAL AGENTS Early theories of the pathogenesis of Adamantiades-Behçet disease proposed a viral or other infectious etiology.[3] Partial transcription of herpes simplex virus type 1 (HSV-1) DNA in patients' peripheral blood lymphocytes was reported.[7] HSV-1 DNA was detected in patients' saliva and oral and genital ulcers, and HSV-1 antibodies were found in patients' serum.

BACTERIAL AGENTS The disease activity has been known to correlate with bacterial infection, particularly streptococci.[7] *Streptococcus sanguinis* dominates the flora of the oral mucosa in patients with the disease and appears to be the most relevant *Streptococcus* strain as a provoking factor for initiation of the disease.[13] *Streptococcus* antigens and anti-streptococcal antibodies are frequently found in the oral mucosa and serum of patients. The involvement of immunoglobulin A protease–producing *S. sanguinis* is proposed as an explanation for a chronic infection leading to initiation of Adamantiades-Behçet disease. High titers of the immunogenic *S. sanguinis* antigen KTH-1 have been detected in patients. In addition, exposure of the patients to *Streptococcus* antigens may be a major provoking factor for disease activity. The lipoprotein of *Mycoplasma fermentas* MALP-404 was found in the serum of patients with Adamantiades-Behçet disease but not in healthy controls.[14] Interestingly, MALP-404 contains a peptide motif, which can be presented by HLA-B51.

Immunologic Mechanisms

Immunologic mechanisms are considered to play a major role in the pathogenesis of Adamantiades-Behçet disease.[7,8,11,12] The disease has currently been classified among the autoinflammatory disorders,[15] which are caused by primary dysfunction of the innate immune system.

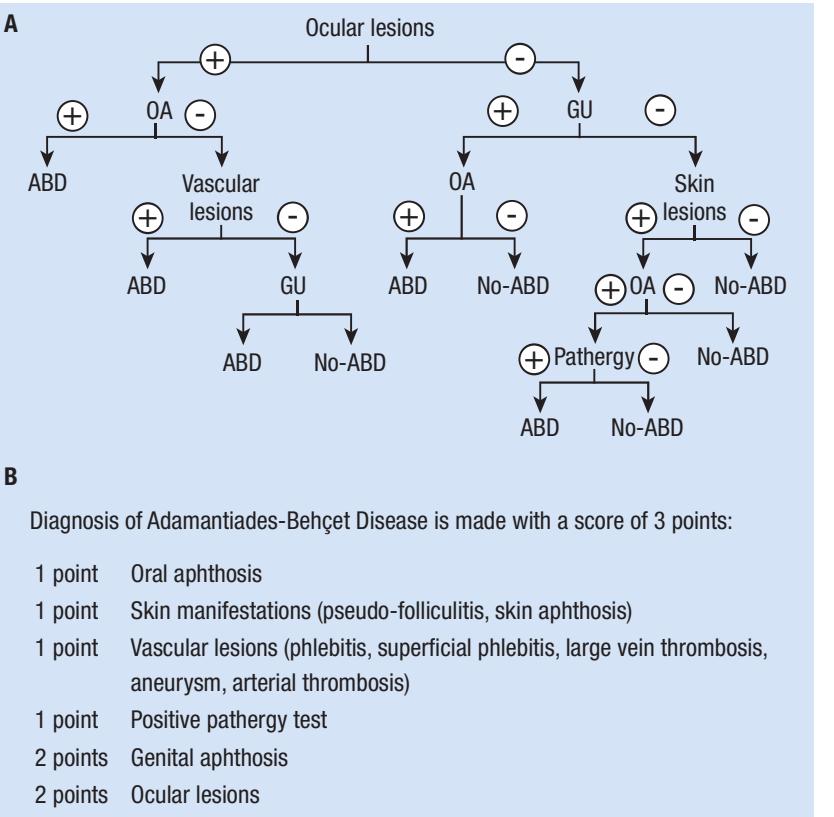
AUTOIMMUNE MECHANISMS The major microscopic finding at most sites of active disease is an immune-mediated occlusive vasculitis. The pathergy reaction (see Clinical Findings) is induced by the rapid accumulation of neutrophils (hyperchemotaxis) and later by T lymphocytes and monocytes/macrophages at the needle prick sites. T cells in the peripheral blood and in the involved tissues are increased, and a predominant T helper 1 immune response induced by interleukin (IL)-12 has recently been demonstrated.[16] Patients' lymphocytes also express CD29 molecules and bind to endothelial cells in active disease. In addition to defective T-cell immunity, B-cell activation is impaired. Circulating immune complexes, together with enhanced neutrophil migration, may be involved; diversity of T cells indicates that specific T-cell responses to several antigens may lead to the variety of symptoms.[17] Tropomyosins and the 160-kd polypeptide kinectin have been detected as autoantigens in Adamantiades-Behçet disease.[18,19]

HEAT SHOCK PROTEINS Increased levels of heat shock protein (HSP)–specific antibodies in serum have been found in Adamantiades-Behçet disease.[20] T cells respond to 60-kd HSP, and four different

peptide determinants within 60-kd HSP identified by T-cell epitope mapping have been suggested to be involved in the pathogenesis of the disease.

CYTOKINE MEDIATORS Various pro-inflammatory cytokines, such as IL-1, -8, -12, and -17 and tumor necrosis factor-α, are elevated in the sera of patients with Adamantiades-Behçet disease. In particular, IL-8 seems to play an important role, can also be released by endothelial cells, has a potent effect on the inflammatory response, and is a sensitive marker of disease activity.[21] Cytokine release may be dependent on the involved organ.

ENDOTHELIAL CELLS The endothelium seems to be the primary target; however it may just be subject to the bizarre behavior of the immune system.[22] An immunoglobulin M–type, 47-kd cell surface HSP against endothelial α-enolase was identified in the serum of patients with Adamantiades-Behçet disease.[23] Plasma endothelin-1 concentrations were found significantly increased, perhaps indicating vasoconstriction and being the direct result of elevated synthesis by injured vascular endothelial cells. Thrombomodulin, a cell surface glycoprotein of vascular endothelium, which is also increased in the plasma of patients with active disease, potentially damages the endothelial cells.



▲ **FIGURE 167-2** Revised International Criteria for Behçet's Disease (International Team for the Revision of ICBD; coordinator: F. Davatchi) according to (**A**) the classification tree format, and (**B**) the traditional format. ABD = Adamantiades-Behçet disease; GU = genital ulcer; OA = oral aphthous ulcer. (From Zouboulis CC et al: Evaluation and revision of the International Criteria for Behçet's Disease (ICBD). Abstracts of the 21st World Congress of Dermatology, Buenos Aires, Argentina, 2007, in press, with permission.)

CLINICAL FINDINGS

Adamantiades-Behçet disease is a chronic, recurrent, multisystem, and, occasionally, life-threatening disorder.[1,6] Recurrent oral aphthous ulcers, recurrent genital ulcers, skin manifestations, ocular lesions, and arthritis/arthropathy are the most frequent clinical manifestations. Vascular, gastrointestinal, neurologic, psychiatric, pulmonary, renal, and cardiac manifestations; epididymitis; and other findings can also occur. The clinical picture usually develops within a few months after the presenting sign; both an acute multisystem presentation and long-term development of the disease over years are possible.

Approach to the Patient with Oral Ulcers, Genital Ulcers, or Iridocyclitis/Posterior Uveitis

Diagnosis of Adamantiades-Behçet disease is based on clinical signs, as pathognomonic laboratory test or histologic characteristics are absent. There are several sets of diagnostic criteria, the most popular of them being the criteria of the International Study Group[24] and those of the Behçet Disease Research Committee of Japan.[25] However, there have been several problems with these criteria, including their performance in selectivity and specificity, so that both of them have currently been revised[2,26] (Fig. 167-2; Table 167-1).

Mucocutaneous Lesions

Recurrent oral aphthous and genital ulcers are the most frequently observed mucosal manifestations. Oral aphthous ulcers are the presenting sign in more than 80 percent of the cases.[1,6,12] Although recurrent aphthous stomatitis is a common disorder, only a few patients progress to Adamantiades-Behçet disease, and it is not possible to determine in whom or when the transition may occur. Typically, lesions are multiple, painful, 1 to 3 cm in diameter, and sharply margined with a fibrin-coated base and surrounding erythema (Fig. 167-3). Oral aphthous ulcers usually heal without scarring (92 percent). Genital ulcers may not recur as often and usually heal with a characteristic scar (64 percent to 88 percent; Fig. 167-4). Spontaneous healing of aphthae occurs within 4 days to 1 month; genital ulcers may persist longer. Large oral ulcerations can also be associated with problems such as pharyngeal involvement, dysphagia, and dyspnea or fistulae involving the pharynx, larynx, trachea, or esophagus. Genital ulcers can occur on the penis, scrotum, vagina, labia, and urethra, and also in the anal, perineal, and inguinal regions.

Skin lesions that should be accepted as diagnostically relevant in Adamantiades-Behçet disease should be confined to pustular vasculitic lesions (including pathergy lesions), erythema nodosum–like lesions, Sweet-like lesions, pyoderma gangrenosum–like lesions, and palpable purpuric lesions of necrotizing venulitis (see Fig. 167-6). All of these lesions are characterized in their early stages by a neutrophilic vascular reaction. Acneiform lesions or follicle-based pustules should not be considered relevant.[27]

Systemic Lesions

Ocular involvement is the major cause of morbidity in patients with Adamantiades-Behçet disease. The most diagnostically relevant lesion is posterior uveitis (also called *retinal vasculitis*), which can lead to blindness (Fig. 167-5A).

TABLE 167-1
Revised Diagnostic Criteria of the Behçet's Disease Research Committee of Japan[a]

- Main points
  - Main symptoms
    - Recurrent oral aphthous ulcers
    - Skin lesions
      - a. Erythema nodosum (see eFig. 167-8.1B)
      - b. Superficial thrombophlebitis
      - c. Papules
      - Skin hypersensitivity
    - Ocular lesions
      - a. Iridocyclitis or sequelae
      - b. Posterior uveitis or sequelae
  - Genital ulcers
  - Additional symptoms
    - Arthritis without deformity or sclerosis
    - Epididymitis
    - Gastrointestinal lesions represented by ileocecal ulcerations
    - Vascular lesions
    - Central nervous system lesions moderate or severe
- Criteria for diagnosis of disease types
  - Complete types: Four main symptoms
  - Incomplete types: Three main symptoms or two main and two additional symptoms or typical ocular lesions and another main symptom or two additional symptoms
  - Suspected disease: Typical main symptoms not fulfilling the criteria for an incomplete type
  - Special lesions: Certain gastrointestinal, vascular, and nervous system lesions
- Clinical laboratory data contributing to the diagnosis (not essential)
  - Negative or positive pathergy test
  - Negative or positive prick test to vaccinate for streptococci
  - Inflammatory response
  - Positive HLA-B51
  - Other pathologic findings
- Additional points
  - Non-typical symptoms should not be diagnosed as Behçet disease.
  - One of the criteria (a) to (c) of the skin lesions and (a) or (b) of the ocular lesions is enough for the diagnosis of the relevant symptom if the lesion occurs frequently.

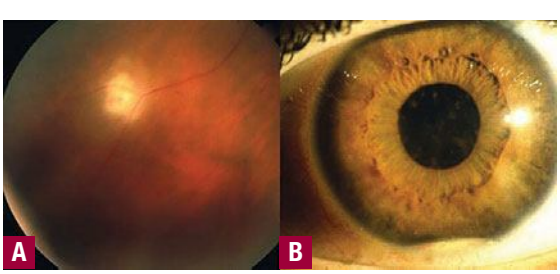
reous involvement, chronic cystoid macular edema, and possible—presumably also vasculitic—involvement of the optic nerve can result in vision loss. Recurrent vasculitic changes can ultimately lead to ischemic optic nerve atrophy.

The characteristic arthritis is a non-erosive, asymmetric, sterile, seronegative oligoarthritis; however, symmetric polyarticular involvement is common. Joint manifestations frequently occur first in one knee or ankle and then the other as migratory monoarthritis, then in both joints simultaneously, and finally affecting nearly all joints. An HLA-B27–positive, erosive sacroiliitis has to be excluded.

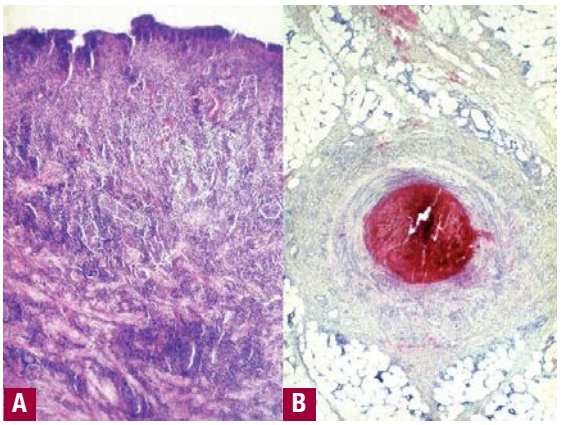
Systemic vascular involvement can be significant and includes venous occlusions and varices, arterial occlusions, and aneurysms, often being migratory. Cases of large-vein thrombosis (inferior vena cava, cranial venous sinuses) or large-artery aneurysms are potentially fatal.[1,6] Arterial involvement is rather rare and usually presents in the form of thromboses and, less often, of aneurysms, resulting from multicentric arteritis. Pulmonary artery aneurysms are the principal feature of pulmonary involvement in Adamantiades-Behçet disease, occasionally resulting in coughing and hemoptysis. Cardiac involvement can include myocarditis, coronary arteritis, endocarditis, and valvular disease. A wide spectrum of renal manifestations can occur, varying from minimal change disease to proliferative glomerulonephritis and rapidly progressive crescentic glomerulonephritis. Immune complex deposition is thought to be responsible for the underlying pathogenesis in some cases of glomerulonephritis. Gastrointestinal complaints can be a symptom for aphthae throughout the gastrointestinal tract and can rarely result in perforation and peritonitis (0.5 percent). Inflammatory bowel disease has to be excluded. Sterile prostatitis and epididymitis can be present in male patients without genital ulcers.

Significant neurologic manifestations occur in approximately 10 percent of patients and may be delayed in onset. Meningoencephalitis, cerebral venous sinus thrombosis, benign intracranial hypertension, cranial nerve palsies, brainstem lesions, and pyramidal or extrapyramidal

Other ocular lesions include anterior uveitis, hypopyon (pus in the anterior chamber of the eye, which is now—due to early treatment—uncommon; see Fig. 167-5B), and secondary complications such as cataract, glaucoma, and neovascular lesions.[28] Retinal inflammation can lead to vascular occlusion and, ultimately, tractional retinal detachment. Severe vit-



◀ **FIGURE 167-5** **A.** Posterior uveitis. **B.** Hypopyon-iritis. (From Altenburg A et al: Epidemiology and clinical manifestations of Adamantiades-Behçet disease in Germany—Current pathogenetic concepts and therapeutic possibilities. *J Dtsch Dermatol Ges* **4:**49, 2006, with permission.)



▲ **FIGURE 167-6 A.** Abundant mixed inflammatory infiltrate dominated by neutrophils in an oral ulcer of Adamantiades-Behçet disease. **B.** Vessel thrombosis in an erythema nodosum–like lesion.

lesions have been described. Poor prognosis is associated with a progressive course, relapses after treatment, repeated attacks, and cerebellar symptoms or parenchymal disease. Neurologic manifestations usually present with severe headache. Further symptoms include gait disturbance, dysarthria, vertigo, and diplopia as well as hyperreflexia, epileptic seizures, hemiplegia, ataxia, or a positive Babinski reflex. Psychiatric symptoms, such as depression, insomnia, or memory impairment, are also signs of neurologic involvement.

HISTOPATHOLOGY

Characteristic histopathologic features of Adamantiades-Behçet disease are vasculitis and thrombosis (Fig. 167-6). Biopsies from early mucocutaneous lesions show a neutrophilic vascular reaction with endothelial swelling, extravasation of erythrocytes, and leukocytoclasia or a fully developed leukocytoclastic vasculitis with fibrinoid necrosis of blood vessel walls.[1,6] Although there are reports of lesions that consist primarily of a lymphocytic perivasculitis, most of these lesions are likely older. The neutrophilic vascular reaction should be considered the predominant histopathologic finding.[27] Aneurysms can also develop in large arteries as a result of vasculitis of the vasa vasorum with penetration of the lamina elastica.

SPECIAL TESTS

Pathergy Test

A positive pathergy test (hyper-reactivity reaction) manifests within 48 hours as an erythematous papule (> 2 mm) or pustule at the site of a skin needle prick or after intracutaneous injection of 0.1 mL isotonic salt solution using a 20-gauge needle without prior disinfection of the injection site (see eFig. 167-6.1A in on-line edition). The skin prick is generally placed at an angle of 45° 3 to 5 mm intracutaneously on the volar forearm. Erythema without infiltration is considered a negative finding. Provoked oral aphthae and genital ulcers after injection or injury (such as chorioretinitis in the corneal region of the eye after photocoagulation of the ocular fundus region) can also be considered as positive pathergy phenomenon. Broader pathergy phenomena also include the occurrence of aneurysms around vascular anastomoses as well as local recurrence of ulcers after resection of affected bowel segments. Although a positive pathergy reaction is a sign of Adamantiades-Behçet disease, it is not pathognomic, as it can also occur in patients with pyoderma gangrenosum, rheumatoid arthritis, Crohn disease, and genital herpes infection.

Radiologic Findings

Scintigraphic evidence of arthritis is found in 50 percent of the patients.[6] Cranial magnetic resonance imaging allows documentation of hypodense or atrophic changes in the brain. Electroencephalographic detection of diffuse α waves is considered a positive finding. Vascular lesions can be detected by angiography.

DIFFERENTIAL DIAGNOSIS

(Box 167-1)[6,29]

Box 167-1

Differential Diagnosis of Adamantiades-Behçet Disease

- Oculocutaneous/mucocutaneous syndromes
  - Erythema multiforme exudativum and variants, including Stevens-Johnson syndrome
  - Vogt-Koyanagi-Harada syndrome
  - Reiter disease
  - Bullous autoimmune diseases: Pemphigus vulgaris, cicatricial mucous membrane pemphigoid, epidermolysis bullosa acquisita
  - Viral infections (herpes, coxsackie, echo)
  - Syphilis
- Articulomucocutaneous syndromes
  - Systemic lupus erythematosus
  - MAGIC syndrome (*m*outh *a*nd *g*enital ulcers with *i*nflamed *c*artilage)
  - Yersiniosis
  - Arthropathic psoriasis
- Gastrointestinal/mucocutaneous syndromes
  - Ulcerative colitis, Crohn disease
  - Tuberculosis
  - Bowel-associated dermatitis-arthritis syndrome
- Aphthae
  - Recurrent aphthous stomatitis (RAS)
  - Cyclic neutropenia
  - Herpes simplex infection
- Genital ulcers
  - Ulcus vulvae acutum (Lipschütz ulcer)
  - Herpes simplex infection
  - Sexually transmitted infections
- Uveitis
  - Other forms of uveitis
- Arthritis
  - Ankylosing spondylitis
  - Juvenile rheumatoid arthritis
- Central nervous system manifestation
  - Multiple sclerosis
  - Neuro-Sweet disease
- Lung manifestation
  - Sarcoidosis

CLINICAL COURSE AND PROGNOSIS

The clinical course of Adamantiades-Behçet disease is variable. There can be a delay of up to several years before the diagnosis is made, and this may influence the prognosis. Mucocutaneous and joint manifestations usually occur first. Recurrent erythema nodosum and HLA-B51 positivity are risk factors for the development of superficial thrombophlebitis and vision loss,[9,30,31] and superficial thrombophlebitis, ocular lesions, and male gender are risk factors for the development of systemic vessel involvement.[9,30,32] A severe course, including blindness, meningoencephalitis, hemoptysis, intestinal perforation, and severe arthritis, occurs in approximately 10 percent of patients. Blindness can often be prevented with early aggressive therapy of posterior uveitis. Lethal outcome

Box 167-2

Topical Treatment of Oral Aphthous Ulcers

- Mild diet
- Avoidance of hard, spicy, or salty nutrients and irritating chemicals, such as toasted bread, nuts, oranges, lemons, tomatoes, spices (pepper, paprika, curry), alcohol- or CO_2-holding drinks, mouthwashes, toothpastes containing sodium lauryl sulfate[a]
- Topical treatment of the aphthous oral ulcers includes:
  - Caustic solutions (silver nitrate, 1%–2%; tinctura myrrha, 5%–10% weight/volume; H_2O_2, 0.5%; methyl violet, 0.5%) 1–2 ×/day
  - Antiseptic and anti-inflammatory preparations (amlexanox, 5% in oral paste[a]; triclosan, 0.1% mouthwash solution and in toothpastes[a]; amyloglucosidase- and glucoseoxidase-containing toothpastes[a]; hexetidine, 1%, chlorhexidine, 1%–2% mouthwash solutions; benzydamine; camomile extracts) 3% diclofenac in 2.5% hyaluronic acid,[a] tetracycline mouthwash (as glycerine solution 250 mg/5 mL glycerine) 2 min 4–6 ×/day[a] (caveat: pregnancy), doxymycine in isobutylcanoacrylate[a]
  - Corticosteroids (triamcinolone mucosal ointment, dexamethasone mucosal paste, betamethasone pastilles) 4 ×/day or during the night (ointment/paste) or intrafocal infiltrations with triamcinolone suspension 0.1–0.5 mL per lesion
  - Anaesthetics (lidocaine, 2%–5%; mepivacaine, 1.5%; tetracaine, 0.5%–1% gels or mucosal ointments) 2–3 ×/day (caveat: allergy)
  - 5-Aminosalicylic acid (5% creme) 3 ×/day (reduces the duration of lesions and the pain intensity)
  - Cyclosporin A, 500 mg solution for mouthwash 3 ×/day (effective as topical immunosuppressive drug)
  - Sucralfate suspension, 5 mL × 4/day[a] (for oral aphthous and genital ulcers)
- A close association of smoking with a decrease of recurrences of oral aphthous ulcers has been described.

[a]Small, randomized, double-blind, placebo-controlled trial against placebo.

has been seen in 0 percent to 6 percent of affected patients in different ethnic groups. Central nervous system and pulmonary and large vessel involvement, as well as bowel perforation, are the major life-threatening complications; death may also result as a complication of immunosuppressive therapy. Markers of severe prognosis include HLA-B51 positivity, male gender, and early development of systemic signs.[9] Onset in childhood does not necessarily predict a poor prognosis. Spontaneous remissions of certain or all manifestations of the disease have been observed. Ophthalmic and neurologic sequelae are leading causes of morbidity, followed by severe vascular and gastrointestinal manifestations, and their effects on morbidity may be cumulative.

TREATMENT

The choice of treatment for patients with Adamantiades-Behçet disease depends on the site and severity of the clinical manifestations of the disease. Recurrent aphthae are most often treated with palliative agents, such as mild diet, avoidance of irritating agents, and potent topical glucocorticoids and local anesthetics[33,34] (Box 167-2). For the topical treatment of genital ulcers and skin lesions, corticosteroid and antiseptic creams can be applied for up to 7 days. Painful genital ulcerations can be managed by topical anaesthetics in cream. Corticosteroid injections (triamcinolone, 0.1 to 0.5 mL/lesion) can be helpful in recalcitrant ulcerations.

Patients with mucocutaneous lesions resistant to topical treatment, those with systemic involvement, and patients with markers of poor prognosis are candidates for systemic treatment. Several compounds have been found effective in randomized, double-blind, placebo-controlled trials[35–44] (Box 167-3). Additional treatments have been successful in studies with a lower grade of evidence.[2,12,33,45–47] Oral and intravenous

Box 167-3

Systemic Treatment of Adamantiades-Behçet Disease[a]

DRUG	DOSE	INDICATION	RCT
Methylprednisolone	40 mg/every 3 wk IM	Erythema nodosum (but not orogenital ulcers)	36
Rebamipide	300 mg/day PO (caveat: pregnancy, lactation)	Oral ulcers	37
Colchicine	1-2 mg/day PO (caveat: pregnancy, lactation—induces oligozoospermia)	Erythema nodosum, arthritis, genital ulcers, (oral ulcers in females)	38
Dapsone	100 mg/day PO (caveat: pregnancy, lactation—methemoglobin increase: ascorbic acid, 500 mg/day)	Oral ulcers, genital ulcers, skin lesions, pathergy test	39
Azathioprine	2.5 mg/kg/day (caveat: pregnancy, lactation, severe liver disease, bone marrow depression, severe infection, children)	Recent onset ocular disease	40
Interferon-α 2a	6×10^6 IU/3 ×/wk SC (caveat: pregnancy, lactation—induces psychotic signs, psoriasis, myopathy)	Oral ulcers, genital ulcers, papulopustular lesions	41
Thalidomide	100 mg/day (caveat: pregnancy, lactation—induces polyneuropathy: minimized at 25 mg/day)	Oral ulcers, genital ulcers, papulopustular lesions	42
Cyclosporin A	10 mg/kg/day PO (against colchicine, 1 mg/day PO) (caveat: lactation, renal insufficiency—induces pathologic central nervous system findings)	Ocular manifestations, oral ulcers, skin lesions, genital ulcers	43
Etanercept	25 mg/2 ×/wk PO (caveat: pregnancy, lactation)	Oral ulcers, nodular lesions, papulopustular lesions (not pathergy test)	44

[a]Evidence grade A—randomized, double-blind, placebo-controlled trial (RCT) against placebo except otherwise mentioned.

prednisolone can be combined with other immunosuppressants, colchicine, dapsone, sulfasalazine, or interferon-α. A synergistic effect with cyclosporin A has been described in patients with ocular involvement. Prednisolone is one of the few medications that can be used during pregnancy. Colchicine can be combined with immunosuppressants and interferon-α. A rapid relapse often occurs after discontinuing cyclosporin A, interferon-α, or dapsone.[46,47]

PREVENTION

- Patients with severe or progressive recurrent aphthous stomatitis should be followed up for years as potential candidates for Adamantiades-Behçet disease, particularly those patients with familial occurrence of the disease.
- Patients with suspected Adamantiades-Behçet disease should be referred early for specialist advice.
- Male patients with systemic involvement as a presenting sign and/or an early age of onset should be treated systemically because of the poor prognosis.

CHAPTER 168

Kawasaki Syndrome

Donald Y. M. Leung
H. Cody Meissner
Anne W. Lucky

Kawasaki syndrome (KS) is an acute multisystem vasculitis that primarily affects infants and young children. Although KS was originally described as a benign illness of early childhood, it is now recognized that this disease is the leading cause of acquired heart disease in children in the United States and Western Europe. Children with KS who do not receive appropriate treatment within the first 10 days of onset of fever have a 20 percent to 25 percent risk of developing coronary artery abnormalities. Early recognition and prompt treatment with the combination of intravenous immunoglobulin (IVIG) and aspirin (ASA) reduce the prevalence of coronary artery abnormalities to less than 5 percent. Thus, acute KS must be diagnosed early and treated promptly. A diagnosis of classic KS is based on the presence of fever plus at least four of five criteria listed in Table 168-1.[1] Atypical or incomplete KS may be diagnosed in a patient with fever and fewer than four criteria.

HISTORICAL ASPECTS

KS, originally called *mucocutaneous lymph node syndrome*, was first recognized and described in Japan in 1967 by Dr. Tomisaku Kawasaki.[2] He reported his experience with 50 children who had been seen during the preceding 6-year period at the Tokyo Red Cross Medical Center. These children appeared to manifest a constellation of findings distinct from any previously described disease. After this description, numerous cases were reported throughout Japan. Dr. Kawasaki's first description of the disease in the English language appeared in 1974. In 1976, the syndrome was first reported in the United States by Melish, Hicks, and Larson in a group of 12 children from Honolulu seen between 1971 and 1973. Since then, KS has been recognized worldwide in children of every racial group. The Kawasaki Disease Research Committee published the fifth revised edition of its diagnostic guidelines in 2005.[3]

TABLE 168-1
Diagnostic Criteria for Kawasaki Syndrome

Fever of 5 or more days without other explanation, and at least four of the five following criteria[a]:

- Bilateral painless bulbar nonexudative conjunctival injection
- One of the following changes in the oropharynx: Injected or fissured lips, injected pharynx, or strawberry tongue
- One of the following extremity changes: Erythema of the palms or soles, edema of the hands or feet, or periungual desquamation
- Polymorphous exanthem
- Acute non-suppurative cervical lymphadenopathy (≥ 1.5 cm in diameter)

[a]A diagnosis of atypical Kawasaki syndrome can be made when less than four criteria are present if coronary artery aneurysms are present.

EPIDEMIOLOGY

Although KS occurs worldwide in children of all racial groups, it is most prevalent in Japan and in children of Japanese ancestry.[4] KS is primarily an illness of young children, with approximately 80 percent of patients being younger than 5 years of age. The ratio of males to females is about 1.5:1.0. The incidence rate is the highest for Japanese children between 6 and 12 months of age, with equal numbers in the first and second years of life. Secondary cases of KS rarely occur in the same school, day care center, or household. Thus, person-to-person transmission of the disease appears to be unlikely. In Japan, the recurrence rate of KS is reported to be 3.9 percent and the proportion of sibling cases 1.4 percent. In those cases of patients whose parents had KS in their childhood in Japan (0.2 percent of more than 32,000 cases) there was a higher rate of sibling cases, a greater likelihood to experience recurrence, additional need for IVIG, and more coronary abnormalities 1 month after onset.[5] The rate of recurrence is highest within the first 12 months after the first episode. These studies suggest a common exposure to an infectious agent in genetically predisposed individuals.

The incidence of KS in Japan increased from 1967 to the mid-1980s.

KAWASAKI SYNDROME AT A GLANCE

- Most common cause of acquired heart disease in children, with highest prevalence in those of Japanese ancestry.
- Major features of acute Kawasaki syndrome include
  - Fever
  - Acute multisystem vasculitis
  - Polymorphous exanthem
  - Bilateral bulbar nonexudative conjunctival injection
  - Inflammation of the oropharynx
  - Erythema of the palms or soles, edema of the hands or feet, or periungual desquamation
  - Acute non-suppurative cervical lymphadenopathy (≥ 1.5 cm in diameter)
- Complications of Kawasaki syndrome include
  - Coronary artery abnormalities, including aneurysms
  - Myocarditis
  - Arthralgia and arthritis
  - Urethritis
  - Aseptic meningitis
- Prompt treatment with the combination of intravenous immunoglobulin and aspirin reduces the prevalence of coronary artery abnormalities.

Nationwide epidemics, with wave-like spread of cases, occurred in 1979, 1982, and in late 1985 to early 1986. Since the mid-1980s, the incidence of KS in Japan has increased steadily such that the incidence rate in 1998 was more than 1.5 times higher than that in 1987.[6] The endemic annual incidence of KS is approximately 111 cases per 100,000 children younger than age 5 years. Both the endemic and the epidemic form of KS in Japan occurs most commonly in the late winter and spring, with another period of slightly increased incidence during late fall. KS has been increasingly recognized in other Asian countries as well. In Taiwan between 1966 and 2002, the epidemiology was similar, with an annual incidence of 146 per 100,000 and a peak in the summer months.

Epidemiologic findings in the United States and Europe reveal striking similarities to those in Japan. KS has been reported in all parts of the United States and Europe, occurring sporadically or as temporally limited community-wide epidemic outbreaks. The highest incidence of KS in the United States has been reported from Hawaii, with a hospitalization rate of 47.7/100,000 children < 5 years of age. Within the continental United States estimates of the incidence of KS range from 9 to 19/100,000 children. The peak age is 18 to 24 months of age. More than 80 percent of cases occur in patients younger than 5 years of age, and most cases occur in patients younger than 2 years of age. Infants younger than 12 months of age, and particularly those younger than 6 months of age, appear to be at an increased risk of developing coronary artery abnormalities. In the United States, the prevalence of KS is highest among Asians, intermediate in blacks, and lowest in whites. Regardless of the racial group affected, however, the clinical picture is similar. Although antecedent respiratory illness and exposure to rug cleaning have been associated with KS, neither has been consistently identified as a risk factor.

ETIOLOGY AND PATHOGENESIS

Considerable evidence suggests that KS is a condition that results from immune activation.[7] First, the acute phase of KS is characterized by increased numbers of activated helper T cells and monocyte/macrophages, as well as a marked polyclonal B-cell activation. Second, there is increased production of multiple proinflammatory cytokines. Serum levels of interleukin (IL)-1, tumor necrosis factor (TNF)-α, IL-6, adrenomedullin, and vascular endothelial growth factor have been reported to correlate with the development of coronary artery abnormalities.[8,9] Third, the histologic lesion in coronary arteries and other medium-sized arteries suggests a role for immune-mediated vascular injury (see Pathology). Fourth, the acute phase of KS is associated with the appearance of circulating antibodies that are cytotoxic against cardiac myosin and vascular endothelial cells pre-stimulated with IL-1, TNF-α, or interferon-γ.[10] Finally, successful treatment of patients with IVIG plus ASA reduces the immune activation associated with this disease.[11] In contrast, KS patients treated with ASA alone have prolonged T- and B-cell activation.

At present, however, there is no consensus regarding the etiology of KS. It is widely hypothesized that KS represents immune activation in response to an infectious agent based on the acute, self-limited nature of this disease, seasonal incidence, geographic clustering of outbreaks, and the unique susceptibility of young children. Despite this consensus of opinion, extensive serologic, tissue culture, ultrastructural, and molecular evaluations have failed to define a single triggering agent. A few years ago, evidence suggested that the disorder was associated with a novel human coronavirus infection.[12] Using polymerase chain reaction, the virus was detected in 73 percent of 11 affected children, but only 4.5 percent of controls. Other investigators have not been able to confirm this observation, which may merely reflect the frequent clustering of cases.[13] The discussion now focuses on whether the infectious agent that triggers the immune activation in KS is a conventional antigen or whether it elaborates a superantigen. Evidence to support both possibilities continues to accrue.

In support of the theory that superantigens may be etiologic are the clinical findings in acute KS (see Table 168-1), including fever, that significantly overlap with bacterial toxin-mediated diseases such as toxic shock syndrome (TSS) or scarlet fever. The activation of T cells and monocytes/macrophages found in acute KS is characteristic of diseases caused by bacterial toxins that act as superantigens.[14] Staphylococcal enterotoxins, TSS toxin-1 (TSST-1), and streptococcal pyrogenic exotoxins (SPEs) are prototypic superantigens that stimulate a large proportion (up to 35 percent) of T cells in a human leukocyte antigen (HLA)-DR–dependent yet unrestricted manner. These bacterial toxins bind directly to conserved amino acid residues outside of the peptide antigen binding groove on major histocompatibility complex (MHC) class II molecules and selectively stimulate T cells expressing specific T-cell antigen receptor (TCR) β chain variable gene segments.

To determine whether the immune activation during acute KS results from stimulation by superantigen(s), T lymphocytes of 19 children with KS were analyzed for TCR Vβ gene usage.[15] Patients with acute KS demonstrated marked expansion of Vβ2 and, to a lesser extent, Vβ8-positive T cells. In

contrast, cells from control subjects showed no evidence for overexpression of TCR Vβs. During the convalescence phase of KS, percentages of Vβ2-positive and Vβ8-positive T cells returned to normal levels. This selective expansion of circulating Vβ2-positive T cells is similar to the changes observed in T cells from patients with staphylococcal TSS, an illness with many clinical similarities to acute KS.

Since the initial description, there have been confirmatory and non-confirmatory reports of Vβ2 expansion in acute KS.[16–26] The ability to find Vβ2-positive T-cell abnormalities in the peripheral blood of patients with acute KS may depend on the timing of the blood collection, as superantigens stimulate the expression of homing receptors, thereby triggering the migration of T cells into inflamed tissues.[16] If superantigens are involved, T-cell activation observed in the peripheral blood of acute KS is most likely mediated by a superantigen that induces Vβ2-positive T-cell expansion based on the high frequency of response but extensive β-chain junctional diversity.[27] Selective expansion of Vβ2-positive T cells in the small intestinal mucosa of patients with acute KS[28] suggests that the gastrointestinal tract may be the primary site of entry for a superantigen-secreting organism causing acute KS. One study identified potential superantigen-producing bacteria in 13 of 16 patients with acute KS (from rectal or pharyngeal, not skin, cultures), but only 1 of 15 control patients ($p < 0.0001$)[29]; of 13 toxin (superantigen)-positive cultures from patients with KS, 11 were TSST-1, secreting *Staphylococcus aureus*, and 2 of 13 were streptococci, producing streptococcal pyrogenic exotoxin B (SPEB) and SPEC. Importantly, TSST-1 and SPEB are known to possess Vβ2 stimulatory activity, whereas SPEC has both Vβ2 and Vβ8 stimulatory activity. These studies further suggest a gastrointestinal site of infection and superantigen[28] and that several superantigens may be involved.

An alternative hypothesis is that a conventional antigen-driven response leads to KS, with the respiratory tract as the site of entry.[30–33] One group has identified oligoclonal immunoglobulin A antibodies in arterial tissue from fatal cases of KS. Human antibodies, synthesized to target prevalent immunoglobulin A genes from patient arterial samples, have detected antibodies in the respiratory epithelium of 10 of 13 patients with KS and none of the nine controls; these antibodies were also detected in inflamed tissues from 17 children with KS. In the ciliated bronchial epithelia of affected children, this KS-associated protein localizes to cytoplasmic inclusion bodies that resemble aggregates of viral protein and nucleic acid.

CLINICAL MANIFESTATIONS

Dermatologic Features

The mucocutaneous manifestations of KS are varied, and not all children exhibit each feature. The major diagnostic criteria for KS are listed in Table 168-1.[1–4] KS is a triphasic illness beginning with an acute phase that lasts 7 to 14 days, followed by a subacute phase of approximately 25 days, and a convalescent phase that lasts nearly 70 days. The cardinal feature of the acute phase is a prolonged high fever that frequently spikes to 40°C (104°F) and is associated with a toxic appearance in virtually all patients. In the absence of anti-inflammatory therapy, the duration of fever is usually 1 to 2 weeks.

Approximately 90 percent of children with KS develop an exanthem in the first days of their acute febrile illness (Fig. 168-1). The eruption favors the trunk and proximal extremities but can be generalized. It can be quite variable, having been described as macular, papular, morbilliform, scarlatiniform, urticarial, and even "target-like," resembling erythema multiforme. The initial rash may be indistinguishable from an acute viral exanthem or adverse drug reaction. It is rarely pustular, vesicular, or bullous.[25] Recently, plaque-type and pustular psoriatic lesions have been described

▲ **FIGURE 168-1** A generalized morbilliform eruption appearing early in the febrile course of a 5-year-old boy with Kawasaki syndrome.

▲ **FIGURE 168-2** Generalized erythema and early desquamation in the perigenital and perineal area of a 4-year-old girl with Kawasaki syndrome. This feature occurs early in the illness and involves 67 percent of affected children.

in the acute phase.[26] There are no diagnostic histologic features.

One of the earliest signs of KS is a characteristic perineal eruption (Fig. 168-2). In one study of 58 children, 67 percent had the perineal eruption.[34] Onset is usually within the first 6 days of the illness and presents as diffuse macular or plaque-type blanching erythema involving part or all of the perineal skin. These involved areas can be warm and tender. Within 48 hours, the erythematous areas begin to desquamate. This desquamation occurs earlier than that of the palms and soles.

In 90 percent of patients, a bilateral, nonexudative, conjunctival injection begins shortly after the onset of fever and generally involves the bulbar conjunctivae more severely than the palpebral conjunctivae. Conjunctival vessels become engorged and dilated. There is no purulent discharge or crusting of the eyelashes, as is seen in bacterial conjunctivitis. Conjunctival injection is associated with anterior uveitis in approximately 83 percent of patients examined within the first weeks of illness.

Oral mucosal findings are very characteristic of KS and occur in almost all cases. The lips become "cherry" red, dry, and often cracked, producing small hemorrhagic fissures. In contrast to staphylococcal scalded-skin syndrome, there is no radial crusting of the perioral skin. There are no punctate ulcerations, as are seen in herpes gingivostomatitis or aphthae, and no diffuse erosions with confluent hemorrhagic crusts, as are seen in erythema multiforme or Stevens-Johnson syndrome (see Chaps. 38 and 39). The tongue has been described as "strawberry," with hypertrophied papillae and

▲ **FIGURE 168-3** Erythema and edema of the distal fingertips are characteristic of the early phase of Kawasaki syndrome.

hyperemia that is indistinguishable from that seen with streptococcal scarlet fever, but only about one-half of the cases seem to have this feature. Diffuse erythema of the oral mucosa is common.

Edema and erythema of the distal aspects of the hands and feet with fusiform swelling of the fingers are also noted in almost all cases (Fig. 168-3). Onset is usually within a few days of the start of illness. These hyperemic areas are subject to desquamation within 2 to 3 weeks after onset of fever during the subacute phase. The desquamation characteristically begins at the tips of the fingers and toes and may develop either fine peeling or shedding of thick "casts" of palmar and plantar skin, similar to that seen in scarlet fever (Fig. 168-4).

Generalized fine desquamation, especially in the areas of the skin that had previously been erythematous, is also common at this time. Recurrent skin peeling, especially in those children with nasal staphylococcal colonization, may occur for several years, usually after upper respiratory tract infections. Because of the severe systemic nature of the illness and the prolonged high fever, it is not surprising that some children develop telogen effluvium, with significant but transient hair loss 6 to 12 weeks after the acute phase of the illness. Similarly, Beau's lines of the nails and/or shedding of the nails have been observed weeks to months later. Transient episodes of psoriasis have been described 4 to 12 weeks after the acute phase, but none of these children has developed chronic psoriasis.[23,26] Lymphadenopathy is the least frequent finding and is seen in less than 75 percent of patients. The adenopathy generally consists of a single, enlarged, nonsuppurative cervical node measuring at least 1.5 cm. When present, adenopathy usually occurs in the anterior cervical triangle, is nonfluctuant, and is either non-tender or only slightly tender. Erythema and induration at a site of vaccination with bacille Calmette-Guérin have been described in Japan and seen elsewhere.

▲ **FIGURE 168-4** Desquamation starting at the tips of the fingers occurs 10 to 18 days after the onset of illness, as illustrated in this 3-month-old infant with Kawasaki syndrome.

Approximately 10 percent of cases do not fit the diagnostic criteria nor do they appear to have another disease. These cases have been labeled *atypical, incomplete,* or *suspected KS*.

Systemic Associations

Table 168-2 lists other associated clinical features of KS. Arthralgia and arthritis occur in approximately one-third of patients. During the acute phase, the arthritis usually involves the small joints, such as the interphalangeal joints, whereas involvement of the large weight-bearing joints is more likely to occur in the second and third weeks of the illness. Urethritis associated with sterile pyuria is frequently present in acute KS. Infants with KS often are more irritable than children with other febrile exanthems. Aseptic meningitis may be present and usually is associated with mild mononuclear cell pleocytosis of the cerebrospinal fluid and with normal glucose and protein. Hydrops of the gallbladder may be present with or without obstructive jaundice. Diarrhea, vomiting, abdominal pain, cranial nerve palsies, tympanitis, and infarction of organs in which the vascular supply is compromised by thrombosis also may be presenting signs. Sensorineural hearing loss also has been associated with KS.

During the convalescent phase, there is generally a paucity of physical findings. Patients who suffer cardiovascular complications from this illness may have persistent cardiac abnormalities, including chronic myocardial dysfunction, aortic or mitral regurgitation, and cardiac arrhythmias. Occasionally, a patient may experience clinical exacerbation, with recurrence of fever and other acute clinical signs, such as rash and conjunctival injection, after they had appeared to resolve. This occurs most often within a few weeks of onset of illness and may be associated with an increased risk of coronary artery disease.

TABLE 168-2
Associated Clinical Features of Kawasaki Syndrome

- Cardiovascular abnormalities, including myocarditis, arterial aneurysms, pericarditis, aortic or mitral regurgitation, ventricular arrhythmias
- Arthralgia and arthritis
- Urethritis with sterile pyuria
- Aseptic meningitis
- Hydrops of the gallbladder
- Diarrhea, vomiting, or abdominal pain
- Sensorineural hearing loss
- Uveitis
- Hepatic dysfunction

Cardiac Manifestations

Abnormal cardiac findings are a hallmark of KS. Myocarditis is frequently observed during the first week after onset of fever. Pericardial effusion may develop toward the latter part of the acute phase and is secondary to myopericarditis. It is rare that these patients progress to cardiac tamponade, and the pericardial effusion generally resolves spontaneously. Rarely, congestive heart failure may occur as a result of myocarditis in the acute phase. During the subacute stage, congestive heart failure is usually caused by myocardial dysfunction secondary to ischemia or infarction.

Coronary artery ectasia or aneurysms occur in nearly 25 percent of patients with KS who are not treated with IVIG. Dilatation of the coronary arteries may be detected by echocardiography beginning 7 days after the onset of fever, usually peaking 3 or 4 weeks into the illness. A minority of patients (approximately 5 percent) may suffer from aortic or mitral regurgitation due to valvulitis, transient papillary muscle dysfunction, or as a complication of myocardial infarction.

On cardiac examination, patients with acute KS often present with tachycardia and gallop rhythms, both in excess of the fever and anemia associated with the illness. In a minority of patients, a pericardial friction rub, dysrhythmias, aortic

and mitral regurgitation, the findings of congestive heart failure, and the appearance of peripheral arterial aneurysms appear during the latter part of the acute phase or during the subacute phase.

LABORATORY FINDINGS

During the acute phase of KS, patients develop a leukocytosis with a predominance of mature and immature neutrophils. A normocytic, normochromic anemia without evidence of hemolysis or reticulocytosis presents during the first week of illness and persists until the inflammatory process subsides. Increased platelet turnover occurs together with marked hypercoagulability in the acute phase. Thrombocytosis is a characteristic feature of KS and peaks typically in the third week after onset of fever at between 500,000 and 1 million/mm^3. Elevation of liver transaminases, usually two- to threefold, is common in the acute phase, usually with a cholestatic profile of elevated bilirubin and alkaline phosphatase. Sterile pyuria caused by urethritis is observed in up to 75 percent of patients during the first week of illness. Early in the disease, acute-phase reactants, such as C-reactive protein and serum α_1-antitrypsin, are increased with the onset of fever and persist for 6 to 10 weeks. Similarly, erythrocyte sedimentation rates are uniformly elevated in patients with acute KS. Elevation of the latter typically persists after resolution of fever, a feature that may help to distinguish KS from common viral illness. Although patients with KS have a polyclonal B-cell activation, their sera do not contain the usual autoantibodies associated with collagen vascular disease (i.e., no rheumatoid factor or anti-nuclear or anti-DNA antibodies). Low serum albumin levels (< 3.5 g/dL) are reported to be a risk factor for the development of coronary artery aneurysms and poor clinical outcome.[35]

Electrocardiographic changes may be present in more than one-half of patients with acute KS. These abnormalities can include prolonged PR interval, left ventricular hypertrophy, abnormal Q waves, ventricular dysrhythmias, and non-specific ST-T wave changes. Two-dimensional echocardiography has been used extensively for the assessment of ventricular function, the anatomy of the proximal coronary arteries, and the presence of a pericardial effusion. Recommendations from the American Heart Association for patients with uncomplicated KS suggest echocardiographic evaluation at the time of diagnosis, at 2 weeks, and at 6 to 8 weeks. Magnetic resonance imaging of proximal coronary artery segments may be useful in selected patients. Cardiac stress testing may demonstrate reversible ischemia in children with coronary artery aneurysms. Coronary arteriography is generally reserved for the patient with persistent abnormalities on echocardiograms or any patient with symptoms of myocardial ischemia. Angiography is useful for visualization of coronary artery stenoses and to determine the extent of collateral artery formation.

PATHOLOGY

Extensive gross and microscopic studies have been carried out at autopsy of KS patients who have died in different phases of their illness. The case fatality rate for KS is approximately 0.4 percent, with most deaths occurring secondary to the cardiovascular complications of this disease. The pathology of this syndrome has been classified into four stages, according to the duration of illness at death.[36] Stage 1 (0 to 9 days after onset) is characterized by acute vasculitis and perivasculitis of small blood vessels. Microscopically, the acute vascular lesion in KS is associated with evidence for endothelial activation and endothelial cell damage.[36,37] The lesion is also associated with the infiltration of both neutrophils and mononuclear cells. The mononuclear cells consist of activated T cells and monocytes/macrophages.[38] MHC II antigens are expressed on the coronary arterial endothelium in acute KS but not in normal controls. Interferon-γ is a potent in vivo inducer of class II MHC antigens, and IL-1, as well as TNF-α, plays an important role in the induction of leukocyte adhesion molecules. The induction of class II MHC antigens on endothelial cells, as well as the observation of leukocyte adhesion to endothelial cells in the vascular lesion of KS, suggests that cytokine-induced endothelial antigens play an important role in the pathogenesis of this disease. In the larger arteries, the initial inflammation involves the intima and the vasa vasorum without inflammation of the media. Pericarditis, myocarditis, inflammation of the atrioventricular conduction system, and endocarditis with valvulitis are also present.

Stage 2 (12 to 25 days after onset) is characterized by a marked infiltration of inflammatory cells into the media of the coronary arteries as well as other medium-sized arteries, and aneurysms with thrombosis begin to form. At this stage, it is presumed that the formation of aneurysms is occurring as the result of destruction of the blood vessel walls that follows release of proteolytic enzymes and inflammatory mediators into the media. In stage 3 (28 to 31 days), the acute inflammatory process regresses, and granulation of the coronary arteries is noted. In stage 4 (40 days to 4 years), scar formation, organization of thrombi, intimal proliferation, and neoangiogenesis continue to occur for several years after onset of the disease. This process can result in severe stenosis of the coronary arteries as well as other medium-sized arteries.

It is worth emphasizing that although coronary arteries are invariably involved in this disease, almost any other medium- or large-sized blood vessel may be involved when examined at autopsy. Aneurysm formation has been reported in the femoral, iliac, renal, axillary, and brachial arteries. KS is a systemic vasculitis that can affect most small- and medium-sized blood vessels. Cutaneous vasculitis, however, is not a prominent feature of KS.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

According to the guidelines set forth by the American Heart Association,[1] the patient with KS should have fever lasting 5 or more days without other reasonable explanation and satisfy at least four of the five following criteria (see Table 168-1): (1) bilateral nonexudative conjunctival injection; (2) at least one of the following mucous membrane changes: injected or fissured lips, diffuse injection of the oral and pharyngeal mucosa, or "strawberry tongue"; (3) at least one of the following peripheral extremity changes: erythema of the palms or soles, edema of the hands or feet during the acute phase, or periungual desquamation during the convalescent phase; (4) polymorphous exanthem; and (5) acute non-suppurative cervical lymphadenopathy (> 1.5 cm in diameter). In incomplete cases, patients with fever for ≥ 5 days and fewer than four of the principal symptoms can be diagnosed as having KS when coronary artery disease is detected by two-dimensional echocardiography or coronary angiography. In some children with prominent findings, KS can be diagnosed before 5 days of fever.[3] Therapy with IVIG and ASA should be initiated whenever the diagnosis of KS is made.

Males younger than 6 months of age are at particularly high risk for incomplete KS and have a high risk of coronary artery abnormalities. *Incomplete KS* is used to describe patients with fever for at least 5 days and at least two criteria for

KS, and no other reasonable explanation for the illness can be found. The laboratory findings are similar to those in patients with classic KS. Incomplete KS is more common in young infants, perhaps accounting for the increased risk of coronary artery abnormalities that has been described in infants < 6 months of age. The diagnosis of incomplete KS should be considered in any infant with unexplained fever for ≥ 5 days and even one of the principal features. Findings that should trigger the search for another diagnosis include discrete intraoral ulcerations, exudative conjunctivitis, and generalized lymphadenopathy, which is rarely seen in acute KS.

KS has clinical features compatible with infection, hypersensitivity reactions, or exposure to environmental toxins. It has a variety of mucocutaneous manifestations, some of which are characteristic, but many of which are shared with these other infectious and reactive disorders. As KS may resemble a multitude of skin eruptions, a site-specific differential diagnostic ladder is helpful (Box 168-1). The correct diagnosis of KS hinges on recognizing the cumulative combination of mucocutaneous, systemic, and laboratory findings. Considerations that help in eliminating certain viruses, such as measles and influenza, from the differential diagnosis include local epidemiology, vaccination history, and culture results. Viral upper respiratory tract illness, particularly due to adenovirus, may mimic the features of KS.

Because KS is based on diagnostic criteria that use clinical characteristics that overlap with other illnesses, diagnostic dilemmas can arise, particularly in atypical cases that do not completely fulfill the diagnostic criteria but that are associated with the development of coronary artery abnormalities. The decision to initiate therapy in children who do not satisfy the criteria for classic KS can be supported by laboratory results showing acute phase reactants (elevated white blood cell count, elevated sedimentation rate), an ultrasound showing a pericardial effusion, or a slit-lamp examination showing anterior uveitis.

Box 168-1

Differential Diagnosis of Cutaneous Manifestations of Kawasaki Disease (Site Specific)

Most Likely

- Lips
  - Stevens-Johnson syndrome/erythema multiforme
  - Staphylococcal scalded-skin syndrome
- Skin
  - Erythema multiforme
  - Drug reaction
  - Staphylococcal scalded-skin syndrome
  - Scarlet fever
  - Toxic shock syndrome
- Lymph nodes
  - Bacterial/tuberculous infection
- Eyes
  - Conjunctivitis
- Tongue
  - Scarlet fever
- Groin
  - Staphylococcal scalded-skin syndrome
  - Streptococcal infection
- Fingers
  - Scarlet fever (late desquamation)

Consider

- Lips
  - Cheilitis
- Skin
  - Viral exanthem (e.g., roseola, rubeola)
  - Drug reaction
  - Dilantin hypersensitivity
- Eyes
  - Leptospirosis
- Groin
  - Candidiasis

Always Rule Out

- Lips
  - Stevens-Johnson syndrome
  - Staphylococcal scalded-skin syndrome
- Skin
  - Staphylococcal scalded-skin syndrome
  - Erythema multiforme
  - Drug reaction
  - Toxic shock syndrome
- Tongue
  - Scarlet fever
- Groin
  - Staphylococcal scalded-skin syndrome
  - Streptococcal infection

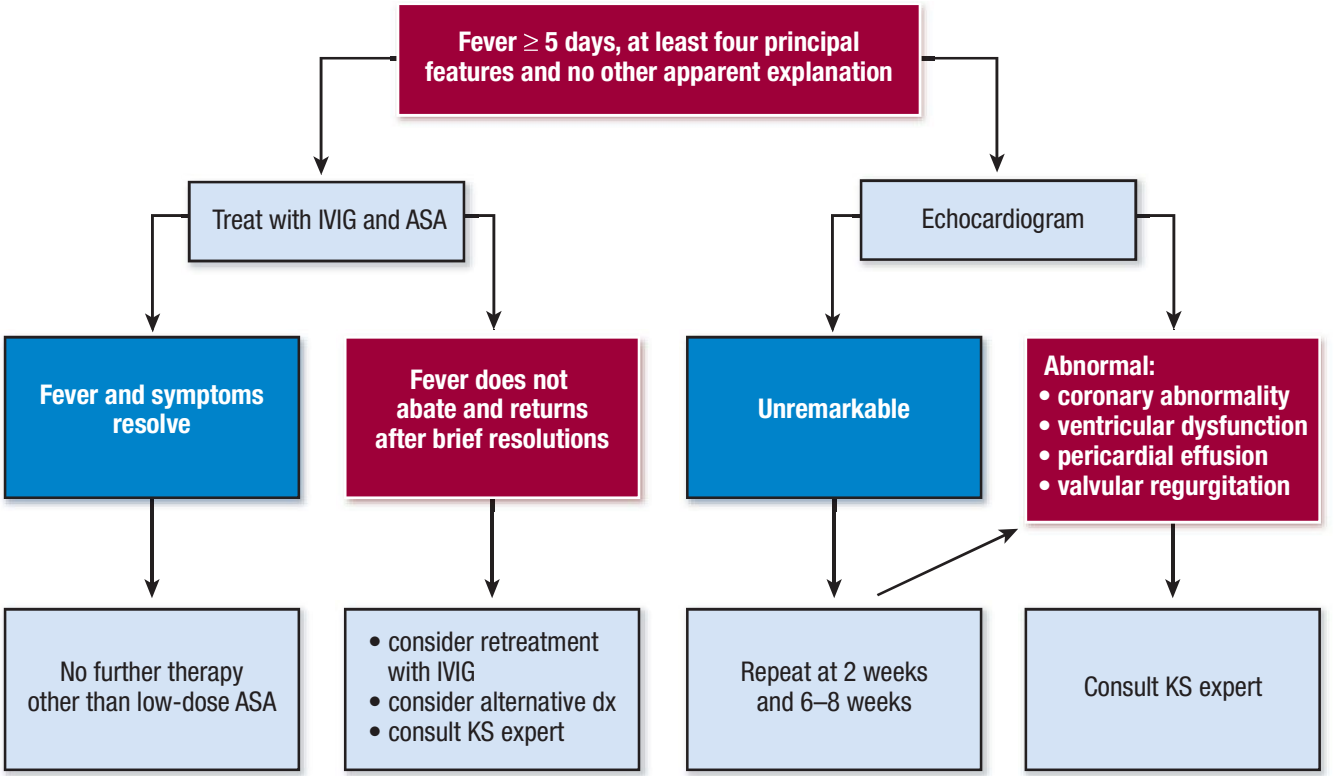
TREATMENT

Current management is aimed at reducing inflammation in the myocardium and coronary artery wall, and at preventing coronary thrombosis (Fig. 168-5). The combined use of IVIG and ASA has formed the basis of treatment of KS for nearly 20 years. ASA is used in the acute stage of illness to decrease the intensity of vasculitis and to provide inhibition of platelet aggregation. ASA will not alter the risk of coronary artery disease, although the dose may affect the duration of fever.[39] High-dose ASA (80 to 100 mg/kg/day in four divided doses) is recommended to maintain adequate serum salicylate levels because of reduced absorption and increased clearance during the acute stage of illness. After the child has been afebrile for 48 to 72 hours, a switch to low-dose ASA (3 to 5 mg/kg/day) can be made and continued until 6 to 8 weeks after onset of illness in the absence of coronary artery abnormalities. ASA therapy is continued indefinitely if coronary artery aneurysms develop and persist. Digitalis and diuretics are used as needed in the patient with congestive heart failure. In patients at risk for cardiovascular complications, some physicians add dipyridamole, 1 mg/kg body weight per day, to further inhibit platelet aggregation. Therapy of the mucocutaneous manifestations of the disease is entirely symptomatic and includes emollients for desquamating skin and antihistamines for pruritus.

No definitive prospective study has demonstrated that high-dose ASA therapy prevents coronary artery abnormalities. In contrast, several randomized multicenter studies have demonstrated that high-dose (greater than 1 g/kg) IVIG in combination with ASA therapy is safe and effective in reducing the prevalence of coronary artery abnormalities.[40–43] IVIG both reduces the overall prevalence of coronary artery abnormalities and prevents the formation of giant aneurysms, the most serious form of coronary abnormality caused by KS. Abnormalities of left ventricular systolic function and contractility also improve more rapidly in children treated in the acute phase with high-dose IVIG together with ASA than in those children treated with ASA alone.[44]

The efficacy of IVIG in prevention of coronary artery abnormalities is dose-dependent, although the optimal dose of IVIG has not been firmly established. Administration of IVIG, 2 g/kg over 10 to 12 hours as a single dose, has benefit over the earlier regimen of a 400 mg/kg dose for 4 days in terms of more rapid elimination of fever and less coronary artery disease at 2 weeks follow-up (although there is not a statistically significant difference at 7 weeks follow-up). The current standard is 2 g/kg plus salicylate before day 10 of fever, which will reduce the risk of coronary artery disease from about 20 percent to < 5 percent. The mechanism of action of IVIG is not known.

Approximately 85 percent of children treated within 10 days after onset of illness will experience prompt defervescence and resolution of signs of inflammation in response to IVIG and ASA therapy. Optimal management has not been established for children who demonstrate ongoing or recrudescent fever and other signs of inflammation 24 to 72 hours or



▲ **FIGURE 168-5** Approach to the patient with suspected Kawasaki syndrome (KS). ASA = aspirin; dx = diagnosis; IVIG = intravenous immunoglobulin.

longer after treatment.[45] For symptomatic children in whom the diagnosis of KS is still considered to be likely after one dose of IVIG, generally a second dose of IVIG, 2 g/kg, is administered because ongoing fever correlates with the presence of proinflammatory cytokines and an ongoing risk of coronary artery ectasia or aneurysm formation. In some instances a third dose of IVIG may be appropriate, although complications have been reported after large doses of γ globulin.

If fever persists after two or three doses of IVIG, intravenous methylprednisolone (pulse doses of 30 mg/kg for 3 days) can be considered. At present, the use of systemic steroids in the treatment of KS is controversial. Several studies from Japan report that patients treated with steroids alone or in combination with ASA have a higher frequency of coronary aneurysms and of subsequent myocardial infarction and death.[46] A more recent study of four patients with KS resistant to IVIG suggested a response to high-dose pulse methylprednisolone therapy (30 mg/kg once daily for 1 to 3 days).[47] In 1999, Shinohara et al. reviewed the experience with prednisolone in children with KS.[48] The authors concluded that prednisolone resulted in a shorter duration of fever and a lower prevalence of coronary artery aneurysms. However, this study was a retrospective review of patients who received different doses and different schedules of IVIG than what is currently used in the United States. Several small case series report either oral or intravenous corticosteroid use in patients with unresponsive disease despite at least two adequate doses of IVIG.[49,50] These reports suggest an improvement in symptoms without detectable progression of coronary artery abnormalities. The small number of patients studied prevents an accurate assessment of the impact of steroids on coronary artery abnormalities. Until controlled studies are available, corticosteroids should not be used routinely in patients with KS.

Other interventions that have been used in acute KS refractory to more than one dose of IVIG include plasma exchange, ulinastatin (human trypsin inhibitor), abciximab (platelet glycoprotein IIb/IIIa receptor inhibitor), infliximab (monoclonal antibody against TNF-α), and cyclophosphamide. The role of these agents in patients with refractory KS is not known.

Patients who develop coronary artery aneurysms must be monitored closely for the long-term cardiac sequelae of KS.[51] Stress echocardiography and coronary angiography may be indicated in patients with evidence of myocardial ischemia. For the KS patients with obstructive changes in one or more coronary arteries, anticoagulant therapy may be required. For more severe cardiovascular symptoms, the options include the use of intravenous streptokinase or urokinase when a thrombus is present, balloon angioplasty, and/or coronary artery bypass grafting.[52,53]

PROGNOSIS

The major long-term morbidity in KS is related to cardiovascular complications from this disease. The majority of children (50 percent to 67 percent) with arterial aneurysms will show angiographic regression within 1 to 2 years after onset of disease.[54] The likelihood of resolution of the aneurysms appears to be determined by the initial size of the aneurysm, with smaller aneurysms having a greater likelihood of regression. Some studies, however, indicate that there is evidence of persistent abnormal vascular wall morphology and vascular dysfunction at the site of regressed coronary aneurysms in patients with previous KS.[55] Patients with giant aneurysms—that is, those with a maximum diameter larger than 8 mm—have the worst prognosis. The majority of patients with giant aneurysms progress to stenosis or obstruction. Nearly all late deaths from KS occur in this subgroup of patients.

The peak time of death is 3 to 4 weeks after onset of the acute illness. Death can occur as early as during the first week of illness and as late as more than 10 years after the acute illness. During stage 1 of KS,

patients usually die of acute myocarditis or cardiac arrhythmia caused by inflammation of the atrioventricular conduction system. In stage 2 of the disease, death can result from rupture of the coronary arteries or myocarditis, including lesions of the atrioventricular conduction system, or myocardial insufficiency caused by thrombosis of the coronary arteries. Sudden death late in the illness (stage 3) or years after recovery from acute KS (stage 4) may occur as the result of myocardial infarction in children with residual coronary artery aneurysms and stenoses.

Children without known cardiac sequelae during the first month of KS appear to return to their previous state of health without cardiac impairment. A study of patients many years after resolution of acute KS, however, using high-resolution ultrasound to study endothelium-dependent vascular responses, showed evidence of persistent endothelial dysfunction, even in patients without detectable early coronary artery involvement.[56] Increased blood pressure, adiposity, and higher fasting triglyceride levels have also been reported in patients with previous KS. Thus, it is generally recommended that children with KS be followed over the long term by a cardiologist to rule out the development of myocardial dysfunction, late-onset valvular regurgitation, or premature coronary artery disease.

CHAPTER 169

Pigmented Purpuric Dermatoses

Theresa Schroeder-Devere

The pigmented purpuric eruptions are a group of dermatoses characterized by petechiae, pigmentation, and, occasionally, telangiectasia in the absence of associated venous insufficiency or hematologic disorders (Table 169-1). Synonyms include *persistent pigmented purpuric dermatitis*, *purpura simplex*, and *purpura pigmentosa chronica*. They are found most commonly on the lower extremities; however, the lesions may involve the upper body and rarely become generalized. There are reports of palm, sole, genital, and oral mucosal involvement. These benign, generally asymptomatic eruptions tend to be chronic, with remissions and flares. They share common histopathology features, including capillaritis, erythrocyte extravasation, and hemosiderin deposition.

EPIDEMIOLOGY

Pigmented purpuric eruptions are rare. There seems to be no ethnic or gender predisposition, and most patients are in their 30s and 40s (see Table 169-1), but children may be affected.

PATHOGENESIS

There are three different views of the pathogenesis of pigmented purpuric eruptions. The first is that they are due to a disturbance or weakness of the cutaneous blood vessels, leading to capillary fragility and erythrocyte extravasation. However, this does not account for the inflammatory infiltrate common to these disorders. The second proposed mechanism is humoral immunity. This suggested pathogenesis is supported by direct immunofluorescent studies showing vascular deposition of C3, C1q, immunoglobulin M, or immunoglobulin A. However, several cases have not shown these deposits. The third proposed mechanism is cellular immunity.[1,2] The infiltrate in pigmented purpuric dermatoses consists of lymphocytes, macrophages, and Langerhans cells. This inflammatory infiltrate leads to vascular fragility and subsequent leakage of erythrocytes. Aiba and Tagami used immunohistologic studies in eight cases of Schamberg disease to demonstrate that the dermal infiltrate was predominantly composed of helper-inducer T cells and OKT6-reactive cells,[3] whereas the epidermis showed intercellular staining with human leukocyte antigen (HLA)-DR antibody and OKT6 antibody. Based on this study, they concluded that a cellular immune reaction, specifically the Langerhans cell, likely plays an important role in the pathogenesis.

Pigmented purpuric dermatoses may be induced by drugs (Table 169-2),[4–14] but other causes have also been implicated (Table 169-3).[15–22] The mechanism behind drug-induced or other

PIGMENTED PURPURIC DERMATOSES AT A GLANCE

- A group of dermatoses characterized by petechiae, pigmentation, and, occasionally, telangiectasia.
- Are found most commonly on the lower extremities; however, the lesions may involve the upper body and rarely become generalized.
- Are benign, generally asymptomatic eruptions that tend to be chronic with remissions and flares.
- Share common histopathology features, including capillaritis, erythrocyte extravasation, and hemosiderin deposition.
- Clinical variation between eruptions led to their subclassification into eponymic groups.
- Frequent overlap may make differentiation difficult.

F = female; M = male.

causes may be immune-mediated; however, this is unproven. Gravity and increased venous pressure may account for the lesions localizing to the lower extremities.

TYPES OF PIGMENTED PURPURIC DERMATOSES

Progressive Pigmentary Dermatosis (Schamberg Disease)

Schamberg first described in 1901 a pigmented eruption on the legs of a 15-year-old boy that consisted of irregularly shaped reddish-brown patches with "pin head sized reddish puncta, closely resembling grains of cayenne pepper."[23]

Although described in children and adolescents, the average age of onset of Schamberg disease is in the fifth decade.[24] The lesions tend to develop insidiously on either or both lower legs. Lesions can involve the trunk or the upper extremities (Figs. 169-1 and 169-2). Schamberg disease is generally asymptomatic and persistent. Remissions and flares can occur indefinitely.

TABLE 169-2
Drugs Implicated in Pigmented Purpuric Dermatoses

- Acetaminophen
- Aminoglutethimide
- Bezafibrate
- Carbamazepine
- Carbromal
- Carbutamide
- Chlordiazepoxide
- Diltiazem
- Topical fluorouracil
- Furosemide
- Glipizide
- Infliximab
- Interferon-α
- Medroxyprogesterone acetate
- Meprobamate
- Raloxifene
- Tartrazine (food additive)
- Thiamine
- Trichlormethiazide

Purpura Annularis Telangiectodes (Majocchi Purpura)

The original case of purpura annularis telangiectodes, described by Majocchi in 1896, was a 21-year-old man with annular patches of follicular and punctate reddish-brown macules, with telangiectasias and purpura on the lower extremities.[25] The annular pattern is the distinctive characteristic of this sub-type (Fig. 169-3). The individual lesions may have central hypopigmentation and slight atrophy, with peripheral telangiectasias. Linear and irregularly shaped patterns may also occur. The lesions most often present symmetrically on the lower extremities; however, the upper extremities and trunk may be involved. The lesions are asymptomatic and usually last several months with relapses and remissions. This sub-type occurs more commonly in young adult females.

TABLE 169-3
Other Implicated Causes of Pigmented Purpuric Dermatoses

- Contact dermatitis
  - Disperse dyes
  - Paraphenylenediamine

  - Methylmethacrylate
  - Eutectic mixture of local anesthetics
- Venous stasis/acroangiodermatitis
- Step aerobics
- Rheumatoid arthritis
- Diabetes mellitus
- Benign hyperglobulinemic purpura (of Waldenstrom)/dysproteinemic purpura
- Hodgkin disease
- Hepatitis B, C
- Odontogenic infection
- Polycythemia
- Purpuric mycosis fungoides

Pigmented Purpuric Lichenoid Dermatosis (Gougerot and Blum)

In 1925, Gougerot and Blum reported a pigmented eruption on the lower extremity of a 41-year-old man.[26] The distinguishing feature of this sub-type is the primary lesion, a reddish-brown polygonal or round lichenoid papule, in association with purpura or telangiectasia. Individual papules frequently coalesce into plaques with or without overlying scale. The term *lichenoid* describes the clinical appearance rather than a histologic feature. The color and morphology of the lesions can be mistaken clinically for Kaposi sarcoma (Fig. 169-4). Like the other sub-types, this eruption is found on the lower extremities and, occasionally, the arms. It occurs in males more often than females and has a chronic course.

▲ **FIGURE 169-1** Pigmented purpuric dermatosis: Schamberg disease. Multiple, discrete, and confluent non-palpable, non-blanching purpuric lesions of many months' duration on the legs. Acute microhemorrhages resolve with deposition of hemosiderin, creating a disfiguring dark-brown peppered stain.

▲ **FIGURE 169-2** "Cayenne pepper" appearance of Schamberg disease. (Used with permission from S. Mallory, MD.)

Eczematid-Like Purpura of Doucas and Kapetanakis

Doucas and Kapetanakis reported a group of patients with an asymptomatic seasonal eruption occurring in the spring and summer.[27] Its distinguishing quality is the mild scale overlying the typical patches and pinpoint erythematous macules. These spread rapidly over a period of 15 to 30 days, involving the legs and, occasionally, the upper body. This eruption fades without treatment over several months to years.

Itching Purpura (Disseminated Pruriginous Angiodermatitis)

The acute onset and widespread involvement of orange-brown to purpuric macules with severe pruritus distinguishes itching purpura (Fig. 169-5).[28,29] It usually appears first on the lower extremities and may become generalized. This disorder also has a chronic course, but there can be spontaneous remissions. Middle-aged men are most commonly affected.

▲ **FIGURE 169-3** Pigmented purpuric dermatosis: Majocchi disease. Multiple non-palpable, non-blanching purpuric lesions arranged in annular configurations and associated with tiny telangiectasias. Note brownish discoloration of older lesions.

▲ **FIGURE 169-4** Lichenoid dermatosis of Gougerot and Blum. (Used with permission from S. Mallory, MD.)

Lichen Aureus (Lichen Purpuricus)

Marten first coined the term "lichen purpuricus" in 1958,[30] and Calnan later termed the same eruption "lichen aureus."[31] In this condition, *lichen* refers to the clinical and histopathologic descriptions. A dense, band-like, dermal, inflammatory infiltrate differentiates lichen aureus from the other pigmented purpuric dermatoses. Clinically, there are circumscribed areas of confluent gold to copper-orange to, less commonly, purple macules or papules (Fig. 169-6). Although these lesions may be intensely pruritic, they are typically asymptomatic. They are most commonly unilateral and localized on the lower extremities, but they can affect the forearms and trunk. This disorder has a predilection for young adults, with a peak incidence in the second and third decades. The lesions tend to be chronic, remaining stable or progressing slowly. Spontaneous resolution rarely occurs in adults, but in children the eruption may be self-limited.

▲ **FIGURE 169-5** Disseminated pruriginous angiodermatitis (itching purpura). (Used with permission from S. Mallory, MD.)

Unilateral Linear Capillaritis (Segmental Pigmented Purpura)

Riordan et al. reported a linear and pseudodermatomal distribution of pigmented purpura in four young men (average age, 22 years).[32] The patients all had a macular, pigmented, unilateral eruption involving the foot, leg, or buttock. Clinically, the lesions most closely represented lichen aureus; however, the pathology did not show a lichenoid infiltrate. Furthermore, all four cases resolved spontaneously in approximately 2 years, unlike the typically chronic course of lichen aureus. There are also several reported cases of segmental or zosteriform lichen aureus and Schamberg disease. Two cases have been associated with trauma, and one case preceded the development of localized morphea.[33–45]

Granulomatous Pigmented Purpura

Saito and Matsuoka reported a granulomatous variant of pigmented purpuric dermatosis in 1996,[46] and Wong reported two additional cases.[47] The

▲ **FIGURE 169-6** Lichen aureus. (Used with permission from S. Mallory, MD.)

mean age of onset was 59 years; all patients were of Asian descent, and all occurred only on the dorsum of the feet. Histopathologic examination showed a dense mononuclear cell infiltrate with granulomas in the papillary dermis, thickened capillaries, and hemosiderin deposits. The duration of the lesions ranged from 2 months to 20 years.

Pigmented Purpuric Dermatosis/ Mycosis Fungoides Overlap

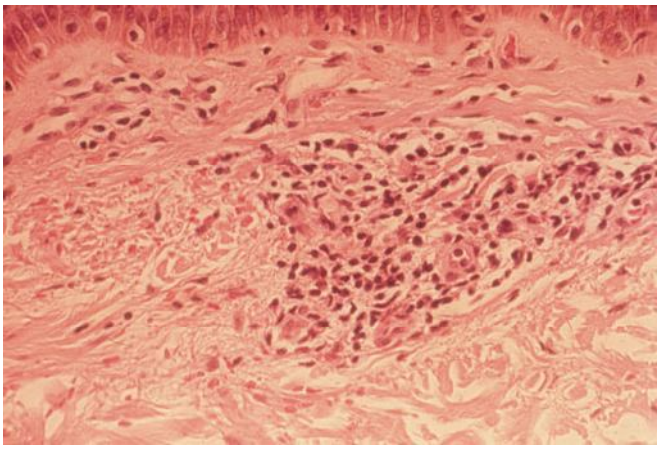
Some cases of persistent pigmented purpuric dermatoses have eventually been diagnosed as mycosis fungoides. In fact, the first patient diagnosed with lichen aureus in the United States was later diagnosed with mycosis fungoides. Is there a relationship between the two disorders, or are these cases of mycosis fungoides merely mimicking pigmented purpura clinically? Some evidence supports the idea that lichenoid variants of pigmented purpuric dermatoses may be precursors of mycosis fungoides, with similar histologic findings and clonal populations of lymphocytes.[48–55] Long-term follow-up of these patients is needed to determine if their lesions will evolve into mycosis fungoides.

HISTOPATHOLOGY

The pigmented purpuric dermatoses share similar histopathology. In early lesions, a lymphocytic perivascular infiltrate is found in the papillary dermis with extravasated erythrocytes (Fig. 169-7). The epidermis may show spongiosis and parakeratosis, especially in the pigmented purpuric lichenoid dermatitis of Gougerot-Blum and in the eczematid-like purpura of Doucas and Kapetanakis. In older lesions, there is less inflammation, and extravasated red cells may no longer be present. Hemosiderin is deposited primarily in macrophages. In lichen aureus, the mononuclear infiltrate in the upper dermis is distributed in a band-like fashion with a grenz zone.

DIAGNOSTIC STUDIES

Diagnosis is generally made clinically and supported by histopathologic examination. No consistent laboratory abnormalities have been identified. The clinical measurement of capillary fragility by application of a sphygmomanometer (Hess test) does not appear to be reliable, because some reports show an increased capillary fragility in pigmented purpuric eruptions, and others were normal. Review of the patient's medical history, medications, and potential contact allergens is advised. Skin biopsy may be indicated to rule out vasculitis, especially if the lesions are papular. Mycosis fungoides should be considered if the lesions are chronic and unremitting.



▲ **FIGURE 169-7** Pigmented purpuric dermatosis showing superficial perivascular lymphocytes and extravasated erythrocytes.

DIFFERENTIAL DIAGNOSIS

(Box 169-1)

MANAGEMENT

Treatment is often ineffective, and most treatments are anecdotal. If the eruption is induced by a drug or contact allergen, discontinuation of the causative drug or contact allergen can lead to complete resolution. However, residual pigmentation may persist for years. Oral bioflavonoid (rutoside, 50 mg bid) and ascorbic acid (500 mg bid) given to three patients with chronic pigmented purpura in an open trial led to clearance in all three patients within 4 weeks.[56] Corticosteroids have been reported to be successful; in particular, triamcinolone spray or potent topical (fluorinated) steroids. Systemic corticosteroids and cyclosporine are often effective but are not indicated due to the benign nature of the disorder.[57] With both topical and systemic steroids, recurrence of the lesions is the rule when steroids are discontinued. Treatment with topical pimecrolimus twice daily cleared lichen aureus lesions in a 10-year-old boy.[58] In a pilot study, calcium dobesilate, 500 mg twice daily, was given to nine patients for 3 months.[59] Seven patients had some mild to moderate improvement that was sustained at 1 year after cessation of therapy. Griseofulvin, 500 mg to 750 mg daily, improved existing lesions within a week and stopped new lesions within a mean of 33 days in an open trial of six patients.[60] Colchicine, 0.5 mg twice daily, cleared a 28-year-old woman with recalcitrant Schamberg disease.[61] Minocycline has also been reported to be beneficial.

Pentoxifylline, which inhibits T-cell adherence to endothelial cells and keratinocytes, may be helpful. A randomized, investigator-blinded trial compared pentoxifylline, 400 mg thrice daily, with topical betamethasone dipropionate cream, 0.05 percent twice daily, for 2 months. Patients treated with pentoxifylline had significantly greater improvement than those treated with the topical steroid. However, the response was not sustained after discontinuation of the medication.[62] Psoralen and ultraviolet A light and narrow band ultraviolet B have both been reported to clear lesions.[63–66] The phototherapy-induced immunosuppression of cell-mediated response is the proposed mechanism. Supportive stockings should be worn when lesions are on lower extremities.

Box 169-1

Differential Diagnosis of Pigmented Purpuric Dermatoses

- Contact dermatitis
- Cutaneous necrotizing vasculitis
- Stasis dermatitis and purpura
- Angioma serpiginosum
- Kaposi sarcoma (Gougerot-Blum)

CHAPTER 170

Cryoglobulinemia and Cryofibrinogenemia

Milan J. Anadkat
Lynn A. Cornelius
Thomas J. Lawley

CRYOGLOBULINEMIA

Epidemiology

Cryoglobulins are circulating immunoglobulins complexed with other immunoglobulins or proteins that reversibly precipitate in the cold. Wintrobe and Buell first noted the existence of cryoproteinemia as a clinical entity in 1933.[1] They noted precipitates of varying size within sera stored at low temperature that disappeared during incubation at 37°C (98°F). Lerner and Watson coined the term *cryoglobulins* in 1947.[2] They also performed the first large-scale examination of patient sera for cryoglobulins and identified precipitates in 11 percent of the specimens examined. Incidence rates vary, however, depending upon the patient population examined.

Etiology

The classification of cryoglobulinemia described by Brouet et al.[3] consists of three distinct groups: types I, II, and III, based upon immunoglobulin type (Table 170-1). Type I cryoglobulins consist of a single monoclonal immunoglobulin, typically immunoglobulin G (IgG) or IgM. Patients with type I cryoglobulinemia usually have an underlying hematologic malignancy, such as multiple myeloma or B-cell lymphoma. These patients may present with occlusive vasculopathy or may not exhibit any specific clinical manifestations.

TABLE 170-1
Types of Cryoglobulin[a]

- Simple (single-component) cryoglobulins (type I)
  - IgG
  - IgM
  - IgA
  - Immunoglobulin light chain
  - Complexed to other proteins
- Mixed cryoglobulins
  - IgM rheumatoid factors
    - Monoclonal (type II)
    - Polyclonal (type III)

Ig = immunoglobulin.
[a]The M components seen in types I and II cryoglobulinemias are most frequently IgM molecules, and it has been estimated that approximately 10% of all Waldenström macroglobulins are cryoprecipitable. IgM type I cryoglobulins are approximately 1.5 times more prevalent than IgG type I cryoglobulins. Thus, significant skewing exists among type I cryoglobulins in the IgM isotype, especially considering that, overall, IgM accounts for only about 15% of gammopathies, a number that reflects closely the contribution of this isotype to the total vascular body pool of immunoglobulins. This skewing toward IgM is even more striking among type II cryoglobulins, which are almost invariably IgMκ molecules utilizing the VκIII subgroup and selective V-region heavy- and light-chain genes.
Reproduced with permission from Kallemucukkal U, Gorevic, PD: Evaluation of cryoglobulins. *Arch Pathol Lab Med* **123**:119, 1999.

Mixed (type II and type III) cryoglobulins are immune complexes consisting of a rheumatoid factor (RF, the antibody), usually IgM, complexed with IgG (the antigen). Type II cryoglobulins are single monoclonal immunoglobulins (usually IgM) that co-precipitate with polyclonal IgG. Type III cryoglobulins are polyclonal immunoglobulins that form cryoprecipitates with polyclonal IgG or a nonimmunoglobulin serum component. These monoclonal (type II) or polyclonal (type III) RF-IgG complexes usually occur with a concomitant disease process such as connective tissue disease, infection, hepatic disease, or lymphoproliferative disease. Patients with mixed cryoglobulinemia typically present with vasculitis.

CRYOGLOBULINS AT A GLANCE

- Cryoglobulins are circulating immunoglobulins complexed to other immunoglobulins or proteins that reversibly precipitate in cold temperatures.
- Type I cryoglobulins consist of a single monoclonal immunoglobulin, typically immunoglobulin G (IgG) or IgM.
- Patients with type I cryoglobulinemia present with a noninflammatory occlusive vasculopathy.
- Mixed (type II and III) cryoglobulinemia is an immune complex disease resulting in an inflammatory vasculitis and glomerulonephritis.
- Type II cryoglobulinemia consists of a monoclonal antibody, usually IgM, complexed with polyclonal IgG. Type III cryoglobulinemia consists of polyclonal antibodies that precipitate with either polyclonal IgG or another serum component.
- Purpura, typically at a distal site, is the cutaneous hallmark of cryoglobulinemia. Livedo reticularis, acrocyanosis, ulceration, or gangrene may also be seen.

The term *essential cryoglobulinemia* is reserved for instances of mixed cryoglobulinemia without an identifiable underlying disease. A majority of patients with essential mixed cryoglobulinemia were historically found to have evidence of chronic active hepatitis or cirrhosis, but the exact triggering antigen was unable to be localized. In 1977, Levo et al. identified hepatitis B surface antigen, hepatitis B surface antibody, or Dane particles within patients' sera and

cryoprecipitates, and implicated the hepatitis B virus as the causative agent.[4] Later studies invalidated these findings, however.[5,6] In the early 1990s, authors first began to describe a relationship between hepatitis C virus (HCV) and the presence of mixed cryoglobulinemia.[7–10] The prevalence of HCV antibody and/or RNA in serum samples of patients with the diagnosis of essential mixed cryoglobulinemia ranged from 44 percent to 96 percent of patients studied, as documented by recombinant immunoblot assay or polymerase chain reaction, respectively.[11] Chronic HCV infection may result in either type II or type III cryoglobulinemia; however, type II cryoglobulins are the most commonly isolated precipitates. It is now believed that the vast majority of historical cases previously classified as essential cryoglobulinemia actually represent instances of HCV-associated mixed cryoglobulinemia. Patients with type I cryoglobulinemia may be seropositive for HCV at a low incidence. By definition; however, the cryoprecipitate does not contain the virus or antibody.

It is unclear why only select patients with chronic HCV develop mixed cryoglobulinemia. The role of host factors such as immunoglobulin subsets has been shown to be insignificant thus far. Some propose that a specific viral phenotype may predispose to vasculitis, most notably HCV genotype 2a.[12] Others postulate that HLA sub-types play a role in the development of HCV-associated mixed cryoglobulinemia. Cacoub et al. examined 158 HCV infected patients and found an increased risk of mixed cryoglobulinemic vasculitis in patients with HLA-DR11 phenotype; conversely, a decreased incidence of vasculitis was seen in patients with HLA-DR7.[13]

Pathogenesis

TYPE I CRYOGLOBULINS Type I cryoglobulins are monoclonal immunoglobulins, typically IgG or IgM, although IgA and Bence Jones proteins have been identified. In a review of 86 patients with cryoglobulinemia, Brouet et al.[3] reported that 25 percent of patients had only monoclonal cryoglobulins with a predominance of IgM immunoglobulin. A larger cohort study of 443 patients was conducted by Trejo et al.,[14] in which 90 cryoprecipitates were analyzed, revealing 34 percent of patients with type I disease; IgGκ and IgMκ were equally represented. Complement components are not routinely found within type I cryoprecipitates. Type I cryoglobulins, even when present in large amounts, may not result in signs or symptoms of disease.

Type I cryoglobulins demonstrate a self-association of monoclonal immunoglobulins at temperatures ranging from 0° to 30°C (32° to 86°F) or more. Monoclonal cryoglobulins are present in substantial amounts, often ranging from 1 to 30 mg/mL. They may precipitate as a gel, a flocculent precipitate, or in some instances as crystals. The specific physical forces involved in causing precipitates of type I cryoglobulins seem to include temperature-induced conformational changes, deficient carbohydrate side chains, and nucleation reactions.

The large molecular size of IgM monoclonal cryoglobulins may predispose these immunoglobulins to precipitation; some believe that cryoprecipitation may represent an extension of normal immunoglobulin solubility. In certain monoclonal IgG cryoprecipitates, earlier work suggested that the cryoprecipitate determinant resided in the variable region of the immunoglobulin, because the activity could be retained in the F(ab′)2 fragment.[15] Some idiotypic relatedness may exist among monoclonal IgG cryoglobulins, suggesting similar variable region structures and, possibly, similar antigenic specificity.[16]

MIXED CRYOGLOBULINS Types II and III cryoglobulins are typically present in relatively small amounts. These monoclonal (type II) or polyclonal (type III) RF-IgG complexes usually occur with a concomitant disease process such as connective tissue disease, infection, hepatic disease, or lymphoproliferative disease. The exception, as mentioned earlier, is the occurrence of "essential" mixed cryoglobulinemia, where an underlying disease process cannot be identified.

Type II cryoglobulins consist of two immunoglobulin components, one of which is monoclonal. The most common scenario is that of a monoclonal IgM RF complexed with a polyclonal IgG. Some evidence suggests that there is an increased prevalence of κ light chains in the monoclonal IgM, and that the monoclonal IgM has restricted specificity for IgG. A typical monoclonal spike is not always apparent on immunoelectrophoresis in type II cryoglobulinemias, even at relatively high serum concentrations. IgG monoclonal RFs are identified in a small percentage of patients with type II cryoglobulinemia, and IgA monoclonal RFs are rare.

Certain monoclonal IgM idiotypes have been preferentially associated with type II mixed cryoglobulinemia. Chronic HCV infection drives a non-malignant monoclonal B-cell expansion that typically regresses with antiviral therapy. These B cells produce a monoclonal IgM with polyreactive RF activity. This monoclonal IgM clone displays cross-reactivity with the Wa^+ idiotype, which is encoded by the Ig heavy chain variable gene V_H1-69 and the light chain variable gene V_L kv325.[17] HCV infection-driven lymphocyte proliferation may result in lymphocyte transformation into a B-cell non-Hodgkin lymphoma, which is characterized by the production of a monoclonal IgM cryoglobulin with RF activity. Specific VH and VL genes also encode the majority of antibodies expressed in these tumors, notably V_H1-69 and V_L kv325.

Type III cryoglobulins usually occur in low concentration and consist of polyclonal immunoglobulin complexes or polyclonal immunoglobulin-nonimmunoglobulin cryoprecipitates. These cryoglobulins are found in association with diseases that may involve the formation of immune complexes; IgM-IgG cryoglobulins are the most frequent scenario. The finding of complement system components, particularly C1q,[18] provides evidence for the immune complex nature of this phenomenon. Indeed, these cryoglobulins may activate complement in vitro, and patients with type III cryoglobulinemia often have decreased serum complement levels. Both autologous and exogenous antigens have been found associated with polyclonal immunoglobulins in this disease.

Analysis of types II and III cryoglobulins often reveals the presence of complement in addition to immunoglobulins. More specifically, type II cryoprecipitates may fix complement, where in type III disease, complement may be an integral component of the cryoprecipitate. Early work on the complement system in cryoglobulinemia revealed decreased "functional complement activity" (CH50), C1, C4, and C2.[19] A number of clinical studies have since identified patients with mixed cryoglobulinemia with depressed levels of C3, along with decreased levels of CH50, C2, and C4.[14] Similar studies have shown that patients with HCV-associated cryoglobulins demonstrate a higher frequency of hypocomplementemia than do patients without HCV. Cold-dependent activation of complement is common in the setting of HCV[20] and may itself affect CH50 levels in these patients.

TABLE 170-2
Clinical and Laboratory Findings with Cryoglobulinemia

- Type 1[a]
  - Severe cold-dependent symptomatology, including
    - Raynaud syndrome
    - Acrocyanosis of the digits or helices of the ears
    - Gangrene in the absence of other known causes of vascular occlusion
    - Livedoid vasculitis
    - Gelling of blood on blood drawing
    - Pathologic evidence of occlusive vasculopathy due to immunoglobulins
- Type II
  - Clinical presentation of
    - Cutaneous vasculitis-purpura/leg ulcers
    - Arthralgias/arthritis
    - Immune-complex nephritis
    - Neuropathy
  - Renal disease characterized histologically by
    - Membranoproliferative glomerulonephritis
    - Hyaline inclusions in glomeruli, positive for immunoglobulin M
    - Vasculitis
    - Congophilic-negative fibrillar inclusions in glomeruli by electron microscopy
  - Sjögren syndrome complicated by nephritis, glomerulonephritis, or gammopathy
  - Chronic hepatitis with extra-hepatic clinical manifestations
  - High-titer rheumatoid factor activity in the absence of rheumatoid disease
  - Markedly depressed levels of C4
- Type III
- Chronic infections (e.g., bacterial endocarditis) complicated by vasculitis, nephritis
  - Extra-articular manifestations of rheumatoid arthritis
  - Vasculitis and/or nephritis complicating:
    - Known rheumatic diseases
    - Chronic inflammatory liver diseases
    - Chronic inflammatory bowel diseases

[a]Many patients with type I cryoglobulins do not manifest specific symptomatology, suggesting that other factors may be important to the clinical expression of disease.
Reproduced with permission from Kallemucukkal U, Gorevic PD: Evaluation of cryoglobulins. *Arch Pathol Lab Med* **123**:119, 1999.

▲ **FIGURE 170-1** Leukocytoclastic vasculitis in a patient with mixed cryoglobulinemia manifested as palpable purpura and acrocyanosis. Patient with tuberculosis, positive anti-nuclear antibody, and hepatitis.

Clinical Findings (Table 170-2)

HISTORY Cryoglobulinemia may be painless (type I) or painful (type II or III) and typically appears as a shower of purpura, especially over the distal extremities. Patients should be questioned regarding the onset of their lesions and associated symptoms. Interestingly, cold sensitivity is not an invariable feature of cryoglobulinemia. A thorough review of the medical history will help to exclude similar vasculopathies in Differential Diagnosis. A targeted review of systems will guide the physician towards potential complications (arthralgias, visual changes, hematuria) or underlying disease triggers (i.e., infection, connective tissue disease, etc.).

CUTANEOUS LESIONS Purpura is considered to be a cutaneous hallmark of cryoglobulinemia. It is usually located distally, most typically on the lower extremities. Showers of these lesions may occur spontaneously, provoked by cold exposure or induced by long periods of standing or sitting. The appearance of purpura is usually preceded by local pricking sensations or paresthesia, not frank pain. Resultant ulcerations characteristically appear above the malleoli and often spontaneously regress.

Noninflammatory purpura, with histologic evidence of an amorphous eosinophilic precipitate within the vasculature, is characteristically seen in type I cryoglobulinemia and less commonly occurs in types II and III disease. Raynaud phenomenon is frequently evident, involving the hands, feet, ears, nose, or lips. Acrocyanosis, livedo reticularis, arterial thrombosis, and gangrene have also been reported to occur with type I cryoglobulinemia.[14,21]

Leukocytoclastic vasculitis (see Chap. 164), presenting clinically as palpable purpura, is the characteristic hallmark of mixed cryoglobulinemia (Fig. 170-1). The lesions are intermittent in nature (typically lasting 3 to 10 days) and usually are non-pruritic. Cutaneous manifestations such as Raynaud phenomenon, cutaneous vasculitis, psoriasis, porphyria cutanea tarda, lichen planus, urticaria, urticarial vasculitis, and cold urticaria have also been described.[22–24]

RELATED PHYSICAL FINDINGS The clinical picture of cryoglobulinemia is often heterogeneous. The organ systems typically affected in cryoglobulinemia are the skin, kidneys, liver, and musculoskeletal and nervous systems. Patients may also have serum cryoprecipitates in the absence of clinical symptoms. Typically, type I cryoglobulins are associated with thrombotic vasculopathy, presenting as acrocyanosis, retinal hemorrhage, Raynaud phenomenon, or arterial thrombosis. Renal disease and peripheral neuropathy are much less common.

Types II and III cryoglobulins are associated with arthritis, arthralgias, renal disease, and neurologic symptoms. Few studies exist comparing HCV-positive and HCV-negative cryoglobulinemic patients. Most believe that cutaneous and systemic disease is much more severe in HCV-positive patients, but more recent studies have found little difference between the two cohorts. The most recent comparison by Rieu et al. of 49 patients with symptomatic cryoglobulinemia found HCV-positive patients to differ only by increased transaminase levels and more severe arthralgias.[25]

Renal Disease. Early reports indicated that up to 60 percent of patients with essential mixed cryoglobulinemia have, or will develop, renal involvement.[15] Later studies have demonstrated a slightly lesser frequency.[26] Pathologic evaluation classically reveals predominantly a membranoproliferative glomerulonephritis. In fact, a specific membranoproliferative

"cryoglobulinemic glomerulonephritis" has been recognized in association with HCV-induced type II cryoglobulinemia having characteristic findings.[27] The initial clinical presentation of membranoproliferative glomerulonephritis may include diastolic hypertension, edema, or frank renal failure. Laboratory findings may include proteinuria, hematuria, pyuria, and red call casts. In contrast to skin, immunofluorescence is typically positive and reflects the immunoglobulin and/or complement components identified in the isolated cryoprecipitate.

Other Physical Findings. Articular manifestations, more common in types II and III cryoglobulinemia, rarely present as distinct arthritis, but rather as arthralgias. The knees, hips, metacarpophalangeals, and proximal interphalangeals are the most commonly affected sites.

Hepatic involvement was initially described in a majority of patients with "essential" mixed cryoglobulinemia, as discussed earlier (see Etiology); these patients are now recognized to have positive hepatitis B or C serologies. Hepatomegaly and splenomegaly may be evident, as well as liver function abnormalities. Histologic evaluation of transcutaneous liver biopsies reveals a variety of findings: microsteatosis, portal lymphoid aggregates, sinusoidal cell hyperplasia, intralobular necrosis, and changes consistent with active chronic hepatitis, or cirrhosis.

Neurologic symptoms are typically peripheral and believed to occur secondary to epineural vasculitis. Peripheral neurologic disease can present with one of two distinct forms. The majority of affected patients develop a progressive, chronic distal sensory polyneuropathy of the lower legs. Conversely, an acute mononeuritis multiplex may result with loss of strength, often manifesting as a foot-drop. Central nervous system involvement, such as transient dysarthria, hemiplegia, or confusion, is less common.

Other constitutional manifestations, such as fever, weight loss, asthenia, or diffuse abdominal pain, may also occur.

ASSOCIATED DISEASES (Table 170-3) Lymphoproliferative disease, autoimmune disorders, and infectious etiologies are the most frequently associated diseases. Human immunodeficiency virus infection may be present, usually co-existent with HCV. Lymphoproliferative diseases, such as macroglobulinemia and lymphomas, are associated with types I and II cryoglobulins; autoimmune disorders and HCV are associated with types II and III (see Pathogenesis). Autoimmune disorders, especially rheumatoid arthritis, systemic lupus erythematosus, and Sjögren syndrome, are associated with 15 percent of patients with type I and with 26 percent of patients with mixed cryoglobulinemia.[14]

TABLE 170-3
Disease Associations

- Type I
  - Multiple myeloma
  - Waldenström macroglobulinemia
  - Other lymphoproliferative diseases with M components
- Type II
  - Chronic hepatitis C virus infection[a]
  - Sjögren syndrome
  - Waldenström macroglobulinemia
  - Chronic lymphocytic leukemia
  - Non-Hodgkin lymphoma
  - Autoimmune diseases
  - Cold agglutinin disease
- Type III
  - Chronic infections
    - Viral (Epstein-Barr virus, cytomegalovirus, human immunodeficiency virus, hepatitis viruses)
    - Bacterial (subacute bacterial endocarditis, leprosy, spirochetal)
    - Fungal, parasitic
  - Autoimmune diseases
    - Systemic lupus erythematosus
    - Rheumatoid arthritis
    - Inflammatory bowel diseases
    - Biliary cirrhosis

[a]The authors believe that the majority of cases previously designated as essential cryoglobulinemia actually represented undiagnosed hepatitis C infection.

Laboratory Tests

Kallemuchikkal and Gorevic described the isolation and characterization of cryoglobulins in detail.[28] When cryoglobulinemia is suspected, blood is drawn with a syringe warmed to 37°C (98.6°F) and left to clot at the same temperature. Serum obtained by centrifugation of the blood at 37°C (98.6°F) is then refrigerated at 4°C (39.2°F) for several days. If positive, a cryoprecipitate will form at the base of the test tube (Fig. 170-2). Initial screening includes the determination that the precipitate is capable of resolubilization when the serum is re-warmed. Once formed, the cryoprecipitate is isolated, resuspended in saline at 37°C (98.6°F), and the protein components are characterized by immunofixation. Most type I cryoprecipitates will be evident within 24 hours, whereas mixed type III cryoglobulins may require several days of cold incubation for precipitation. Therefore, it is important to hold serum for approximately 1 week before final determination is made of the presence of a cryoprecipitate. Cryoglobulins may become associated with serum lipids and remain suspended during centrifugation, thereby obscuring the formation of a visible precipitate.[29] Conversely, in patients undergoing heparin therapy, an insoluble cryoprecipitate may form with other serum proteins, specifically fibronectin.[30]

▲ **FIGURE 170-2** Whitish cryoprecipitates after keeping tube at 4°C (39.2°F) for 48 hours and centrifugation.

Once a cryoprecipitate is identified, additional serum studies may aid in their further determination. Although not always present, serum protein electrophoresis may demonstrate the presence of a monoclonal spike, suggesting a gammopathy consistent with type I or II cryoglobulins. Detection of cryoglobulin can be increased by collecting the sample, and running the electrophoresis, at 37°C (98.6°F). Serum immunofixation will characterize an identified monoclonal spike, which involves electrophoretic serum protein separa-

tion on an agarose gel, followed by incubation with antisera specific to immunoglobulin classes and light-chain types. This method is highly sensitive for immunotyping a monoclonal gammopathy.[31] Quantitative immunoglobulin determination may aid in further identification of cryoglobulin-associated diseases (i.e., lymphoproliferative diseases).

The concentration of cryoglobulins may be expressed as a percentage of the volume of the total collected serum (cryocrit), or, alternatively, as the concentration of protein in the dissolved cryoprecipitate (expressed in milligrams per milliliter). Type I cryoglobulins are typically present in concentrations greater than 5 mg/mL. In contrast, type III cryoglobulins are usually present in lesser amounts (i.e., cryocrit < 1 percent).[32] Symptom severity does not necessarily reflect cryoprotein concentration in the serum or the temperature at which cryoprecipitation takes place.[33] Isolated cryoglobulin precipitates are typed by immunofixation, immunoblotting, two-dimensional gel electrophoresis, and capillary zone electrophoresis.[28] Immunofixation methods are the most sensitive and most widely used.

Differential Diagnosis (Box 170-1)

Box 170-1

Differential Diagnosis of Cryoglobulinemia and Cryofibrinogenemia

- Autoimmune disease
  - Lupus erythematosus
  - Scleroderma
  - Dermatomyositis
  - Rheumatoid arthritis
  - Anti-phospholipid antibody syndrome
- Hematologic disease
  - Protein C or S deficiency
  - Disseminated intravascular coagulation
  - Thrombotic thrombocytopenic purpura
  - Idiopathic thrombocytopenic purpura
- Vasculopathies
  - Thromboangiitis obliterans
  - Leukocytoclastic vasculitis
  - Henoch-Schönlein purpura
  - Cholesterol emboli
  - Septic emboli
- Infectious etiologies
  - Hepatitis C
  - Rocky mountain spotted fever
  - Meningococcus
- Drug-related reactions
  - Raynaud
    - Bleomycin
    - Ergot
  - Livedo reticularis
    - Amantadine
  - Purpura
    - Warfarin
    - Heparin

Treatment

Treatment of cryoglobulinemia is based on the severity of disease presentation. Mild cutaneous symptoms may not require therapeutic intervention. Nonsteroidal anti-inflammatory drugs may improve dermatologic and articular manifestations. More severe visceral involvement, particularly renal disease, may require corticosteroid therapy in conjunction with cytotoxic agents. Melphalan, chlorambucil, or cyclophosphamide may benefit some patients with underlying lymphoproliferative disorders. Rituximab, a chimeric monoclonal anti-CD20 antibody proven to be efficacious against B-cell lymphomas, has been shown to be efficacious in type II disease,[34] but has questionable benefit in type I disease.[35]

Plasmapheresis has been used in patients with rapidly progressive disease refractory to conventional therapy, but a postpheresis rebound in disease activity may occur. Plasma exchange successfully decreases the hyperviscosity seen in type I disease and is usually instituted together with immunosuppressive or cytotoxic agents in an attempt at better disease control as well as avoidance of rebound. Cryofiltration is a method of combining a refrigerated membrane unit with pheresis and has been used in patients refractory to more conventional therapy.[36]

Patients with HCV-associated cryoglobulinemia have experienced only marginal success with interferon-α (IFN-α) monotherapy.[37–39] There also exist concerns regarding potential complications of IFN in the setting of systemic cryoglobulinemia, such as neuropathy, renal crisis, or delayed ulcer healing.[40] Other studies attempting to combine IFN-α with ribavirin have provided improved results. The current standard of treatment for patients with chronic HCV infection is with combination polyethylene glycol-IFN-α and ribavirin; the resultant antiviral response achieved with this regimen over 18 to 24 months makes it the best choice for HCV-mediated vasculitis, as well.[41] Similarly, patients with mixed cryoglobulinemia in the setting of chronic hepatitis B may show benefit with lamivudine.[42]

CRYOFIBRINOGENEMIA

Epidemiology

Cryofibrinogenemia is an extremely uncommon disorder characterized by precipitation of patients' native fibrinogen or fibrin by-products. Symptomatic disease due to cryofibrin precipitates is even more rare. One study by McKee et al. reported the prevalence of essential cryofibrinogenemia as 3 percent (among 135 healthy residents) in Oklahoma City.[43] The same study noted the prevalence of secondary cryofibrinogenemia among 665 hospitalized patients to be 13 percent; samples from these patients were observed for 48 hours. Another study by Smith et al. examined 36,000 hospitalized patients and noted the prevalence of secondary disease at only 3.4 percent; blood samples from this study were only followed for 24 hours, however.[44] Secondary cryofibrinogenemia has a female predilection, reportedly occurring at a female-male ratio of 4:1.[44] Whether this is due to the higher incidence of connective tissue disease in women has not yet been validated. An age or racial predilection does not appear to exist, however.

Such epidemiologic data on primary and secondary cryofibrinogenemia are somewhat outdated, and interpretation of findings is often difficult. In fact, most authors recommend observing blood samples for 72 hours to detect cryofibrinogens, and, as with the studies cited above, a majority of prior studies failed to follow this protocol. In addition, the characteristics of hospitalized patients have changed over the years

CRYO-FIBRINOGENS AT A GLANCE

- Cryofibrinogens are protein complexes that precipitate in both cooled serum and plasma. They consist of fibrin, fibrinogen, or fibrin split products complexed with albumin, plasma proteins, or immunoglobulins.
- Cryofibrinogenemias are classified as either primary, with no known etiology or precipitating underlying disease, or secondary.
- The cutaneous findings of cryofibrinogenemia are similar to those of cryoglobulinemia.

with an increase in immunosuppressed patients and a variation in infectious disease etiologies. Whether this changes the current epidemiology of cryofibrinogenemia is unclear.

Etiology

Korst and Kratochvil first described cryofibrinogens in 1955.[45] Cryoprecipitates are cold, insoluble complexes of fibrinogen, fibrin, and fibrin split products with albumin, fibronectin (cold-insoluble globulin), factor VIII, immunoglobulins (rare in patients with isolated disease), and other plasma proteins.[46,47] Cryoprecipitates may, in fact, be composed of normal plasma proteins demonstrated on freeze thawing of plasma.[15] Heparin may produce false-positive precipitates (heparin-precipitable fraction) through the formation of heparin-fibronectin cryoprecipitable complexes, the formation of which may be further enhanced by the presence of fibrinogen.[15]

Cryofibrinogenemia is classified as primary, without known etiology or disease association, or secondary. Secondary cryofibrinogenemia may occur in patients with connective tissue disease, infections, malignancies, and thromboembolic disorders and is more frequently found in patients with associated cryoglobulinemia.[45] Diabetes, hyperglycemia, chronic lung disease, hypothyroidism, and acute myocardial infarction have been described as disease associations, as has pregnancy and the use of oral contraceptive agents.[43,48–52] In one study of patients with associated cryoglobulinemia,[46] immunoglobulins were a predominant constituent of the cryofibrinogen precipitate, and, not surprisingly, of the same class as that characterizing the cryoglobulinemia. Similarly, fibronectin was found in the cryoglobulin cryoprecipitate.

Pathogenesis

Cryofibrinogen products clot with thrombin and then reversibly precipitate in the plasma on cooling to 4°C (39.2°F). The precipitate then dissolves readily upon re-warming to 37°C (98.6°F). They represent cryoproteins in plasma that has been anticoagulated following blood draw with oxalate, citrate or ethylenediaminetetraacetic acid (as opposed to heparin). The proteins consumed in the clotting process are the necessary substrates for formation of cryofibrinogens and therefore, the precipitate requires whole plasma. Cryofibrinogens, unlike cryoglobulins, cannot precipitate in cooled serum. Plasma levels of cryofibrinogens may range from 0.05 g/L to > 1 g/L.[46] In patients with isolated cryofibrinogenemia, and in those with co-existent cryoglobulinemia, plasma fibrinogen levels may be elevated.

The exact mechanism responsible for the formation of cryofibrinogens is not known. The current hypothesis is based upon findings of increased α_1-antitrypsin and α_2-macroglobulinemia in patients with cryofibrinogenemia.[44,50] α_2-Macroglobulin seems to be elevated more frequently.[53] These proteins inhibit the major plasma fibrinolytic agent, plasmin, resulting in an accumulation of protein cryoprecipitates (fibrinogens, fibrin, etc.). Both α_1-antitrypsin and α_2-macroglobulinemia can readily be identified by serum protein electrophoresis.
